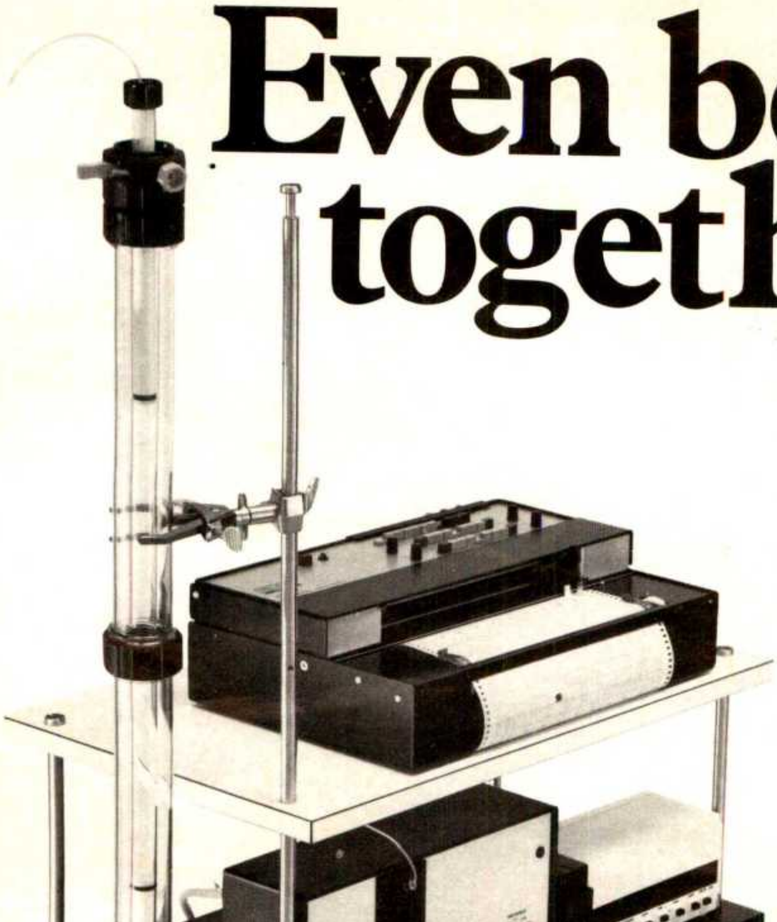
PREDATION OF UNPALATABLE BUTTERFLIES

Even better together.



Individually, LKB chromatography instruments provide outstanding reliability and consistently accurate results.

But together, they form total, integrated systems that are unequalled in their ease of use and dependability. The LKB 2111 MultiRac® Fraction Collector is the core of just such a system.

LKB excellence in design

The LKB 2111-MultiRac® system combines the ultra-reliable 2111 Fraction Collector with the new MicroPerpex® peristaltic pump, 2210 dual channel recorder and high sensitivity 2138 Uvicord®S UV monitor in one compact package. This entire system takes up less than 2 square feet of bench or cold room space. Yet, every instrument is easy to reach and adjust.

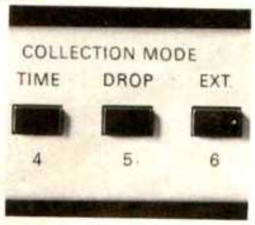
Integrated ease of operation

With the programmable 2111 MultiRac controlling the run, you're assured of accurate, no waste, no problem collections. And with precise pump control of fraction volumes, automatic flow stop function during tube changes and continuous display of flow rate on the MicroPerpex pump, the system needs minimal interaction time with laboratory personnel.

Versatile and reliable

This new LKB collector draws on years of design experience and incorporates the most advanced circuitry. Because the MultiRac precisely shifts the drop head, it can accommodate a large variety of collection vessels.

The sophisticated microprocessor controller of the collector lets you select time, drop or precise volume modes, diverts void volumes to waste and can be programmed to save tubes by collecting valleys in large volumes, peaks in small.



See it all together

Ask your LKB representative for more information on LKB complete chromatography systems. See how they work even better together.

Cover: Monarch butterflies are eaten in different ways by their two major predators in the Mexican overwintering sites. The black-backed oriole (*Icterus abeillei*) seizes a butterfly by its wings, holds the butterfly underfoot, and uses its narrow and delicate bill to strip out the abdominal contents (top left) and thoracic muscles (top right). By leaving the exoskeleton intact and by taste selectivity, the oriole avoids ingesting substantial amounts of the emetic cardenolides. In contrast, the black-headed grosbeak (*Pheucticus melanocephalus*, bottom), after dismembering a monarch with its heavy bill, may eat the various body parts in their entirety. Drawings by Katherine Doktor Sargent, based on field observations by L.S. Fink and L.P. Brower (see p.67) and photographs by George D. Lepp and L.P. Brower.

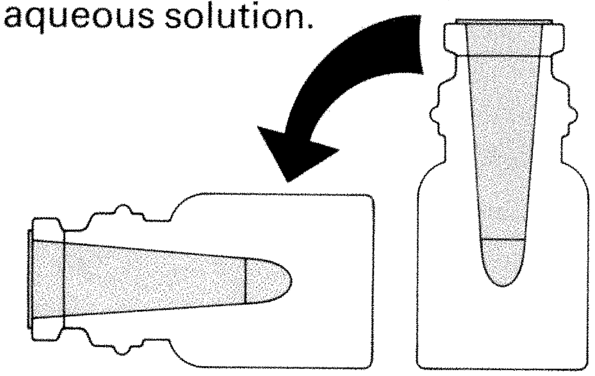
Accidents will happen...

...but all may not be lost!

Amersham's aqueous solutions* of ^{32}P-nucleotides at 10mCi/ml are supplied in "Duoseal V-vials". In an experiment designed to simulate a laboratory accident, 10 open "Duoseal V-vials" were knocked over, each containing 100μl of aqueous solution.



In all cases the surface tension prevented any loss from the specially designed V-insert.

Other advantages of the V-insert

- will accept standard pipette tips
- minimum loss of product, <2% per week lost by absorption
- is not 'wetted' by the solution
- will fit caps from small centrifuge tubes

Aqueous solutions of ^{32}P-nucleotides available weekly from Amersham in "Duoseal V-vials".

Call Amersham or your local representative for further details.

* contains 5mM 2-mercaptoethanol.

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should be identified in the margin on their first appearance. Equations should occupy single lines if possible: exp (*a*) is preferred to e^a if '*a*' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

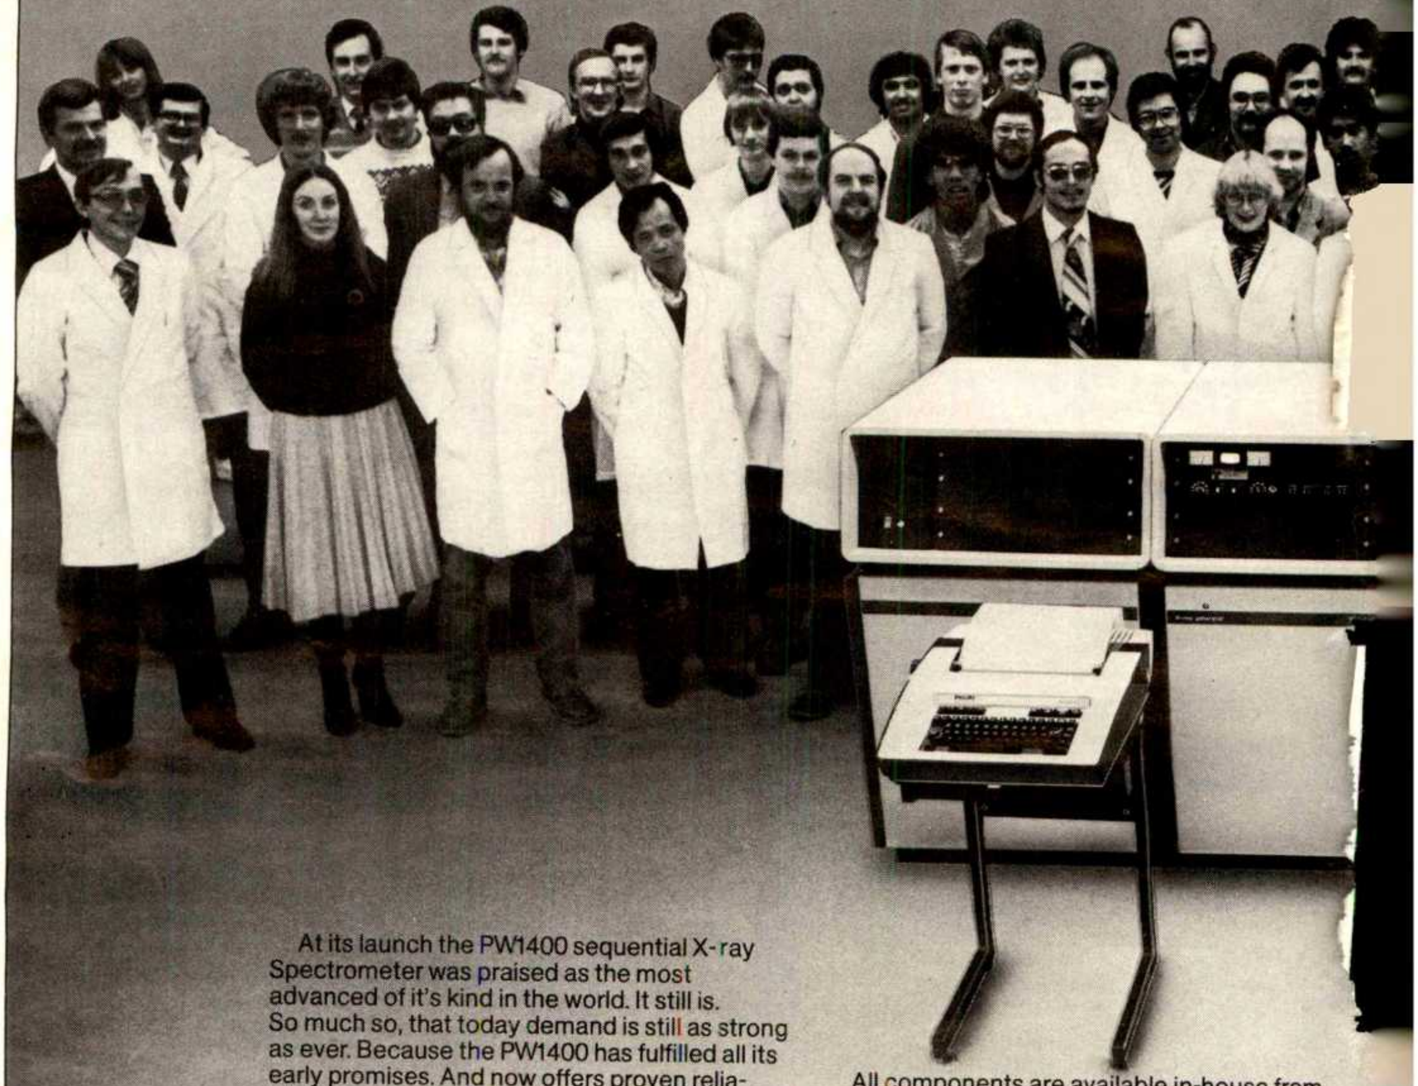
Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. ideally, an unlettered original and three lettered copies should be provided; labelling on halftones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov. (1976).

Why over 250 of the wo
laboratories use one



At its launch the PW1400 sequential X-ray Spectrometer was praised as the most advanced of it's kind in the world. It still is. So much so, that today demand is still as strong as ever. Because the PW1400 has fulfilled all its early promises. And now offers proven reliability. In performance, specification and design, it seems the PW1400 has the happy knack of pleasing all of the people all of the time. It's modular in construction and comes with a choice of generators, sample handlers, data reduction systems and input/output devices.

All components are available in-house from Philips for added reliability. And the system can be connected to a wide range of computers. In terms of back-up we offer extensive software packages, operator training programmes, highly specialised know-how from several application laboratories, and a sophisticated service network.

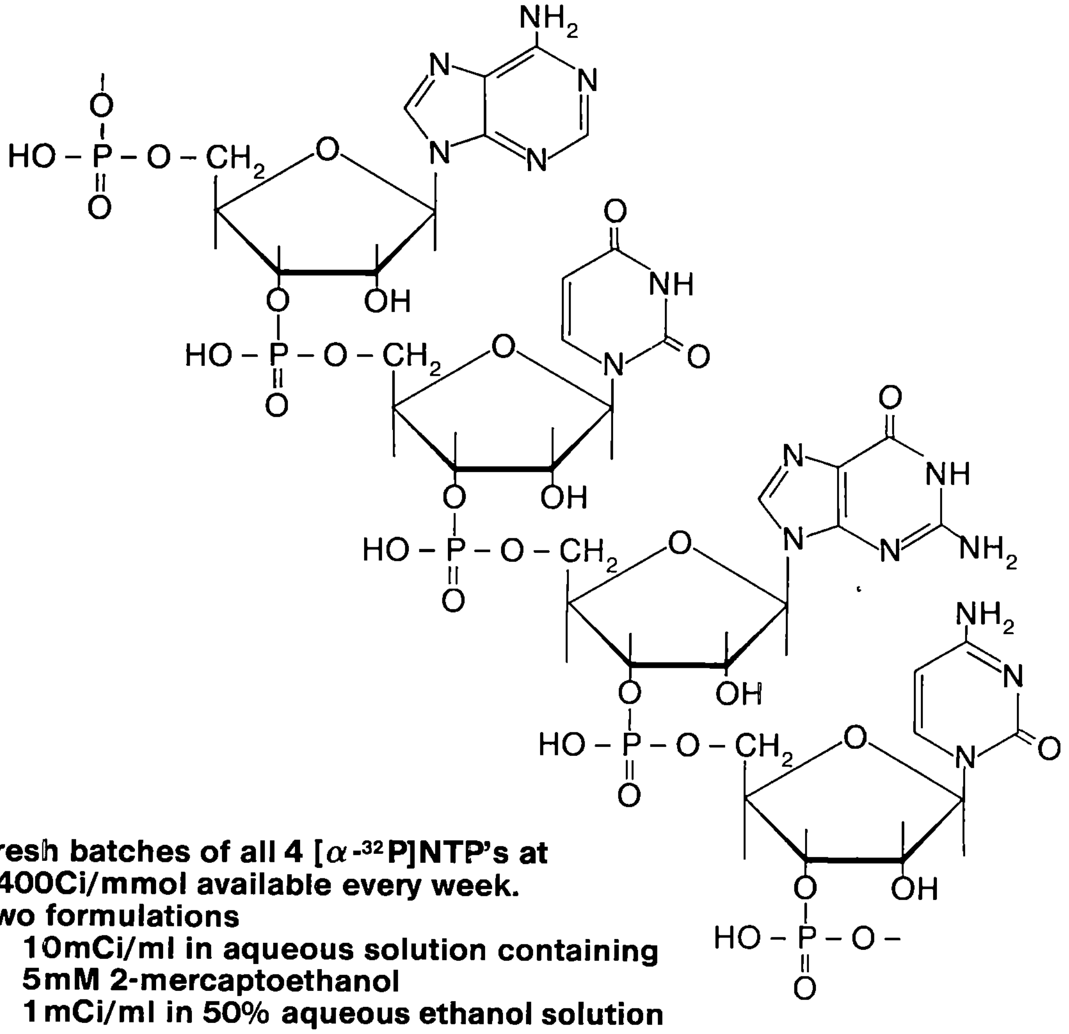
Ribonucleoside $5'$-[α-^{32}P] triphosphates Straight from the bottle every week! From 7th May 1981



Fresh batches of all 4 [α-^{32}P]NTP's at >400Ci/mmol available every week.
Two formulations

- **10mCi/ml in aqueous solution containing 5mM 2-mercaptoethanol**
- **1mCi/ml in 50% aqueous ethanol solution**

Radiochemical Purity

- All batches analysed by HPLC

Aqueous solutions at 10mCi/ml

- Supplied in "Duoseal V-vials"
- Reduced need for evaporation of the solvent
- Avoids the risk of decomposition during evaporation
- Reduced handling minimizes risk of wastage, spillage and contamination

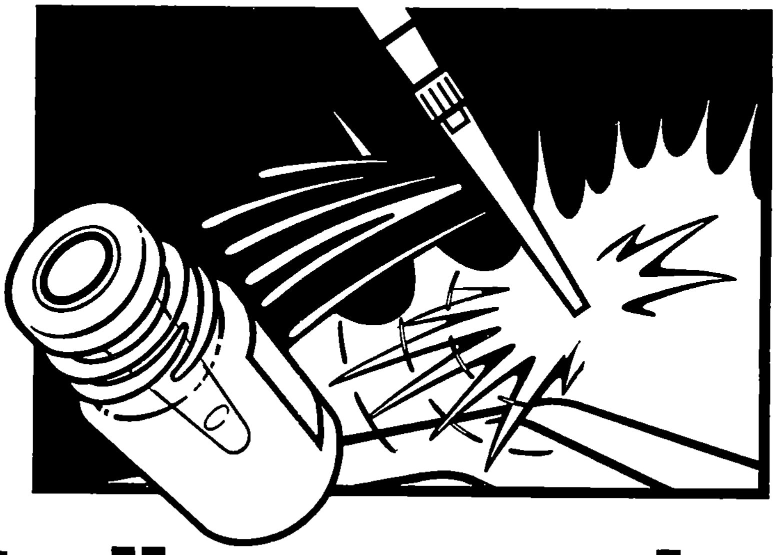
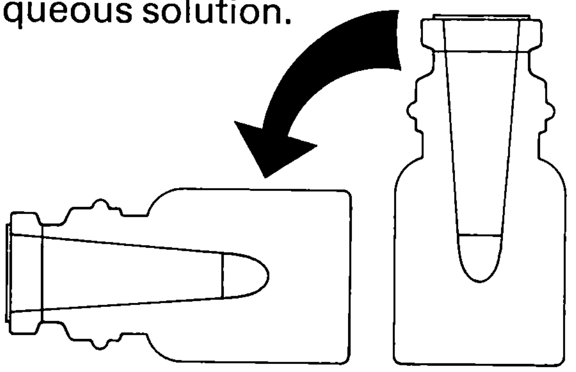
Nature® (ISSN 0028-0836) is published weekly, except the last week in December, by Macmillan Journals Ltd Annual subscription for USA and Canada US $173 Orders (with remittance) and change of address labels to Macmillan Journals Ltd, Brunel Rd, Basingstoke RG21 2XS, UK Second class postage paid at New York, NY 10010 and additional mailing offices US Postmaster send form 3579 to *Nature*, 15 East 26 Street, New York, NY10010

Accidents will happen...



...but all may not be lost!

Amersham's aqueous solutions* of ^{32}P-nucleotides at 10mCi/ml are supplied in "Duoseal V-vials". In an experiment designed to simulate a laboratory accident, 10 open "Duoseal V-vials" were knocked over, each containing 100μl of aqueous solution.



In all cases the surface tension prevented any loss from the specially designed V-insert.

Other advantages of the V-insert

- will accept standard pipette tips
- minimum loss of product, <2% per week lost by absorption
- is not 'wetted' by the solution
- will fit caps from small centrifuge tubes

Aqueous solutions of ^{32}P-nucleotides available weekly from Amersham in "Duoseal V-vials".

Call Amersham or your local representative for further details.

* contains 5mM 2-mercaptoethanol

PRODUCT REVIEW This week's product review (page xxix) covers tissue culture

GUIDE TO AUTHORS

- Review articles should be aimed at a relatively wide readership Many reviews are invited, but submitted articles may also be accepted, it is advisable to consult us before writing a review article
- Articles may be up to 3,000 words long with at most six displayed items (figures and tables), they are reports of major research developments
- Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words, they have at most three or four displayed items
- 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*

Articles should be accompanied by an abstract of not more than fifty words Letters should begin with a paragraph giving the background and main conclusion in terms intelligible to as wide a readership as possible

Manuscripts may be submitted either to London or New York Three typed copies should be submitted, each including lettered copies of figures Typing (including references) should be double spaced The title should be brief and informative Pages should be numbered References, tables and figure legends should start on separate pages Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends Units should be identified in the margin on their first appearance Equations should occupy single lines if possible exp (a) is preferred to e^a if 'a' is more than one character

References are indicated by superscripts in the text See any contemporary *Nature* for style, but note

(i) only one reference number need be used if the reference is to several papers by identical authors

(ii) first and last pages of references should be cited

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65) Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references Their publisher and place of publication should be clearly indicated 'Personal communication' and 'unpublished' should be incorporated in text

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials Most figures are reduced to one column width so originals should be about as wide as a page of *Nature* To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material ideally, an unlettered original and three lettered copies should be provided, labelling on halftones should, if possible, be avoided entirely Magnifications quoted should be for the figures as submitted We are always glad to see artwork for possible use on the cover but cannot guarantee its return

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish

Nature's publishing policy is outlined in **258**, 1 (1975) and **264**, v, 11 Nov (1976)

Arolla is at the very back of the Val d'Hérens, separated from Zermatt and the celebrated Matterhorn by 25 km as the crow flies, and by the 4357-m Dent Blanche

Like almost every Swiss hamlet it has a public telephone, of course, and there is nothing unusual about the one at Arolla

You dial direct from here to almost anywhere in Europe (if you have enough change) The telephone functions day and night And if someone should not know how it works, there's a set of instructions

The instructions are in German, French, Italian, and English And this is where things start to get very Swiss indeed

Because our country is in fact quadrilingual, and since we also have to make an effort to understand and to be understood even within this small area, we can also appreciate the position of a guest who speaks a different language Accordingly, as most Swiss are conditioned to expect that strangers will be coming, and they do not want them to feel like strangers, it is no surprise to find the telephone instructions include a version in the world-wide English language, rather than our own fourth national tongue, Rhaeto Romanic

Neither is it a surprise that we have one of the world's most closely meshed rail networks, to help visitors to reach their holiday destinations as fast and

SAFE

in the knowledge of Barr & Stroud technology at work

A commonplace scene on a busy road, but safer if Barr & Stroud fibre optic traffic signs were installed.

Our signs allow virtually no misleading phantom images even in the most difficult conditions.

We are a leading light in the fibre optics field, where our experience spans a wide spectrum of equipment, systems and applications – in computers, process control, medicine, colour detection, automatic inspection, as well as traffic signs.

Barr & Stroud's leadership and innovative skills in today's technologies are at the service of science and industry.

We have proved it in fibre optics; we have proved it in other areas. Because of our serious commitment to research and development, engineers and designers everywhere can rely on our expertise to solve their most complex problems.

Barr & Stroud

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible

Review articles should be accessible to the whole readership Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable)

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding The text should not exceed 3,000 words and six displayed items (figures plus tables) A draft abstract (50 words) is required

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*

Manuscripts may be submitted either to London or New York (decisions being made only in London) Manuscripts should be typed (double spacing) on one side of the paper only Three copies are required, each accompanied by copies of lettered artwork No title should exceed 80 characters in length Reference lists, figure legends, etc should be on separate sheets, all of which should be numbered Abbreviations, symbols, units, etc should be identified on one copy of the manuscript at their first appearance

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963–65) The first and last page numbers of each reference should be cited References to books should clearly indicate the publisher and the date and place of publication Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text

Each piece of artwork should be clearly marked with the author's name and the figure number Original artwork should be unlettered Suggestions for cover illustrations are welcome Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published

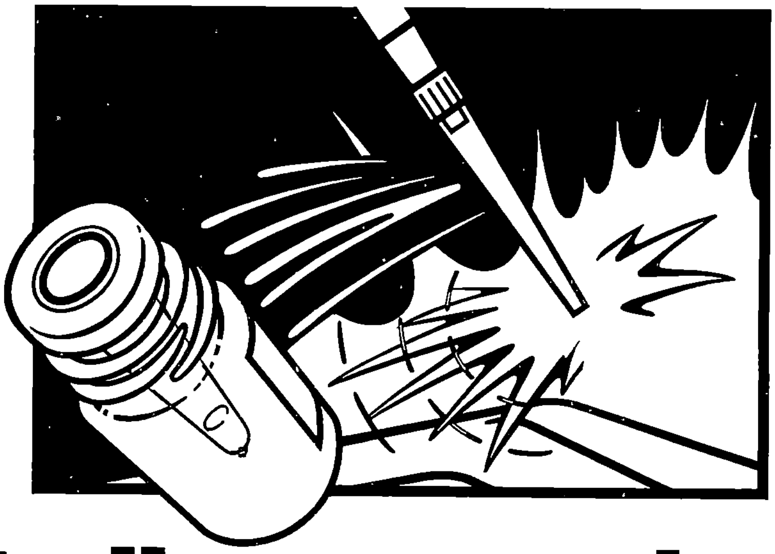
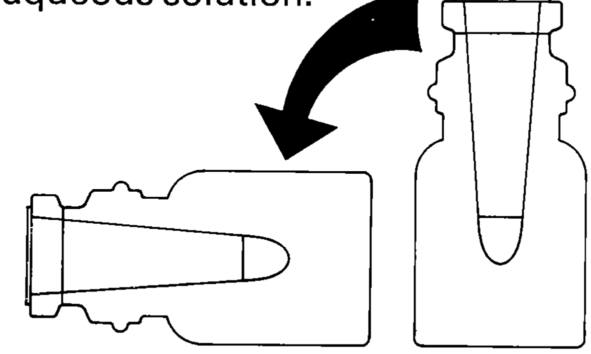
Accidents will happen...



...but all may not be lost!

Amersham's aqueous solutions* of ^{32}P-nucleotides at 10mCi/ml are supplied in "Duoseal V-vials". In an experiment designed to simulate a laboratory accident, 10 open "Duoseal V-vials" were knocked over, each containing 100μl of aqueous solution.



In all cases the surface tension prevented any loss from the specially designed V-insert.

Other advantages of the V-insert

- will accept standard pipette tips
- minimum loss of product, <2% per week lost by absorption
- is not 'wetted' by the solution
- will fit caps from small centrifuge tubes

Aqueous solutions of ^{32}P-nucleotides available weekly from Amersham in "Duoseal V-vials".

Call Amersham or your local representative for further details.

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible

Review articles should be accessible to the whole readership Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable)

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding The text should not exceed 3,000 words and six displayed items (figures plus tables) A draft abstract (50 words) is required

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*

Manuscripts may be submitted either to London or New York (decisions being made only in London) Manuscripts should be typed (double spacing) on one side of the paper only Three copies are required, each accompanied by copies of lettered artwork No title should exceed 80 characters in length Reference lists, figure legends, etc should be on separate sheets, all of which should be numbered Abbreviations, symbols, units, etc should be identified on one copy of the manuscript at their first appearance

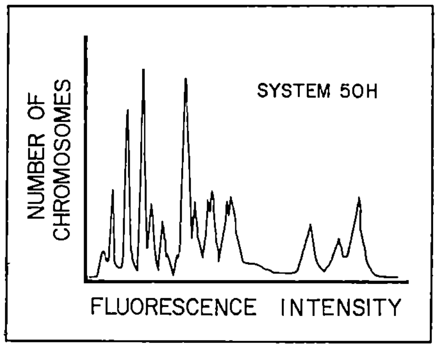
References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963–65) The first and last page numbers of each reference should be cited References to books should clearly indicate the publisher and the date and place of publication Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text

Each piece of artwork should be clearly marked with the author's name and the figure number Original artwork should be unlettered Suggestions for cover illustrations are welcome Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published

No other commercially available cell sorter and analyzer approaches the power, precision and versatility of the Ortho Systems 30/50 The instrument is offered in two basic configurations System 30—a high resolution, 21 parameter analytical flow cytometer, and System 50—which adds cell sorting capabilities to the System 30 flow cytometer Both feature dual lasers as standard equipment for increased analytical power

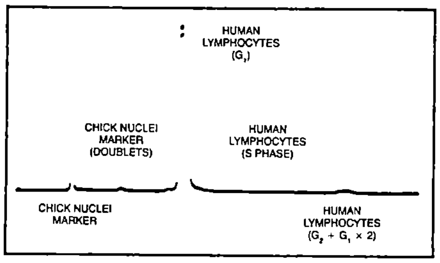
System Components

To appreciate the far-reaching capabilities of these Ortho instruments, consider that the System 50 combines two lasers—a 8 milliwatt helium-neon for ultra high precision scatter measurements and a 5 watt argon type for fluorescence measurements (optional argon-ion, and krypton-ion lasers with U V capability are available), four detectors—two of the photo-multiplier type for right angle scatter, and fluorescent emission detection (S-20 response, 185 nm–850 nm), and two solid state sensors for axial light loss and narrow angle forward scatter a sophisticated optical system incorporating fiber optics a multiplexed multichannel analyzer, with C R T display the signal processor unit and an advanced cell sorter module Additionally, the Model 2150 computerized 8 parameter data handler/sorter controller is available as an option* The 2150 System features simultaneous data acquisition, and real time processing while sorting is in progress



2 Histogram of CHO chromosomes stained for D N A. Ethidium Bromide/Chromomycin A_3

Cytofluorograph System 50H Laser-250mw @ 457nm Red Fluorescence



2 Histogram of human lymphocytes utilizing a chick nuclei marker for standardization and stained for D N A with Propidium Iodide C V = 1 65% (Human Lymphocytes)

System Capabilities

Together, these modules allow the System 50 to provide and analyze morphological information—a significant first for a flow cytometric instrument With four detectors and the ability to display pulse height, pulse area or pulse width analysis for each—a total of 21 distinct measurement parameters can be studied

The System 50 also features two bidimensional regions of interest, dual histogram multi-channel analyzer with cytogram mode, super-sil quartz optics with which the cells are analyzed and easy sample entry

In order to provide customers with complete support, Ortho maintains an Applications Laboratory that is available for confirmation and consultation services Additionally, an international network of service technicians is ready to aid customers should calibration or repairs ever be required

Remarkable Results

The histograms and cytograms displayed were produced by the System 50 Evaluate them And consider the difficulty of deriving this data by any other means The capabilities of this unique Ortho instrument will speak for themselves

State-of-the-art cell sorting and analysis from Ortho

The Cytofluorograf® Systems 30/50

System 50H with optional argon ion and krypton ion lasers installed

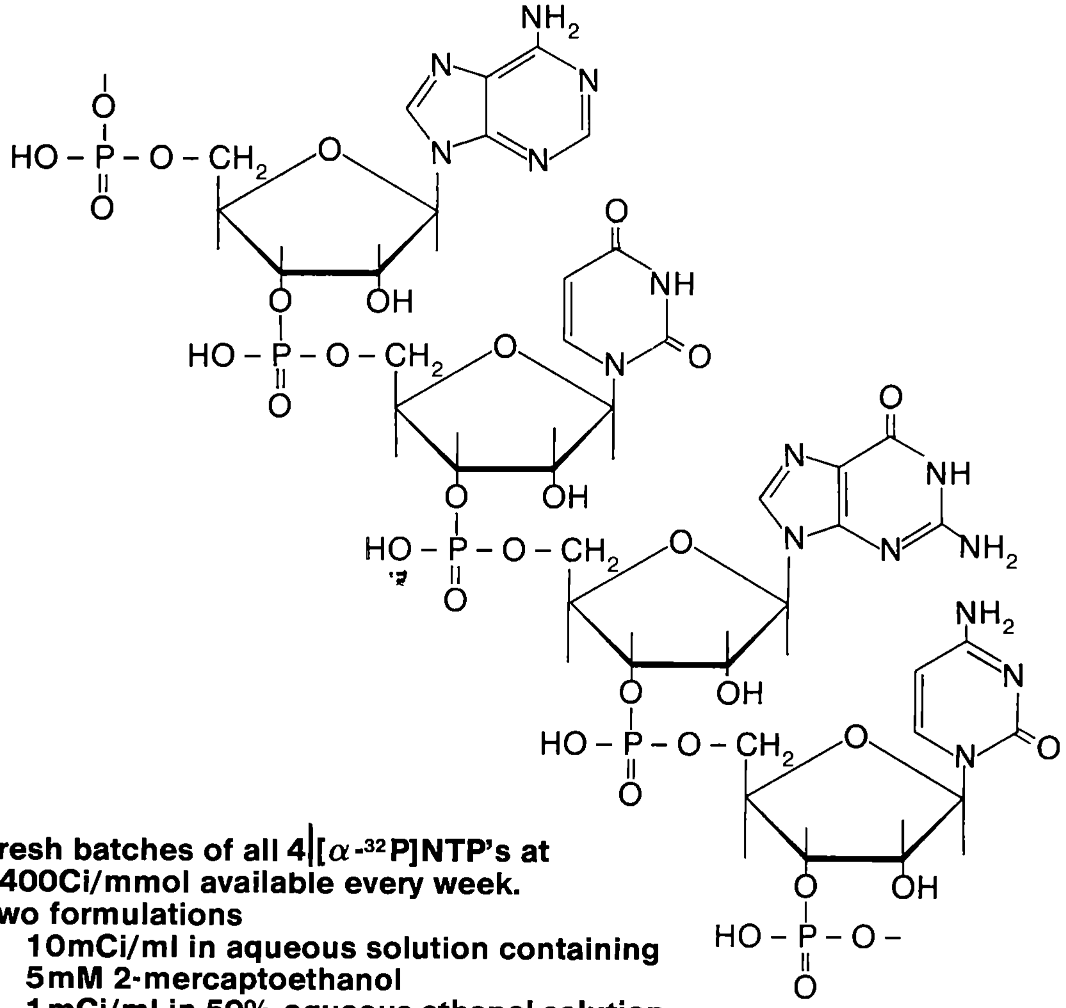
Ribonucleoside 5′-[α-^{32}P] triphosphates Straight from the bottle every week! From 7th May 1981



Fresh batches of all 4 [α-^{32}P]NTP's at >400Ci/mmol available every week.
Two formulations

- **10mCi/ml in aqueous solution containing 5mM 2-mercaptoethanol**
- **1mCi/ml in 50% aqueous ethanol solution**

Radiochemical Purity

- All batches analysed by HPLC

Aqueous solutions at 10mCi/ml

- Supplied in "Duoseal V-vials"
- Reduced need for evaporation of the solvent
- Avoids the risk of decomposition during evaporation
- Reduced handling minimizes risk of wastage, spillage and contamination

For photomicrography or cinemicrography, it pays to match Olympus microscopes with something equally outstanding The Model PM-10AD The PM-10AD faithfully records the high image resolution, definition and clarity of Olympus microscopes And it does so with the convenience of fully automatic exposure

The time and effort you save are remarkable Thanks to a built-in microcomputer and a Silicon Blue Cell (SBC) that relays information to it quickly and accurately, you need no longer worry about complicated adjustments

The automatic exposure range is extremely wide, from 1/5000 of a second to 2 hours The microcomputer automatically corrects the reciprocity failure characteristics of the film you are using and operates continuously to yield perfect exposures

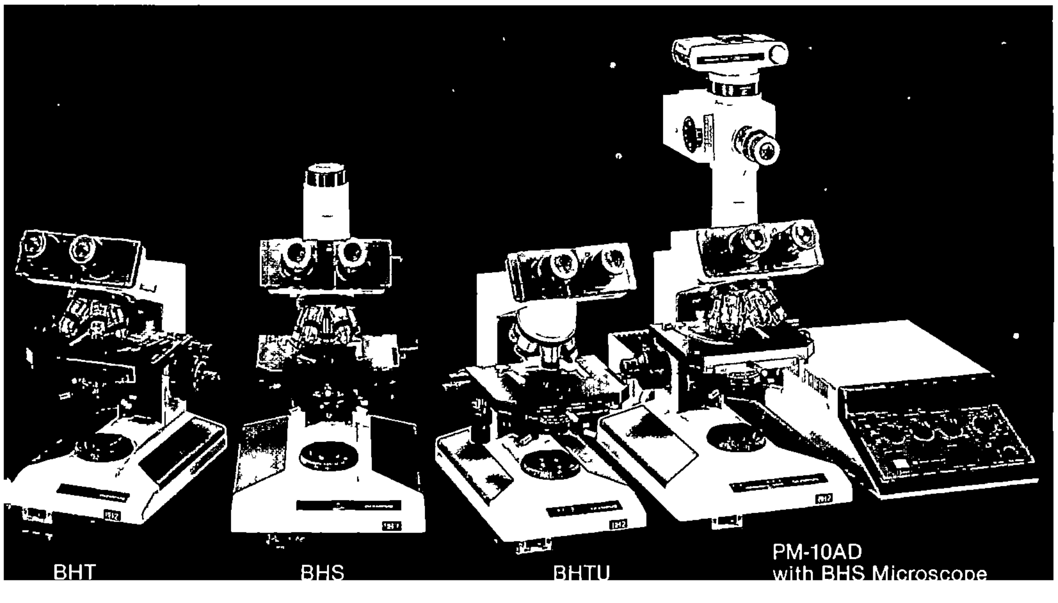
The PM-10AD allows automatic and manual operation In either mode, it can be used not only for conventional purposes but also for multiple exposures of double-stained fluorescence specimens and panorama photography, in which case uniform density is assured

Other features

- Clear digital displays include estimated and actual exposure times, time remaining to complete exposure and recall of the previous exposure time
- Unique vibration-free electromagnetic shutter The contact-free design provides a shutter life of at least 100,000 operations with absolutely no adverse effects on image quality
- Optional PM-CTR color temperature meter module for simple checking and adjustment of color temperature

A TRIUMPH OF INSPIRED SIMPLICITY.

PM-10AD Photomicrography and Cinemicrography System



BHT BHS BHTU PM-10AD with BHS Microscope

The PM-10AD is a triumph of inspired simplicity—a simplicity that means optimum results

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible

Review articles should be accessible to the whole readership Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable)

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding The text should not exceed 3,000 words and six displayed items (figures plus tables) A draft abstract (50 words) is required

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*

Manuscripts may be submitted either to London or New York (decisions being made only in London) Manuscripts should be typed (double spacing) on one side of the paper only Three copies are required, each accompanied by copies of lettered artwork No title should exceed 80 characters in length Reference lists, figure legends, etc should be on separate sheets, all of which should be numbered Abbreviations, symbols, units, etc should be identified on one copy of the manuscript at their first appearance

References should appear sequentially indicated by superscripts in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963–65) The first and last page numbers of each reference should be cited References to books should clearly indicate the publisher and the date and place of publication Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text

Each piece of artwork should be clearly marked with the author's name and the figure number Original artwork should be unlettered Suggestions for cover illustrations are welcome Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published

MACMILLAN PUBLISHERS

THE ECOLOGY & CONSERVATION OF LARGE AFRICAN MAMMALS

S. K. ELTRINGHAM

DEPARTMENT OF APPLIED BIOLOGY,
UNIVERSITY OF CAMBRIDGE.

£15.00; 288pp; ISBN 0 333 23580 0.

"Keith Eltringham has produced a valuable book which treats the ecology of large African mammals in the widest context In a compact volume he considers their social behaviour, population, biology, and feeding in an ecological framework. Perhaps the most important sections are the last three chapters which deal with conservation, wild life management, and man and national parks"
BIOLOGIST, APRIL 1980

"Eltringham's book is written as a textbook for undergraduates but he also had in mind the value of making the book of interest to those with a more cusory contact with African habitats. Accordingly, it is written with a pleasant directness, lack of jargon, and wry humour"
TIMES HIGHER EDUCATION SUPPLEMENT, MARCH 1980

"The appearance of this book is timely Many talk about conservation without doing anything about it Keith Eltringham has done an excellent job by providing much needed information. He has obviously drawn from his vast experience as a wildlife biologist in East Africa for many years Writing about a subject he knows so well makes the account vivid and very much alive"
AFRICAN JOURNAL OF ECOLOGY, MARCH 1980.

"This immensely readable book will be essential for any undergraduate studying mammals and ecology but it will also be attractive to a wider audience – not only those who have been fortunate enough to visit Africa Many people are now familiar with these animals through films, television, zoos and safari parks, and this book will interest all those who wish to know how they are living together and surviving in the world
BRITISH BOOK NEWS, APRIL 1980

Macmillan books are available from all leading booksellers.

In case of difficulty write to Frances Roach, Macmillan Retail Ltd., Houndmills, Basingstoke, Hampshire, England, enclosing remittance plus 70 pence (p&p).

Reagan's need of a proliferation policy

Another bout of anxiety about the proliferation of nuclear weapons is plainly in prospect. The announcement last week by the government of South Africa that it had started to manufacture enriched uranium is certain to rekindle anxiety about the republic's long-term intentions. Driblets of news, not easily verified, from Pakistan, seem calculated to have the same effect. And the disagreement between the United States and India about the supply of American enriched uranium for Indian reactors seems finally to have led to the proposal that the treaty between the two countries on the supply of nuclear materials, first signed in 1963, should now be abandoned. The consequence will be that the Indian Atomic Energy Commission will be able to use the reactors covered by the agreement as it wishes, and that there will be no external restraints (except the shortage of resources) on its enrichment of uranium. Taken separately, these developments are not as worrying as they may seem to some. A more substantial cause for anxiety is that they coincide with the Reagan Administration's failure to work out its policy on nuclear proliferation.

One difficulty, not as far beyond President Reagan's control as it may seem in what has been called his second honeymoon, is that the nomination of Mr James Malone as the assistant secretary at the State Department responsible for the non-proliferation policy is held up in the Senate. That, however, need not mean that nothing can be decided. The most urgent need is that the new Administration, which cannot welcome being bound (as it still is) by the terms of President Carter's Anti-Proliferation Act, should decide whether it wishes to amend the act, and how, or whether it should simply repeal it. The essential folly of the act is that it seeks to apply to all potential purchasers of nuclear materials from the United States a unilateral policy which overrides pre-existing agreements (as in the case of India), even with those states that have ratified the non-proliferation treaty (which India has not). The act is also closely linked with President Carter's interdiction against the reprocessing of nuclear fuel for the extraction of plutonium. Applying this rule to all buyers of United States uranium was scarcely palatable when the United States itself was not reprocessing spent uranium. This policy will be less defensible if, as seems inevitable, reprocessing of fuel begins again in the United States in the next few years. But even deciding what should be done domestically is hampered by the Administration's ill-preparedness. Thus the leaderless Nuclear Regulatory Commission is at sixed and sevens (see *Nature* 30 April, p 727), and unlikely to be able to contribute much to constructive policy formation.

Another imponderable is that nobody can tell how Congress would respond to suggestions that present policies should be modified. President Carter's men, when persuading Congress to enact the present legislation, did much (and more than they should have done) to persuade anybody who would listen that the risk of the emergence of nuclear weapons elsewhere must be simply proportional to the quantity of plutonium in existence. That message, however over-simple, may have stuck. Certainly Congress is unlikely willingly to give up the powers that act has almost fortuitously presented it with. Having wished the Non-Proliferation Act on Congress and himself, President Carter had to suffer the humiliation of asking Congress to make an exception of the provision of enriched uranium required of the United States by the 1963 bilateral agreement between itself and India. President Reagan cannot risk asking Congress to embark on a piecemeal amendment of existing legislation. He needs both a coherent domestic policy on the development of nuclear power, with our without reprocessing, and an external policy that makes some concessions to the principle that countries overseas need to know in advance what is required of them when they buy American nuclear materials. And, even then, Congress will have to be re-educated. That, presumably, is one of Mr Malone's intended tasks.

So what should the Reagan Administration require of its nuclear customers overseas? The Non-Proliferation Act requires that potential customers should sign the Non-Proliferation Treaty (which previously unwilling Egypt has now done). In that respect, the United States is asking more of its customers than other suppliers of nuclear materials, France for example. There is, however, nothing wrong with that provision — would that other suppliers made the same demands. The iniquity of the act is that even those customers who have ratified the treaty, and thus bound themselves both not to carry out nuclear explosions and to open all nuclear installations to the international inspectors, are required not to extract plutonium from their spent fuel. (Technically, the act allows reprocessing if the objective is to obtain plutonium for research on fast reactors, but only then with the prior agreement of the United States.) President Carter appeared not to have appreciated how offensive were these provisions overseas. Some states can fairly argue that they need to reprocess spent uranium for economic reasons. All non-nuclear powers among them can rightly say that if they have, at the urging of the United States, ratified the Non-Proliferation Treaty, it is inequitable that further restrictions should then be arbitrarily imposed. Can it be, they say, that the United States does not believe in the international system of safeguards that it has helped to create? Worse still, does the United States assume that states bound by international treaties will nevertheless break their word whenever they have the chance?

The plain truth, of course, is that there is no necessary connection between the amount of plutonium within a country's borders and the chance that it will go on to make nuclear weapons. There is plenty of evidence that the factors that drive states to one policy or another are political, not technical. Except for the five well-advertised nuclear powers, political considerations appear so far to have argued for restraint and propriety. Israel has gone further along the nuclear road than most other non-nuclear states, and has been compelled to do so in a significant way. The word has been put about that nuclear technology in Israel is advanced, and that there may be plutonium sufficient for several weapons tucked secretly away. So Israel is a kind of crypto-nuclear power. The snag (from the Israeli point of view) is that it would be exceedingly dangerous to carry out a nuclear test, or openly to confess that there is a stock of bombs. For then the wrath not merely of the Middle East but of the super-powers would be visited on the Israeli government. It is not unreasonable to guess that South Africa may be dickering with a similar policy. The Indian nuclear explosion in 1974 (which prompted the still unanswered question of when the second explosion will take place) had more ambiguous motives, but served quickly to remind the Indian government of its dependence on economic assistance from overseas.

The Reagan Administration is as well placed as its predecessors to manipulate political pressures such as these, and thus to inhibit the proliferation of nuclear weapons. Domestic politics would probably prevent the Administration from demanding that Israel should sign the Non-Proliferation Treaty (now that Egypt has

0028-0836/81/190001-02$01 00

done so) if it is to continue receiving assistance with conventional armaments Pakistan would be an easier target, however — and Pakistan's signature of the treaty would go a long way to persuade India that playing about with bombs is not worthwhile The strangest feature of President Carter's advocacy of the Non-Proliferation Act of 1978 is that, although used to decrying what are called "technological fixes" in other contexts, he relied on just such a device in the battle against proliferation. The question now is whether President Reagan will be more subtle He will have to persuade Congress that the American influence on the pace of proliferation is best left to him and to the State Department, not left to the wooden interpretation of an over-restrictive piece of legislation At the same time, he will have to persuade both Congress and its electors that nuclear power is not necessarily the end of the world The more time that slips by, the harder will be the task

Advice and dissent on civil science

The inquiry by the House of Lords Select Committee on Science and Technology seems already to have unearthed a substantial problem, the constitution of the committee known as the Advisory Board on the Research Councils (see page 3) Much of the evidence so far sent in to the committee, that from the Royal Society for example, has argued that the board's interpretation of its function has been unhelpfully narrow Constitutionally the board is advisory to the Secretary of State for Education and Science, who is in turn responsible for writing the cheques that keep the research councils alive Since it was set up a decade ago as part of the Rothschild reorganization of civil science, the board has been almost exclusively a forum for horse-trading between the research councils. Which budgets should be increased more quickly than inflation, which should be trimmed? Given the inevitable dominance of the board by the powerful figures of the chief executives of the research councils, and the prospect that research budgets will indefinitely stagnate, the board's concentration on mere money and its distribution is understandable. The complaint is that, in the circumstances, there is no mechanism for tackling more general questions central to the administration of civil science

The charge is valid even though the board seems recently (to its credit) to have taken on some general questions of common concern to the research councils as a group Thus the board has begun an investigation of the relationship in the funding of research of the University Grants Committee and the research councils — and has made very little progress There is an inquiry into graduate education and the basis on which research councils support graduate students in universities and other institutions, and also into the employment (and fate) of postdoctoral researchers not members of academic staffs In due course, if the busy people who have committed themselves to work on these questions can find the time, the research councils may be helped to a better understanding of some important questions. But they are largely domestic questions They do not apparently include the long overdue appraisal of the Rothschild reorganization which among other things gave operational departments charge of part of the budget for civil science Instead, the board has lent its name to the piecemeal dismantling of the Rothschild system typified last year by the transfer back to the Medical Research Council of funds earlier transferred to the Department of Health

The vein of discontent with the advisory board that the House of Lords has tapped is in no sense a new discovery Ironically, however, the narrowness of the board's terms of reference is itself a consequence of the Rothschild reorganization In 1971, the Council for Scientific Policy (the board's predecessor in the 1960s) and Lord Rothschild independently embarked on a consideration of how the British government's support for civil science should be organized The council concluded that there should be an advisory committee (called a board) with wide powers to consider the research policies of government departments and research councils. Lord Rothschild eventually came to the opposite conclusion — that the Council for Scientific Policy should become strictly advisory, and that its chief task should be to recommend the division of the funds available between the research councils Sir Frederick Dainton, the council's chairman at the time and already incensed that his own recommendations were kept secret while the Rothschild inquiry was under way, was understandably infuriated that the government of the day should have accepted Rothschild's view that the committee's terms of reference should be narrow but should then have called that watered-down version of the standing advisory committee a "board", almost the only proposal of Dainton's to be accepted. The implication is that the advisory board, however unsatisfactory, has been doing this past decade what was expected of it.

The temptation now, in the House of Lords and elsewhere, will be to tinker with terms of reference. Sir Alec Merrison, the chairman for the time being of the board (and of a host of other committees) said last week that his board should have a wider remit but should not be encouraged to poach on the ground occupied by another advisory committee, the Advisory Council on Applied Research and Development. The modesty is seemly but inappropriate. There is no reason why broader terms of reference should of themselves allow the committee to function more effectively. If it cannot get through the work it has already set itself, what reason is there to expect the same committee with a similar way of working to cover more ground effectively? At the same time, now that the board has come into being, and seems anxious (given time and resources) to tackle a variety of problems common to the research councils, it would be a misfortune if yet another reorganization should bring this good work to a stop

Where, then, should the House of Lords look for a solution? The most glaring weakness of the advisory board is its lack of independence from the research councils as such (which is not to disparage the work of the independent members of the board) The advisory council, theoretically more influential because it reports to the Cabinet Office rather than to a department, and whose members are all independent persons, suffers from being if anything too detached from the problems that concern government from day to day. The result is, so far as the public knows, that the council has spent its time drawing attention to fields of science or technology in which research might be expected to be worthwhile. Structural questions — the relationship between the research councils and the University Grants Committee for example — seem not to have arisen Yet these are precisely the questions on which the British government needs not merely advice but policies. The obvious solution is to leave the Advisory Board for the Research Councils much as it is, with responsibility for advice on the coordination of largely academic science, but to strengthen the advisory council For now that the research councils have begun talking to each other in the presence of outsiders about the coordination of their work, it would be a pity ot throw away the opportunities thus provided Strengthening the advisory council is more than merely a matter of redrafting terms of reference. With the best will in the world (and even with a chairman as able as Sir Alfred Spinks), busy people meeting occasionally cannot be expected to do the hard work that circumstances require At the least, the chairman should be a full-time appointment (in which case he or she might usefully double as chairman of the advisory board). But the committee also needs a professional staff, not mere minute-takers represented by promising young recruits to the civil service Both changes would be easier if, as in the 1950s, responsibility for civil science were removed from the Department of Education and Science. They, and the others in prospect, would have more meaning if some British government would believe its own declaration about the importance of this subject.

Recombinant DNA guidelines wear thin

NIH moves to voluntary regulation

Washington

The US National Institutes of Health (NIH) have taken the first steps towards removing mandatory controls on the conduct of recombinant DNA research. Meeting in Bethesda, Maryland, the institutes' Recombinant DNA Advisory Commitee (RAC) set up a subcommittee to discuss whether the present guidelines, which all federally-sponsored scientists have to observe, should be turned into a voluntary code of practice, and the answer is likely to be yes.

The committee's decision was in response to a proposal from two of its members, Dr Allan Campbell of Stanford University and Dr David Baltimore of the Massachusetts Institute of Technology. They suggested that the guidelines should be voluntary — eliminating the formal need for review bodies such as local Institutional Biosafety Committees — and that there should be major reductions in the containment levels recommended for various types of experiments (*Nature* 26 March, p.281).

Their proposal, which was published in the *Federal Register* on 20 March and would involve eliminating virtually all the regulatory requirements contained in Part III of the current guidelines, has generated considerable support in the scientific community.

Most members of the committee seemed to agree with the spirit of the proposition. Their willingness to relax the guidelines was illustrated in an earlier vote on reducing containment requirements for experiments involving *Escherichia coli* K12 and laboratory strain *Saccharomyces cerevisiae* host vector systems. The committee adopted the most liberal option, recommending that such experiments, making up about 80 per cent of all recombinant DNA experiments, be totally exempted from the guidelines.

Several committee members pointed out, however, that there is still considerable public concern about the potential social effects of recombinant DNA research. Hence should such research be regulated, it must be seen to be done in a responsible manner as otherwise federal or state legislation might be provoked. Other members, particularly those from the public interest community, argued against reducing the containment conditions too quickly, pointing out that although a few experiments seemed to confirm that recombinant DNA experiments posed no greater risks than other experiments with the same organisms, this hypothesis had not yet been rigorously tested. Even Dr Campbell and Dr Baltimore agreed that experiments over 10 litres should still be subject to special review by the director of NIH, since large-scale experiments might still result in unsuspected hazards.

The committee members finally agreed that, rather than recommending to NIH director Dr Donald Fredrickson the immediate transmutation of the guidelines from formal restrictions into a voluntary code of practice, a subcommittee should look into the whole question of the future of the guidelines.

The proposal made by Dr Campbell and Dr Baltimore would result in the recommendation that most experiments involving recombinant DNA be carried out in P1 containment conditions, these representing prudent laboratory practice. Potentially hazardous microorganisms would be classified and handled according to procedures recommended by the Center for Disease Control (CDC) in Atlanta, Georgia. Several scientists have expressed concern about proposed revisions to these procedures, published by CDC last year, arguing that in certain cases they would be more restrictive than necessary. However, Dr Baltimore told the committee that he believed CDC "will eventually produce a document that is a useful guide to the appropriate laboratory practice".

Dr Baltimore also stressed that RAC would still be needed to maintain surveillance over recombinant DNA research in the future, to make decisions about experiments which may present particular dangers and to help in the evaluation of ethical issues, which were going to become a very important part of a recombinant DNA activities.

David Dickson

Plea to keep guidelines

A report published by the Office of Technology Assessment, after a two-year study of the impact of applied genetics, says that there are several reasons for not eliminating the guidelines completely, pointing out that "sufficient scientific concern exists for the guidelines to prohibit certain experiments and to retain containment for others", and that most experiments can already be carried out at the least burdensome containment levels.

Although conceding that NIH showed flexibility in liberalizing the restrictions as evidence showed lower risk levels than originally feared, there is criticism of the way that NIH have played the role of oversight body. Several shortcomings are listed, including the virtual non-existence of monitoring for compliance to the guidelines, and the lack of systematic evaluation of other techniques, such as cell fusion, that might present risks.

The report, which lists some of the many applications of recombinant DNA techniques in a wide range of industries, says that Congress might wish to consider the need for regulating work with all hazardous microorganisms and viruses, whether or not they are products of genetic engineering.

Role of advisory committee questioned

The United Kingdom's Advisory Board for the Research Councils could provide government with advice on a wide range of public policy issues with a scientific content if its terms of reference were extended, according to its chairman, Sir Alec Merrison. At present, the board is constrained by its remit to advise the Secretary of State for Education and Science chiefly on the distribution of the science vote amongst the research councils.

The board is like a "huge torpedo" that is not being launched "at anything very much" Sir Alec told the House of Lords Select Committee on Science and Technology last month as part of its investigation into the provision of scientific advice to government. The expertise of the board's members, senior scientists and administrators, could be put to better use if it took on a role similar to the Advisory Council on Scientific Policy, which provided advice on science policy through a chief scientist to the government before its demise in 1963. Any extension of the board's remit, however, would require very careful thought, said Sir Alec, to avoid treading on the toes of the Advisory Council for Applied Research and Development which does a good job in advising on scientific aspects of industrial policy.

Informal contact with the Department of Education and Science was generally good, Sir Alec said. But it had not worked in the case of the government's White Paper on public expenditure, published on budget day last March. Although the implications of the White Paper for the support of basic science in the universities were "profound", the board only learnt of the government's plans in a brief letter a few days before the budget statement.

Sir Alec said that by thinking that it could protect science by maintaining the level of the science vote while considerably reducing the grant for student fees, the government had clearly not understood the way in which university science is funded. The implications for that system, known as the dual support system, are so grave, said Sir Alec, that work on a report that the board is preparing into its workings has had to stop.

Carter's science team

Yesterday's men

Washington

As the Reagan Administration continues to have difficulty in filling many of its top jobs — posts which remain vacant include the directorship of the Office of Science and Technology Policy (OSTP), the chairmanship of the Nuclear Regulatory Commission, and the directorship of the Office of Energy Research — science policy officials from the Carter Administration are having mixed success in finding new positions. Most have slipped back into academic posts — the traditional fall-back for Democrats, in contrast with Republicans, who usually return to the private sector after leaving office. But for some, the prospects are still uncertain.

Most successful in finding a new job has been Dr Frank Press, Mr Carter's science adviser and director of OSTP, who was recently elected to succeed Dr Philip Handler as president of the National Academy of Sciences. Dr Press takes up his new position in Washington at the beginning of July, and has meanwhile returned temporarily to his old post as professor of geology at the Massachusetts Institute of Technology.

Of Dr Press's three original associate directors at OSTP, Dr Gilbert Omenn, responsible for health sciences, has returned to the University of Washington in Seattle, where he is professor of medical genetics, having spent the last year of the Carter Administration as associate director of the Office of Management and Budget. Dr Philip Smith, associate director for natural resources, has temporarily joined the staff of the National Science Board, the overseeing body of the National Science Foundation. The third, Dr Benjamin Hubermann, remains at OSTP keeping the director's seat warm until a successor to Dr Press is appointed.

Dr Robert Frosch, administrator of the National Aeronautics and Space Administration (NASA) under Mr Carter, is already established as president of the newly formed American Association of Engineering Societies. Dr Hans Mark, previously secretary of the Air Force and before that director of NASA's Ames Research Laboratory, was at one point tipped to succeed Dr Frosch, but has now been nominated as deputy to NASA's new administrator, Dr James Beggs.

Another academic who has returned to her former base is Dr Eula Bingham, previously Assistant Secretary of Labor responsible for the Occupational Safety and Health Administration (OSHA). Dr Bingham has rejoined the University of Cincinnati, from which she had been on leave as professor of environmental health.

In contrast, Dr Bingham's counterpart at the Environmental Protection Agency, ex-administrator Mr Doug Costle, is entering the academic world for the first time. Before his appointment under Mr Carter, Mr Costle had been an assistant director of the Congressional Budget Office, and commissioner of environmental protection in the state of Connecticut. A lawyer by profession, he was recently named as a visiting scholar at Harvard University's School of Public Health, and a lecturer at the John F. Kennedy School of Government.

Moving in a different direction is Dr Edward Frieman, brought in to succeed Dr John Deutch as head of the Office of Energy Research. Before coming to Washington, Dr Frieman was deputy director of the Plasma Physics Laboratory at Princeton. He has now joined a Washington-based consulting firm, Science Applications Incorporated, which deals in a range of energy issues.

Two appointments have remained unchanged. Dr Donald Fredrickson, orginally appointed by President Ford as director of the National Institutes of Health for a six-year term, has stayed in that position. Also staying put is Dr John Slaughter, brought in during the last months of the Carter Administration as director of the National Science Foundation partly on the understanding that Mr Reagan would not send him straight back to Washington State University, where he had only recently been appointed provost.

Less fortunate has been Dr Anthony Robbins, previously director of the National Institute for Occupational Safety and Health (NIOSH). Dr Robbins became the target of a bitter attack by conservative groups for his support of labour union positions on some occupational health issues, and was summarily removed from his post by the new Health Secretary Mr Richard Schweiker, as well as being stripped of a commission in the US Health Corps.

At the State Department, Thomas Pickering, previously head of the Bureau of Oceans and International Environmental and Scientific Affairs, has returned to his position as a career foreign service official. And William J. Perry, previously Under-Secretary for Defense for Research and Engineering, has joined a San Francisco investment banking firm.

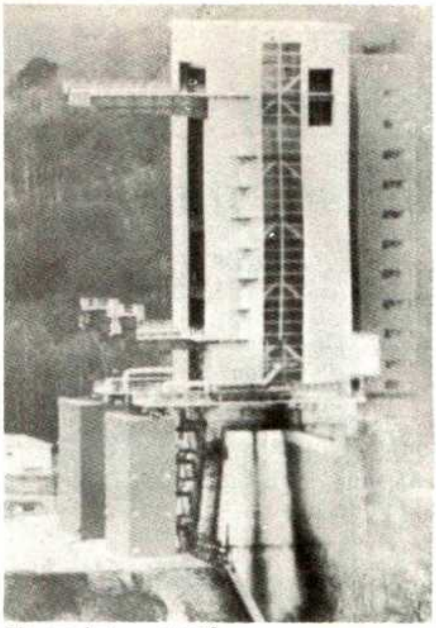
David Dickson

Ariane development

Launch at last?

The European Space Agency (ESA) has announced that the third test launch of the Ariane launcher, with two satellites on board, is to take place on 19 June. After extensive testing and some modifications, the problems associated with the first-stage engines have apparently been solved.

Europe's three-stage launcher programme encountered a major setback during the second Ariane test launch on 23 May 1980. Subsequent analysis revealed that instabilities in the injection system caused pressure oscillations at 2,300 Hz to develop inside the combustion chamber of one of the four first-stage Viking engines. The oscillations caused structural damage which in turn hindered cooling and resulted in rupture of the engine. Subsequent ground tests also revealed oscillations at 2,700 Hz.



Up, up, but . . . away?

Liquid-fuelled rocket motors are notorious for such instabilities, which still confound theorists. ESA's trial and error approach to the problem has involved months of testing of alternative modifications to the injector system. One design, in which the injection nozzle diameters have been slightly widened, resulted in a complete absence of pressure oscillations during ground tests, and has now been adopted. As a further safety measure, manufacturing tolerances have been tightened.

Like its predecessors, the third Ariane is to be launched from Kourou in French Guyana. It will carry Meteosat 2, a European meteorological satellite, and APPLE, an Indian telecommunications satellite. If all goes well, the fourth and final test launch will take place in October.

Ariane's problems have hindered its progress as competitor to the United States shuttle. However, contractors such as Intelsat — the international telecommunications satellite organization — have not cancelled their options on Ariane as a result of the delays.

Philip Campbell

British aerospace

Limbering up

Further evidence of the UK government's sudden eagerness to enter the space race came last week in the form of a new committee set up as a forum for the views of the space industry, users and government. This Space Consultative Committee has held its first meeting to try to determine its role.

The diverse membership of the committee, which includes representatives of government departments, the Science

0028-0836/81/190004-02$01.00

Research Council, the broadcasting authorities, British Telecom and satellite and telecommunications equipment manufacturers, suggests that it is intended to coordinate views from a variety of sources, a role that in other countries might be taken by a national space agency.

Mr Keith Marshall, Under-Secretary of State in the Department of Industry, who will chair the committee, said in parliament that it would also be investigating topics such as the future programmes of the European Space Agency in telecommunications and remote sensing satellites, a satellite communications system for the Ministry of Defence and the marketing strategy of British satellite and ground-station technology abroad. He also indicated that the government would expect industry to put up all the finance for promising projects.

The committee will shortly have before it the conclusions of two reports commissioned by the government. The report of the Home Office study on direct broadcasting should be published later this month and the conclusions of the report of the Central Policy Review Staff on Britain's future in space are to be made available to the committee.

Hopes that an abbreviated version of the review body's report would be published, however, were quashed at the end of last month by a statement in the House of Commons — the government apparently fears breaching industrial confidentiality by allowing open discussion of the report. So far the only conclusions to emerge have been rather bland, such as that the United Kingdom should continue its commitment to the European Space Agency. It is to be hoped that the committee will provide a focus for wider debate. **Judy Redfearn**

European Parliament

Nuclear ban debate

Brussels

A moratorium on nuclear power in Europe will be the subject of a debate in the European Parliament this week. Also on the agenda is a motion on the Geneva Appeal which was launched as a protest against France's fast breeder reactor, Super-Phénix.

The moratorium debate will focus on a report by Sir Peter Vanneck (European Democrat) who is strongly opposed to the idea. The report was adopted by the energy committee by 13 votes to 7 following a resolution by three independent Members of the European Parliament in December 1979. The moratorium would be used as an opportunity to look into the problem of storing nuclear waste, harmonizing safety standards and promoting widespread public discussion. In his report, Vanneck concedes the benefit of these points but feels that the cure would be more painful than the disease.

Depending on how widespread the moratorium would be, Vanneck calculates that by 1990 it would leave the Community short of between 45 and 115 GW, equivalent to 76 or 170 million tonnes of oil a year. By 1990, 34 per cent of the EEC's electricity needs will be supplied by nuclear power. Vanneck also points out that in 1975 electricity from nuclear power caused no deaths in the United Kingdom, while maritime transport (of oil and coal) caused 86 deaths per 100,000 employees and coal mining caused 23.4 deaths per 100,000.

The underlying cause of public concern, says Vanneck, is that plutonium produced in nuclear power stations may be used for military needs. This issue will certainly be linked with the debate on the Geneva Appeal. In October 1978, more than 30,000 French and Swiss, including a number of leading figures, signed an appeal asking the political community in Europe at large to consider alternatives to fast breeder reactors. The appeal reflects the fears of both Swiss and French living in the neighbourhood of the 1,250 MW Super-Phénix fast breeder reactor under construction at Greys Malville in France.

The Council of Europe had held public hearings on breeder reactors in 1979. The present motion, if adopted, would call on all governments concerned to suspend work connected with breeder reactor projects. The EEC itself does not directly contribute to any fast breeder construction programme. The European Commission, however, is preparing a report on the state of the nuclear fuel reprocessing industry.

Both debates, are nevertheless rearguard actions of the anti-nuclear group in the parliament. Most parliamentarians, as previous resolutions have shown, are firmly in the nuclear camp. But the anti-nuclear minority represents nearly a fifth of the members, who are effective in keeping up pressure on the Commission and member states.

Jasper Becker

East Germany banks on research

High technology will be the keynote of East Germany's economic strategy for the 1980s, First Secretary Erich Honecker told last month's Congress of the Socialist Unity Party. An intensive drive to modernize and automate industry, he said, should save the country some 2,800 million man-hours during the next five years, primarily through the application of microelectronics and an increase in the number of industrial robots to be introduced into industry during the period from an original estimate of 9,000 to some 40,000.

By 1985, the country should be virtually self-sufficient in the production of microprocessors and their components. Other priority areas will include fibre optics, laser technology, industrial applications of microbiology, hydrogen and biomass energy sources and the development of new sophisticated technologies to make the maximum use of raw materials at the minimum cost in energy. (The recent shortfall and future uncertainty of coal supplies from Poland have caused planners to pay renewed attention to the country's own lower-grade fossil fuels, mainly lignite).

Although Mr Honecker's review of the work of research establishments, from the Academy of Sciences downwards, stressed the technological and applied aspects, he did pledge the party to a systematic development of basic research "as the source of new discoveries on logical relations in nature and society". The univerisities, including their extension and evening courses for full-time workers, came in for special commendation as did the preliminary training courses for students at their future work-places.

The situation in the lower educational echelons, however, seems less satisfactory. Too few young people seem to be interested in scientific and technical subjects, and Honecker urged teachers and the media to make science and technology more attractive. **Vera Rich**

British countryside

Ever onward

The British government's Wildlife and Countryside Bill — regarded as the last opportunity for major legislation on nature conservation matters this century — is likely to generate as much controversy during its passage through the House of Commons as it did in the House of Lords earlier this year. The Lords considered a record 560 amendments to the bill and defeated the government on seven of them. Many of the arguments thrashed out then, on numerous topics relating to nature conservation, will be raised again, with the government trying to reverse some of the Lords amendments and various lobbyists trying to introduce more.

During the bill's second reading in the Commons last week, Mr Michael Heseltine, Secretary of State for the Environment, said that the government was still convinced that conservation would not be well served by compulsion. This is the chief bone of contention over clauses in the bill relating to the protection of sites of special scientific interest (SSSIs). In the Lords, the conservation lobby attempted — unsuccessfully — to amend clauses giving statutory protection to a few specially selected SSSIs to cover all such sites. The debate is likely to continue in the House of Commons committee appointed to debate the bill in detail.

The committee, which began sitting on 5 May, has 20 members, including Keith Hampson and Hector Munro for the

0028-0836/81/190005-02$01.00

government and Tam Dalyell and Stephen Ross for the opposition. As well as protection for SSSIs, other controversial topics include the banning of shooting on Sundays, allowing bulls on public footpaths and how to maintain marine nature reserves.

Judy Redfearn

Reagan's cuts

Handler objects

Washington

Dr Philip Handler, in his farewell address last week as president of the National Academy of Sciences, came close to accusing the National Science Board of cowardice in its failure to protest at the Reagan Administration's cut in the budget of the National Science Foundation (NSF).

The proposal is that the foundation's budget for 1982 be trimmed to $1,033 million, more than 30 per cent less than Mr Carter's request for $1,353 million. At its meeting in March, the board, which is formally responsible for the activities of NSF, approved a statement on the cuts in which it complained that it had been excluded from the budget decision.

The statement also mentioned "problems of serious concern" such as the need to upgrade university research equipment and its "limited capability to reprogram funds to take advantage of emerging research opportunities". There is, however, no direct criticism of the Reagan Administration's decision as such.

Dr Handler said plaintively last week "Would that that statement were not quite so subtle". Handler accepts that the board is constrained by its formal place within the Administration, but he told the academy that the board members' "statutory responsibility to establish the priorities and allocate resources had, in fact, been usurped". And he added: "In not saying so, in unequivocal language, they may allow this incident to become a precedent".

Handler admitted that for the members of the board to have been more forthright might have meant a confrontation with the Administration in which the National Science Foundation would be the loser. "But in crafting a statement in which protest is to be found only by sophisticated reading between the lines . . . the board seemed to be party to the actions of the Office of Management and Budget."

Handler also quoted the board's contention that it was difficult to be engaged in policy decisions about budget cuts in the light of the "economic emergency", which precluded the normal discussion with the board of NSF priorities. "Emergency? What emergency?" asked Handler. "The fact that NSF was given but 24 hours, when the board was not in town, to defend its right to support social science and science education, *inter alia*, is preposterous."

David Dickson

Nuclear power in Yugoslavia

Staying independent

Belgrade

Core loading is now under way at Yugoslavia's first nuclear power station in Krsko. Formally, the station — based on a Westinghouse light-water reactor — is years behind schedule, but this is in part due to an over-optimistic target of five years for construction.

The station has been built jointly by the republics of Slovenia and Croatia. The leading physics institutes of the two republics, the Rudjer Boskovic Institute (Zagreb) and the Josef Stefan Institute (Ljubljana), have been training staff for the new station while building was being completed, and working out the final safety report for the reactor.

Yugoslavia's commitment to nuclear power is strengthened by the presence of uranium deposits at Zirovski Vrh in Slovenia. There are few dissenting voices, notably hotel-keepers on the Dalmatian coast objecting to the proposed siting of the country's second reactor near the tourist resorts, and veteran anti-nuclear campaigner Dr Ivan Supek. Most Yugoslavs apparently see nuclear power as a way to greater energy self-sufficiency.

The TRIGA II reactor at the Josef Stefan Institute, used for heavy metal monitoring.

Before uranium mining and milling operations begin, however, a group from the Josef Stefan Institute is making a detailed survey of background radiation in the area. And this survey forms part of an international project to map the radio-ecology of the Danube basin.

Also being measured in the survey are heavy metal trace elements, including cadmium, arsenic and mercury. The area has a history of mercury mining and once the price of mercury picks up again the old mine is likely to be reopened. The mine closed in the mid-1970s and there is evidence of considerable mercury poisoning in the mine-workers involved. But studies of the effects of mining are being hampered by shortage of finance for a much-needed survey of the non-mining population in the mining area.

This highlights a general shortage of funds for research in Yugoslavia. There is no longer any central planning of science, and funds come either from direct contracts with industry, or else from a structure of "Self-Management Communities of Interest for Science" which administer funds voted from profits of individual commercial enterprises.

The Josef Stefan Institute gets 40 per cent of its funds from the Slovenian assembly of such communities and 60 per cent from contracts. But neither source has shown much interest in studying mercury levels in their region and monitoring a control population elsewhere. **Vera Rich**

Proton decay hunt

New Delhi

Indian and Japanese physicists have discovered three "candidate" proton decay events in a massive iron detector system set up 2,300 metres underground in the Kolar gold mines 100 km north of Bangalore in South India. Begun nearly five months ago, the experiment is to last two years during which at least six of these rare events are expected to be observed provided the proton lifetime does not exceed 10^{31} years.

The detector system consists of 140 tonnes of iron: 100 tonnes for the detector elements and the remainder for shielding. The detector elements are 4 m and 6 m long iron tubes of cross-section 10cm × 10cm. The 1,650 proportional counters are stacked to make a giant 35-layer cake that is 6m long, 4m wide and 4m tall.

The on-line electronics system and the detector configuration enable the total energy of the decay process, the decay vertex and a three-dimensional plot of the tracks of decay products to be obtained. There are some 10^{32} nucleons in the iron and assuming a detector efficiency of 50 per cent, it is hoped to reach a proton lifetime limit of 5×10^{31} years.

The main background to the decay events comes from cosmic rays. Neutrinos and some muons created in cosmic ray events in the atmosphere can penetrate down to the detector; but the Kolar equipment is so deep most of the muons are absorbed in the rock above. Nevertheless, by the end of last week Kolar had recorded 223 vertical muons; 8 horizontal muons, probably coming from neutrino interactions in the rock beside the detector; three neutrino events in the detector; and three events which so far can be explained in no other way than as proton decays. However, all three events have a track which reaches (or emanates from) the edge of the chamber, so they may yet be false events, mimicked by a particle entering the chamber from outside. If the events are confirmed, the corresponding proton lifetime would be $1–3 \times 10^{30}$ years, around the number being predicted by theories which unify the weak, electromagnetic and strong interactions into one grand "gauge theory with spontaneous symmetry breaking".

K.S. Jayaraman

0028-0836/81/190006 01$01.00

CORRESPONDENCE

Conservation sites

Sir — Since private landownership and private incentive are among the basic tenets of Western ideology, I have to agree with Muir (*Nature*, 12 March, p.82) that the populace must suitably entice landowners if it expects them to conserve rather than utilize their land. But it is a callous and immoral science that will not use funds to intervene in natural selection or in "the very evolution of the inanimate world" if these are observed to be proceeding in a deleterious direction. Surely the spending of funds on research directed towards new forms of medical treatment, or of flood or erosion control, is not an "affront to reason", bearing condemnation, and no-one is being misled by the professed importance of these or similar interventions.

Also, thankfully, I know of no science which claims that we can study anything in nature to the limits of its information content so that "nothing new will be learned by preservation". Such would be a conceited science indeed. And, a science that attaches no value to the existence of an object, save for its information content, shows a blatant contempt for existence itself. As Santayana has written (in *Reason in Science*), "If science deserves respect, it is not for being oracular but for being useful and delightful, as seeing is".

Unique usefulness and ability to delight are also properties of jewels or "gems" and of conservation sites, although Muir, in his derisive analogy, has conveniently overlooked these. He has also ignored the one striking difference between them: the virtual indestructibility of jewels as compared with the fragility of ecological systems.

So, must we look forward dispassionately to Muir's future world with its myriad rats, biting insects and noxious weeds, with its computer data banks full to overflowing, but without museums, zoos or conservation sites? Or, should we intervene to ensure a better future where usefulness and delight remain and where Muir's biologically deficient species are not extinct before their time?

A. H. Bretag

South Australian Institute of Technology,
Adelaide, South Australia

Literature search

Sir — PhDs normally take longer than three years to complete and their exact purpose is not agreed upon (*Nature* 22 January, p.217). As an SRC-supported research student, I would like to make a few relevant comments.

I have spent several months in my library carrying out the customary literature search. As time progresses, more and more literature has to be searched and one can only presume that the time to complete a PhD will increase! However, because I spent so long "doing" a search, I found cases of "published rediscoveries" which are attributable I think to: (1) a lack of time spent on a literature search, and (2) a language problem.

The time factor is overcome, at present, only by carrying out a minimal literature search (which in all likelihood will turn out to be inadequate) and by ignoring the language problem altogether by ignoring the literature published in a foreign language. The dilemma facing a research student is obvious. If he/she tries to carry out a thorough literature search and learn a new language then the time spent doing this bites into those three years of support. At a recent course which I attended, which was specifically designed to teach scientists how to translate scientific Russian or German, only five people attended. The conclusion is (from albeit scanty evidence) that researchers choose to ignore the language problem.

Regarding actual literature searching it is only recently that I have found out about "computerized" abstracts, although, I'm told, they have been available for a few years. I would urge the SRC to look into the use (or lack of use) of "computerized" abstracts, if they are not doing so already, as such facilities will become increasingly important and have the potential for saving a lot of time.

I suggest that it would be beneficial if research students were given, from the outset, a course on library and information science so that they are aware of all possible sources of information. I would also suggest that it be made compulsory for research students to learn a foreign language relevant to the scientific discipline. These proposals may take up money and indeed time but to me, at least, appear a necessity if good efficient research is to be carried out. On reflection, what I have suggested favours a more "training for research" type of PhD.

Andrew Brooks

Department of Astronomy,
University of Edinburgh, UK

Avoiding fraud

Sir — The recent alarms about fraud in American science raise the more general problem of quality-control in research. As you correctly observe (*Nature* 9 April, p.433), peer review must be supplemented by "full and frank discussion within individual laboratories". But the process cannot stop there. When I analysed this problem in my book (*Scientific Knowledge and its Social Problems*, Oxford University Press, 1971), I remarked on the inherent difficulty of the quality-control operation in science, since there is no possibility of creating an external inspectorate for assessing the products of the complex and subtle craft skills of science.

Research is therefore necessarily a largely self-regulating activity in this respect, accomplished by peer-review and journal refereeing; but the problems of iteration, "who guards the guardians?" are then even more severe. My conclusion was that integrity and morale, at the highest professional levels, are more crucial to the health of science than perhaps in any other organized social activity.

The various moral imperatives of science, propounded by Merton, Popper and Polanyi, can thus be seen to be very relevant to the survival of worthwhile science. However, they are not so much *a priori* definitions of "science", as descriptions of attitudes and commitments whose presence and effectiveness are entirely contingent. The variability of standards of quality between fields and between milieux bears this out.

When so much of scientific information relevant to public policy is now produced not as "public knowledge" but rather as "corporate knowhow" (in state bureaucracies or private firms), the traditional ideals and norms of science lack an appropriate social context for their reinforcement and maintenance. Under these circumstances it becomes implausible to maintain that only a prejudiced or malcontented opposition can doubt the factual veracity of any piece of technical information used as official testimony in policy debates.

J.R. Ravetz

Department of Philosophy,
University of Leeds, UK

Cladistic clues

Sir — It is unfortunate that the attempts of Dr Miles and the Department of Public Services of the British Museum to display the most logical basic level of analysis of organisms (the level of relative organism-to-organism comparison) is misinterpreted as an attempt to coerce the general public into accepting "a fundamentally Marxist view of life". As one may perceive from the series of replies to L. B. Halstead and the cladistic literature, cladistics is a method which links many very different individual biologists working from very different sets of preconceptions. However, they seem at least to share the opinion that we learn something about organisms by studying what they are made of. The cladist may converge on the Marxist idea that events occur by "taking the form of a leap from one state to another." The cladist may similarly converge with the catastrophist creationist. However, the cladist's stand can be just the opposite of a dogmatic stand, that is, it can be an admission that there are not enough biologists to fill in all the holes in our knowledge of the history of life, and that our inadequate sample of the history of life allows us to see so little "gradualism" that one cannot dogmatically claim that it is the rule.

Halstead's point that public scientific institutions are accountable to the public is well taken. However, publicly employed scientists are accountable to the public for their salaries with ideas and interpretations which the public at large does not have time to make, as well as being accountable for actual specimen displays. Like any curator in history responsible for exhibitions, Dr Miles shares some ideas with scientists of his day, and has some ideas of his own, all of which are reflected in the exhibits he edits and presents to the public. Like any editor, he is forced to make editorial decisions; as one who studies the taxonomic group that Dr Miles has spent most of his career studying, I see no more competent individual than himself.

However, I share some of S. J. Gould's romanticism for great old halls which are closed and renovated into something that is a total stranger to me. Museums cannot help but be places of accumulation, and this catastrophistic kind of replacement of the old with the new does not seem to be the most accurate portrayal of the museum's progress in

Increased majority

In the correspondence "Majority verdict" published in *Nature* 30 April, p.730, R.L. Batten should be added to the list of signatories.

research. Perhaps the most instructive exhibition policy would be to preserve some small corner of every old exhibition hall which would allow the public to see that which their predecessors saw, and which would allow the museum to see what it stood for in the public eye. In the next generation of British Museum exhibits, maybe we will see evolution not as untestable, unscientific theory, but as a more complex though rather less testable theory than cladistic relationship, and as complex and considerably more testable than creationism.

Cafeteria feeding

Sir — A. S. Cole (*Nature* 2 April, p.356) objects to the phrase "cafeteria feeding", applied to experimental selection of "palatable items of food" by rats. I disagree: it seems an unobjectionable, indeed mildly amusing, and appropriate piece of jargon — for once, easily understood. The only criticism might be that, in the original usage, the *palatability* of items on offer is not a *sine qua non.*

Ten years of natural history

Sir — In 1972, the trustees of the British Museum (Natural History) approved a proposal prepared by a panel of the museum's scientific staff, chaired by the then director, for a new approach to the visiting public. This proposal sought to replace the then existing exhibition which rigidly reflected the divisions of the museum into the five separate scientific departments of Botany, Entomology, Mineralogy, Palaeontology and Zoology. The new approach was timely because it coincided with, *inter alia,* changes in biology teaching in schools and an increasingly sophisticated treatment given to natural history on television.

The aims of the new exhibition scheme were summarized as follows: "To present the public with an integrated view of modern biology. All known forms of life will be included, but the new exhibition will do much more than merely demonstrate the diversity of nature. It will show how living things interact with each other and with their physical environment; it will describe the chemical and physical processes that keep them alive; it will introduce the concepts of heredity and evolution, of ecosystem and energy cycles; and it will examine man's role in the living world[1]." A long-term aim was, and still is, to include a greater number of organisms from a wider range of groups than had been shown in the past, combining both recent and fossil organisms in a single evolutionary arrangement.

The trustees have maintained a continuous and close interest in the implementation of this policy, and have conducted a careful review from which they concluded that the museum's Public Services Department has made a bold and largely successful start on implementing the long-term plan. The trustees now consider it appropriate to outline their plans for the next ten years so that those who visit and use the museum may be aware of changes and of the underlying rationale. The trustees have concluded that the scheme should proceed as shown in the table below.

The trustees believe that the implementation of this programme will be beneficial. It will, for example, allow fossil and recent mammals to be brought together in a single rational system for the first time in the museum, and it will not only give greater space to the insects but it will also relate them to the other arthropod groups.

In addition, the Department of Public Services is developing a proposal for an exhibition devoted to British Natural History to be brought forward to the earliest feasible time. This gallery would be designed to meet the needs of committed naturalists to whom the trustees acknowledge a responsiblity, although the prime commitment of the exhibitions must be to the visiting public in general.

The new stages of the exhibition proposed above will have much in common with the older galleries because they will concentrate on the museum's traditional subject matter, the diversity of living organisms. Eventually diversity exhibits are likely to comprise about two-thirds of the completed exhibition scheme. Some parts of the existing displays from, for example, British Insects and Fossil Mammals, will be used in the new exhibitions.

The trustees are also aware of the need for an exhibition related to the museum's interests in geology and have accepted in principle proposals by a Joint British Museum (Natural History)/Natural Environment Research Council Study Group for a co-ordinated display of minerals, gemstones, rocks and meteorites in the BM(NH) and the Geological Museum.

These proposals will necessarily involve a considerable upheaval in the public galleries during the next decade. In order to minimize the effects of this disruption: (1) A temporary display will be provided when any major group of organisms is not represented in a permanent display for a substantial period of time. (4) Access to the Whale Hall will be maintained even though work may be in progress there; thus the Blue Whale will be continuously on display to the public. (3) The larger fossil mammal specimens will be inaccessible only during the period of transit from one gallery to another, as was the case with dinosaurs. And (4), the insects will be off display for a matter of weeks only.

Changes of this magnitude will cause many difficulties and the museum welcomes constructive suggestions, either now or as the work proceeds. The trustees are aware of the controversy aroused by the first phases of the new policy. However, a paper by Dr G. C. S. Clarke and Dr R. S. Miles[2] of the museum's Department of Public Services explained the ideas behind the changes which had provoked the controversy and invited constructive criticism. No replies were received. The museum has continuously monitored the effectiveness of the new exhibition and the responses of the visiting public and has good evidence that the vast majority of the visiting public, especially schoolchildren and their teachers, greatly appreciate the new exhibitions[3]. Suitable modifications have been made when they would lead to improvements.

To assist visitors to understand the complicated changes which are taking place the museum is preparing a small temporary exhibit of the plans.

British Museum (Natural History),
London SW7, UK

Exhibitions planned in the next ten years

Subject	**Location**
Origin of Species (to be opened in May 1981)	Upper South-West Gallery
Mammal diversity (1) — cetaceans, artiodactyls, perissodactyls, hyraxes, sirenians, elephants, rodents and related fossil orders	Whale Hall
Mammal diversity (2) — mammal-like reptiles, monotremes, marsupials, edentates, carnivores, insectivores, bats and fossil groups	Galleries now used for insects and marine invertebrates
Mammal diversity (3) — primates	West balcony of Central Hall
Arthropod diversity (1) — insects centipedes, millipedes and Onychophora	East Pavilion and South-East Gallery
Arthropod diversity (2) — Crustaceans	South-East Gallery
Arthropod diversity (3) — spiders, scorpions, ticks, mites and trilobites	South-East Gallery
Unity in diversity — an introduction to all the museum's exhibitions	Entrance to South-East Gallery

Spatial frequency analysis in vision

from Oliver Braddick

READERS of *Nature* will probably be aware that many experimenters and theorists in visual perception and physiology have taken to using the language of Fourier analysis: they test vision with sine wave grating patterns and discuss the behaviour of the visual system in terms of spatial frequency response. Why has this approach become popular, and has it been justified as enhancing our understanding of vision?

Descriptions in terms of frequency are most familiar when speaking of periodic events in time, such as sound or radio waves, but they may be used for spatial patterns in an analogous way. The number of repetitions of a pattern within a unit of distance is its spatial frequency. The mathematics of Fourier analysis which allow any complex sound to be described as a set of harmonics also allow any visual pattern to be described as a sum of spatial frequency components, that is, patterns whose luminance varies across space as a sine wave. A system designed to transmit time-varying signals, such as a hi-fi set, commonly has its performance specified by its frequency response. Similarly, how well a system transmits spatial patterns can be characterised by its response to different spatial frequencies. In optics, this has been a commonplace technique for evaluating lens systems for many years. The performance of the human eye, however, is determined not only by its optical quality in forming the retinal image, but also by how well the visual system signals the information in that image. It therefore seemed natural to extend the idea of measuring spatial frequency response to the whole system[1,2]. This can be done if we make the fairly uncontentious assumption that for a human subject trying to detect a low-contrast grating pattern, a low threshold indicates a high response of the visual system to that spatial frequency, and so on, using thresholds to measure the contrast sensitivity function.

The spatial frequency response of some component within the visual system may also be measurable: this can be done directly in physiological experiments by measuring the response of single nerve cells to gratings of various frequencies, and indirectly in psychophysical experiments by testing whether two gratings interact in their effects on perception. For example, if one grating can mask detection of another, it is concluded that they must be processed by a common neural 'channel'[3].

The flood of experimental work in what has been dubbed 'gratingology' has come largely from the idea proposed by Campbell and Robson[4] that Fourier methods were valuable, not just for characterising the performance of the whole visual system, but also for understanding the way the system is divided into parallel information-carrying channels. It is generally believed that the properties of these channels define the 'language' in which visual information is conveyed to, and perhaps within, the brain. The idea that this language is best analysed in terms of spatial frequency has been vigorously asserted and contested. If we are to avoid this controversy obscuring the significance of the experimental results, we must keep clear the distinctions between various levels at which spatial frequency methods and Fourier theory may be applied to vision.

First, the spatial frequency response of the visual system can be used as a valuable descriptive measure, without commitment to any particular assumptions about the properties of the visual system. Second, insofar as the visual system, or some component of it, can be treated as linear, the spatial frequency response has important predictive power: since any pattern can be considered as the sum of sine wave components, the visual response to any pattern can be predicted by summing the responses to the separate components. Third, it has been proposed that the visual system at some level consists of parallel, independent channels, each responding to its own limited band of spatial frequency. If so, the visual system itself is performing, at least crudely, an analysis of the visual pattern into its frequency components. Fourth, and most radically, it is possible that this division of the visual pathway into spatial frequency channels might indicate a fundamental way in which visual information is organized: that is, perceptual processes such as selective attention, or recognition, might operate on representations of the visual world in terms of spatial frequency components rather than the more familiar kind of representation in terms of spatial location.

The descriptive use of spatial frequency analysis, at its simplest, amounts to saying that it is important to know not only how well vision conveys very fine detail (high spatial frequencies), but also how well it conveys information about the patterning of light and dark in the image at every scale from the very coarse to the very fine. One application of this is clinical: the quality of vision is conventionally measured in terms of acuity (that is, detail resolution) but some patients complain of poor vision even when their measured acuity is normal. In many cases they can be shown to have abnormally low sensitivity to spatial frequencies below the acuity limit. Indeed, differences in the pattern of contrast sensitivity may be diagnostically significant[5]. An important side effect of the descriptive use of spatial frequency response has been to emphasise the usefulness of contrast as a parameter of vision. Even for non-sine wave stimuli, contrast threshold is often a more useful measure than luminance threshold, since contrast can be varied without introducing the radical changes that occur in the visual system with adaptation to different light levels.

If spatial frequency response is found to have predictive as well as descriptive power, that implies that the visual process concerned shows linear spatial summation. This in turn implies that it could be described equally completely in spatial as in spatial frequency terms. This is true, for instance, of one class of retinal ganglion cells (X-cells)[6]: their response to a pattern can be predicted either from the summation of response to its spatial frequency components, or from summation of the local responses given by each point in the receptive field. The spatial sensitivity profile of the receptive field and the spatial frequency response function may be

---

0028-0836/81/190009-03$01.00

mathematically transformed into each other. In experimental practice, this complete description may be more readily achievable by testing the spatial frequency response, since the cell's response to a grating which covers the whole receptive field is stronger and clearer than that to illumination of a small spot at some point within it.

It can be argued, though, that the spatial frequency approach has a particular value when the requirement of linearity is *not* met. This is because frequency analysis provides tests that very clearly indicate the presence and nature of any non-linearity present. Thus, it was through the investigation of response to sinusoidal stimuli that an important class of non-linear (Y) retinal ganglion cells was discovered by Enroth-Cugell and Robson[6], and that the nature of the mechanisms which produce their characteristic behaviour has begun to be understood[7].

Taking the performance of the visual system as a whole, there are clearly various significant non-linearities, but for the conditions under which many detection experiments are done linear predictions work quite well[4]. This means that it is useful to consider the separate visual response to each of the frequency components making up a complex pattern. Using this mathematical analysis does not require us to suppose that the visual system breaks up the pattern into these components in any physical sense. The frequency response can be taken to describe the properties of visual system as a homogeneous linear spatial filter — the 'single channel' model. The alternative is a 'multi-channel' model in which the analysis into spatial frequency components has more physical reality. In this model, the overall frequency response is the envelope of the sensitivity functions of many independent channels, and different channels may respond to components in a complex pattern. A wide range of psychophysical experiments support the idea of multiple spatial-frequency channels[3,8], although there are still considerable quantitative problems to be resolved on how many parallel channels there are[9], and how narrow is the band of spatial frequencies to which each responds[10].

Physiological experiments, too, show that the visual cortex contains cells responding to different bands of spatial frequencies in the same region of the visual field[11]. It is true that, insofar as these cells show linear spatial summation (as many of them do), their receptive field sensitivity profiles equally describe their properties[12]. For fields of similar form, the differences in optimal frequency will correspond to differences in receptive field size. Even so, the frequency description has a good deal of heuristic value. For instance, a qualitative account in terms of receptive field dimension might lead one to expect that such cells would differ strikingly in the width of bright (or dark) bar to which they respond best. In fact, this turns out to characterise their differences much less clearly than does their spatial frequency response[13].

However, spatial frequency response alone does not give all the information expressed in a spatial sensitivity profile. This is because the response is a function of the phase as well as the spatial frequency of a grating. A cell which responds well to bar patterns will show optimal response to different grating frequencies when they have a peak of the waveform in a given position, while responsiveness to edge patterns corresponds to the requirement that waveforms of different frequency should have their maximum gradient in the same position. What is apparent from making the distinction in terms of phase, rather than edges versus bars, is that any pattern can be considered a mixture of the two phase relationships. Both psychophysicists and physiologists[12] are now exploring the possibility that the division into two types of phase response is another form of 'channeling' for encoding spatial patterns in vision.

Given the existence of channels that respond independently to different spatial frequency bands, should we conclude that visual perception operates in the Fourier domain? In modern digital image processing, it is often found useful to perform various operations on an array of, say 256×256 spatial frequencies, each of which is derived in the Fourier transform of an entire picture of 256×256 local elements. It is most unlikely that visual perception works in anything like this way. Physiological and psychophysical evidence concur that, at the levels we have been considering, analysis is fairly local: receptive fields are limited in size. There is a mathematical inverse relationship between the width of the spatial frequency band to which a channel responds and the range of spatial positions to which it responds[14]. It appears that the visual system represents a compromise, dividing the spatial frequency spectrum fairly coarsely within local, but not very small, areas.

In fact, it would probably be pointless for the visual system to measure spatial frequency components, or anything else, over the visual field as a whole. What we usually want to recognise is not the visual field as a unified entity, but objects within it. Could we be recognising an object by means of the spatial frequency components detected by a local set of channels? In most cases, this seems quantitatively unlikely. Analyses of spatial frequency channels in central vision have generally found them only for spatial frequencies above 1 cycle/degree. Such channels could encode an adequate frequency spectrum only for an object that was roughly ½ degree across, or smaller. With the important exception of written characters, we need to recognise most objects over a range of visual angles markedly larger than this. A similar conclusion arises from physiological receptive field sizes, and from the extent of visual field analysed by a single cortical 'hypercolumn'[15]: at the level of visual cortex, a single object will normally be analysed by many, separate, receptive fields. An important aspect of the processing of visual shape must be the 'grouping' of information from local analysers spread out over an area of the visual field.

What, then, might be the role of spatial frequency analysis in the process of perception? Marr and Hildreth[16] have suggested that coincident signals in different frequency channels provide an effective criterion for finding edges in the visual field. In this view spatial frequency analysis is used at a rather low level to define features, which themselves are part of a representation in the domain of space rather than spatial frequency. Separate processing of spatial frequency bands has been proposed as playing a rather similar role of local disambiguation in the computation of stereo disparity[17,18]. In these models, the information signalled by spatial frequency channels is not separately available for higher perceptual processes. This argument has been supported by experimental evidence that patterns can differ quite markedly in the Fourier domain without it being possible to use these differences for perceptual grouping[19] (although this result concerns the ability to separate componets that differ in orientation, not in spatial frequency itself).

On the other hand, one of the best known effects in grating psychophysics is the 'perceived spatial frequency shift' produced by adaptation to a grating[20]. This

effect is best explained by the assumption that perceived spacing of the grating is directly determined by which spatial frequency channel responds most strongly. It can be argued that judging the spatial frequency of a grating is more related to recognising a repetitive texture, in which we are unconcerned with the spatial identity of individual features, than to perceiving the size and shape of a discrete object. Maybe objects are represented in spatial terms, but the textures of their surfaces in spatial frequency terms.

Speaking of 'objects' should not lead us into the assumption that there we divide any particular visual scene in a fixed way. Clearly for some purposes we are primarily concerned with the gross layout of our visual environment, while for others we need information that is present in fine detail. It is tempting to suppose that for different perceptual tasks we might switch our attention to different spatial frequency bands. However, it is hard to find an experimental example that demands an explanation as spatial frequency tuning of attention, and there are certainly instances where we do *not* find it possible to select a frequency band in this way[21].

Many visual scientists who are sceptical or open minded on how far higher perceptual processes speak the language of spatial frequency nonetheless find that language invaluable for describing and manipulating their experimental stimuli and the information signalled in the visual system. New insights come from thinking of the visual image as containing patterns of light and dark over a range of spatial scales, or 'degrees of blurredness'. Formally, this idea, and analyses that embody it, may be expressible as exactly in spatial as in spatial frequency terms. The fact remains that by exploring the implications of the spatial frequency description, and by using stimulus patterns which were simple to describe that way, we have learned a great deal about vision and by all indications have more to learn yet. □

Sliding charge density waves

from P. A. Lee

THE idea of a charge density wave transition goes back to Peierls[1] and, independently, to Fröhlich[2] in 1954. They reasoned that a one-dimensional metal can lower its energy by distorting the lattice and forming a gap at the Fermi surface, thereby making a transition into an insulating state. The term 'charge density wave' refers to the fact that the lattice and the electron charge density form a new periodic structure, with a wavelength λ that is longer than the original lattice period a. Fröhlich further reasoned that if the charge density wave is incommensurate, that is, a/λ is not a simple rational fraction like 1/2 or 2/3, then the entire charge density wave structure can slide through the lattice, thereby contributing to the electrical conductivity. Since these ideas were originally formulated in terms of one-dimensional systems, for many years they were considered with nothing more than theoretical curiosity.

In the early 1970s the interests of many physicists turned to quasi one- and two-dimensional systems. The existence of a charge density wave ground state in these systems turns out to be the rule rather than the exception, and a large number of examples have been discovered. Experimentally the onset of the charge density wave is signaled by a rise in the resistivity at some temperature T_c. In quasi one-dimensional systems a transition to an insulating state often occurs, whereas in the layered compounds the system often stays metallic. The most direct microscopic evidence for a charge density wave transition is the appearance of new superlattice spots associated with the new lattice periodicity λ which is detected by X-ray, neutron or electron diffraction. Prominent examples of charge density wave systems are the organic charge transfer salts[3], such as tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ) and layered compounds[4] formed from transition metals and chalcogens, such as TaS_2 and $NbSe_2$.

However, until 1976, none of the charge density wave systems had exhibited the sliding conductivity envisioned by Fröhlich. This is because the charge density wave was either commensurate or pinned by impurities. Impurities are sensitive to the charge density oscillations and can lock the charge density wave in place, a phenomenon very analogous to static friction[5]. As in friction, a sufficiently large force should dislodge the charge density wave. Thus the observation[6,7] in 1976 of nonlinear electrical conductivity in $NbSe_3$ was greeted with a good deal of interest. In $NbSe_3$ there are two transitions at 59K and 144K; below each of these temperatures the resistivity rises. It was found that beyond a certain threshold electric field[8], which can be as low as a few meV per cm for the low-temperature transition and 0.1 eV per cm for the higher-temperature transition, the resistivity becomes nonlinear and begins to drop, until it saturates to a value close to that expected if the charge density wave transition had not occurred.

The conductivity is also found to be highly frequency dependent, rising with increasing frequency until it coincides with the high field d.c. value at ~ 100 MHz (refs 7 and 9). It soon became clear that the electric field is not destroying the charge density wave, because an X-ray diffraction experiment shows that the superlattice spots are not affected by a current through the sample even when the current exceeds the linear threshold[10]. Diffraction experiments reveal incommensurate lattice distortions with periods λ such that $a/\lambda = 0.24$ and 0.26 for the upper and lower transitions. These data are consistent with an interpretation in terms of impurity pinning of the charge density wave[11]. The charge density wave can undergo small oscillation, thus accounting for the frequency-dependent conductivity. The pinning frequency is very low, possibly because the impurity concentration in $NbSe_3$ is very small. What makes $NbSe_3$ special among charge density wave systems in this respect is not entirely understood at present. The weakness of the pinning also manifests itself in the low-frequency dielectric constant, which has been measured to be greater than 10^8 (see ref. 9). Presumably a small electric field is sufficient to overcome the weak pinning so that the charge density wave can slide in the way envisioned by Fröhlich — an interpretation supported by an experiment in which impurities were introduced into $NbSe_3$ and the threshold electric field was found to increase[12]. Instead of classical depinning, an alternative mechanism involving the quantum mechanical tunneling of macroscopic segments (up to several microns in length) of charge density waves has been proposed[13], but all existing theories are based on the collective motion of the charge density wave ground state described by Fröhlich.

Further study of $NbSe_3$ yielded more surprises. When the current exceeds the threshold, voltage noise across the sample greatly increases. Superimposed on this background noise are periodic components with well defined frequencies[8], which scale linearly with the excess nonlinear current[14] and are typically in the range of kHz to MHz. A model for the noise is that it arises when the charge density wave moves through the impurities or the lattice, much like a particle rolling down a washboard. If certain assumptions are made about the charge being carried by the sliding charge

density wave (a quantity under debate at present), the frequency of the noise can be accounted for[14].

Recently there was a report of dark-field electron microscopy on NbSe$_3$ (ref. 15). An image of an area of the sample is formed using the superlattice reflection alone; thus any feature in the imaging is due to the charge density wave formation. It is found that stripes approximately 200Å wide run along the conducting axis, and across the stripes are bands of lighter and darker intensities, suggestive of a Moiré pattern. It appears that the charge density wave structure may itself be broken into domains and that more than one superlattice wave vector is possible, so that interference between them forms the Moiré pattern. What is even more intriguing is that at low temperatures the bands are found to shift in time, so that the entire pattern shimmers on a time scale of a fraction of a second. This suggests some time-dependent motion of the charge density wave, but it is occurring on such a slow time scale that its connection with the nonlinear and frequency-dependent conductivity is unclear.

It is rare to find a material like NbSe$_3$ that exhibits such a rich variety of unusual properties. At present the idea of a sliding charge density wave provides a framework for the qualitative understanding of many of these properties, but clearly much work remains to be done before a quantitative understanding is achieved. □

Mobile genetic elements: new Soviet studies

from A. D. Mirzabekov

A CONFERENCE devoted to studies of eukaryotic mobile dispersed genetic elements was held on November 14, 1980 as a session of the seminar 'Chromosoma' at the Institute of Molecular Biology (USSR Academy of Sciences, Moscow).

In the *Drosophila melanogaster* genome mobile dispersed genetic (mdg) elements are multiple, scattered throughout the whole genome, and can move around. They are also actively transcribed (G.P. Georgiev*). At present, about 20 families of mdg elements have been described and comprise as much as five per cent of the whole *D. melanogaster* genome. The variable location of mdg elements is the most striking example known of genomic differences between individuals of the same species.

Y.V. Ilyin[1] described the structural organization of the two elements, mdg1 (a ~ 7kilobase (kb) element including the previously described Dm225 and Dm234 sequences) and mdg3 (~ 5 kb) cloned in the plasmid pBR322. In cell culture, mdg1 and mdg3 are amplified but not tandemly repeated. Like all other transposons, mdg1 and mdg3 contain long terminal repeats (LTRs) at the ends of the gene.

Sequence data show the structure of the LTRs of mdg3 (Bayev *et al. Nucleic Acids Res.* **8**; 3263, 1980; A.S Krayer, V. Kulguskin*) to be perfect direct repeats 268 bp long flanked by two mismatched 18 bp inverted repeats. The complete mdg 3 element is then bounded by short (5 bp) direct repeats probably derived from host target sequence duplication. Mdg1 contains longer perfect direct repeats (442 bp) flanked by mismatched 16 bp inverted repeats. In this respect, the organization of mdg1 LTR is similar to LTRs of the *copia* gene (Levis *et al. Cell* **21**; 580, 1980) or terminal repeats of integrated proretroviruses (Beveren *et al. Proc. natn. Acad. Sci. U.S.A.* **77**; 3307, 1980; Dhar *et al.* ibid; 3937, 1980). Within both LTRs, signal sequences for transcription initiation (Hogness box) and polyadenylation (AATAAA) are found.

The whole mdg sequences of mdg1 and mdg3 are transcribed, initiation and termination sites being localized within LTRs (V.G. Chmeliauskaite*). Both DNA strands are transcribed giving rise to the long double-stranded RNA stretches found in total poly(A)$^+$ RNA from cell culture. However, the efficiency of transcription of one strand is much higher than that of the other. At least in *D. melanogaster*, hybridization to very long double-stranded RNA can be used as a diagnostic test in the search for new mdg elements. Besides full-length transcripts, spliced poly(A)$^+$ RNAs were found among mdg1- and mdg3-specific RNA sequences. The major part of mdg transcripts are located in free ribonucleoprotein particles in the cytoplasm and only a minor fraction is bound to polysomes.

M.D. Golubovsky (Institute of Cytology and Genetics, Novosibirsk) showed that the frequency of an unstable mutation in the *sn* locus of *D. melanogaster* can simultaneously increase in geographically distant natural populations of flies. This may be due to 'infection' with a movable element. In addition, a mutation was found which influences both *sn* and *ct* loci and probably depends on the presence of the same element. A correlation between instability in *white* locus and mdg 1 insertion was shown by E.S. Belyaeva†.

The localization of the mdg elements in chromosomes appears highly conserved during differentiation as they have been found in the same position in cells of salivary glands and stomach (E.V. Ananiev†). They are also stable in inbred lines of *D. melanogaster*. The probability of 'jumping' for mdg1 and mdg3 was estimated to be of the order of 10^{-5}.

Drastic changes in mdg1 and mdg3 localization were found to take place during back selection for high sexual activity among inbred flies characterized by low sexual activity (V.S. Gvozdev†). Such transpositions might facilitate adaptation of the organism to the environment through influence on the expression of other genes.

Mdg elements appear species specific: those of *D. melanogaster* cannot be detected in *D. virilis* and vice versa (M.B. Evgen'ev*). A new mdg family has been cloned by G. N. Yenikolopov from *D. virilis* genome. *D. littoralis* chromosomes included in the genome of *D. virilis* are able to accept *D. virilis* mdg copies without crossing-over.

A.N. Gudkov (Oncological Centre, Moscow) discussed endogenous proretroviruses and their similarity to mdg elements. Different strains of hen differ strikingly in the number and localization of proviral sequences as studied by Southern blotting analysis. The existence of a natural strain completely lacking RAVo-like sequences was described. Together with the data of Astrin *et al.* (*Cold Spring Harb. Symp. quant. Biol* **344**; 1105, 1979) this suggests that the presence of proviral sequences is not essential for the organism.

Sequences homologous to the oncogene of mouse Moloney sarcoma virus (putative protooncogene) and to some other sequences of the virus (human C-type proretrovirus) are found in the normal human genome (E.A. Zabarovsky*). The protooncogene-containing sequence has been cloned from the human genome.

D.M. Kramerov* described the properties of two mdg-like elements cloned from the mouse genome selected on the basis of efficient hybridization to long stretches of double-stranded RNA (dsRNA-A). One of these cloned sequences was found to be responsible for the synthesis of intracisternal A-particles. Also, endogeneous C-type proviruses were detected among dsRNA-A-hybridizing sequences of mouse genome.

Structural similarities between mdg elements of *Drosophila* and endogenous proretroviruses were stressed by Georgiev. He also discussed a 'promoter' hypothesis of carcinogenesis (see *J. theor. Biol.* **25**;473, 1969) which considers oncogenic transformation to result from a potential cellular oncogene falling under the control of the viral promoter. Mdg elements may provide an important source of such poorly controlled promoters in the course of nonviral oncogenesis. □

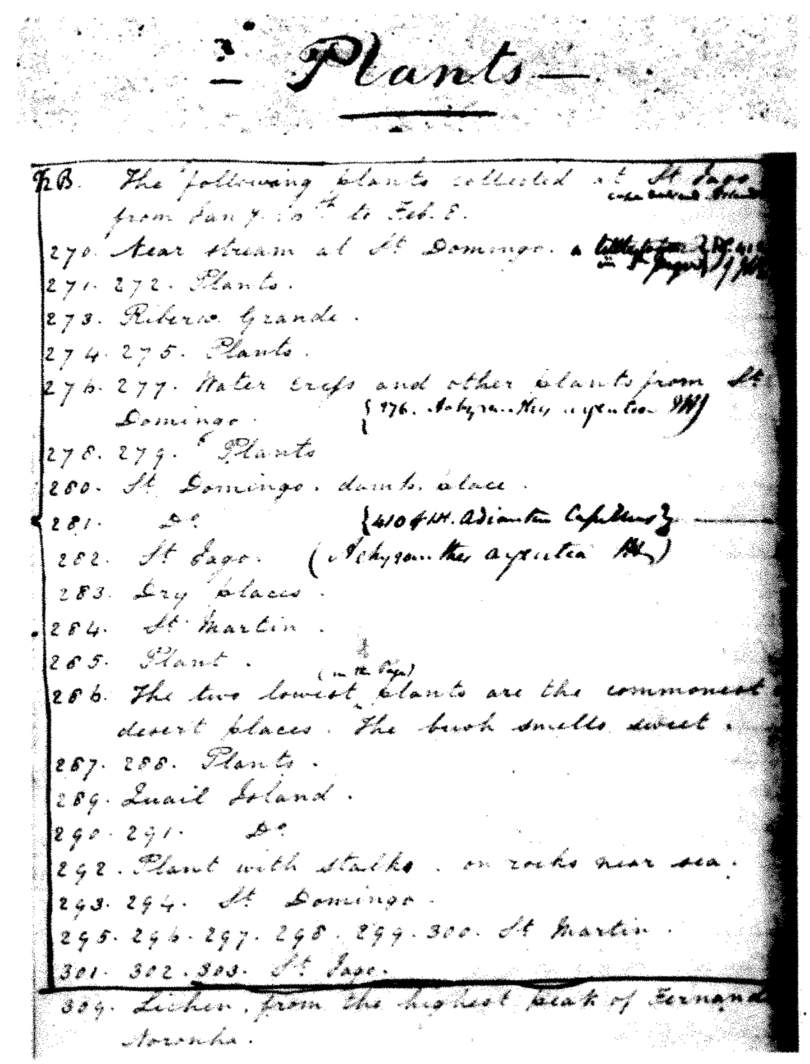
Darwin's missing notebooks come to light

from Duncan M. Porter



The cover legend written by Darwin and part of the first page of the Plant Notes written by Covington with notes added by Darwin and by Henslow.

IN early December 1980, Rita I'Ons, Assistant at the Cambridge University Herbarium, discovered two notebooks titled *C. Darwin's Plants from S. America* and *Darwin's S. American Plants* in a cupboard at the Herbarium. The notebooks, on the plants collected during the voyage of HMS *Beagle* (1831–1836) had been lost for more than a hundred years. Their long absence has caused many problems with the identification of Darwin's plants and has also prevented the botanical aspects of his voyage from being properly appreciated.

The notebooks are in the writing of J.S. Henslow, Professor of Botany at Cambridge and Darwin's mentor, who originally agreed to identify the plants. However, because of other commitments, Henslow was unable to identify more than a few, and the task fell to J.D. Hooker at Kew in the early 1840s. Henslow sent Darwin's notes to Hooker, and presumably they were later returned, but earlier searches at Cambridge and Kew failed to find them[1]. Hooker and others identified a number of Darwin's plants, but the majority remain unclassified to this day. Tied with string into the back of the second notebook are 11 pages of notes titled 'Plants'. They are in the handwriting of Syms Covington, Darwin's servant and amanuensis on the *Beagle* and until 1839. A few notes and corrections have been added in Darwin's hand, as have a few notes by Henslow.

Notes on the plants vary in length from the terse 'Plant' to a page-long discussion on the Wild Potato of Chile's Chonos Archipelago (*Solanum tuberosum* var. *guaytecarum*). The latter was used as the basis for the discussion in Darwin's *Journal of Researches*[2]. Likewise, one can trace other notes to passages in the *Journal*. Some, such as that on the Dwarf Beech of Tierra del Fuego (*Nothofagus antarctica*), make more interesting reading than when published: "Jemmy Button said. 'when leaves yellow, snow all go'. — Captain FitzRoy states that in April the leaves of the trees which grow on the lower parts of the hills turn colour; but not those high up. — I recollect having read a paper to show that in England warm Autumns hastened the falling of the leaves; that the process is a regular part of the vegetation: This fact would seem to show the same law." When published in the *Journal*, Button's quote was excised.

A passage in the Plant Notes describing the forests of Tierra del Fuego seems to anticipate the 'tangled bank' of the *Origin of Species:* "The extreme dampness of the climate favours the course luxuriance of the vegetation: the woods are an entangled mass where the dead and the living strive for mastery." In the last paragraph of the first edition of the *Origin*[3], Darwin writes: "It is interesting to contemplate an entangled bank, clothed with many plants of many kinds, with birds singing on the bushes, with various insects flitting about, and with worms crawling through the damp earth, and to reflect that these elaborately constructed forms, so different from each other, and dependent upon each other in so complex a manner, have all been produced by laws acting around us."

The Plant Notes follow the same format as the lists of notes on *Beagle* zoological specimens at the Cambridge University Library and the British Museum (Natural History). Each series of notes was compiled for the taxonomists who were to identify the various groups of organisms collected (plants, birds, fish, insects, mammals, molluscs, and reptiles and amphibians). As Darwin intended, the Plant Notes are proving quite useful in the identification of his *Beagle* specimens. ☐

The well-managed lawn

from Peter D. Moore

ONE of the most widespread vegetation types, and one which is certainly the most easily accessible to urban populations, is that highly managed piece of anthropogenic grassland, the domestic lawn. It has been estimated that the area of lawn in Britain is approximately 2,700 km^2 (NERC report, *Amenity Grasslands*; 1977), plus a further 1,100 km^2 of playing fields. It is surprising, therefore, that so little academic research has been conducted upon so amenable a habitat.

The work of Falk (*Ecology* **57**; 141, 1976) on his suburban lawn in California made it evident that the lawn is a very appropriate ecosystem for studies of the energetic type. Falk produced a very full energy budget for his lawn, in which net primary productivity was estimated at 4,468 kcal $\text{m}^{-2}\text{yr}^{-1}$ (1.05 kg m^{-2}). Of this 10.4 per cent was harvested by man as mowings, 2.9 per cent was consumed by invertebrate grazers and the remaining 86.7 per cent was considered to enter the decomposer system directly.

Falk's data also take into account the energy investment by man in the management and maintenance of the lawn, mainly in the form of fossil fuel used by the motor mower. This totals 2,029 kcal $\text{m}^{-2}\text{yr}^{-1}$. Thus if we were to consider the lawn in terms of harvest efficiency the outcome is low, with an output : input energy ratio of 0.22. The ratio obtained (Blaxter, *Nature* **252**; 531 1974) for the total energy efficiency of British agriculture is 0.4.

The British lawn is still neglected, but Falk has now provided us with more information about the lawns of the United States (*J. appl. Ecol.* **17**, 689; 1980), this time in the east, near Washington DC. Two lawns were selected for study, one received what was termed 'minimum maintenance', with no irrigation or fertilization and a fortnightly mowing. The other site was well maintained, being fertilized and limed once a year, mowed weekly and irrigated during the summer. Both lawns were mowed to a height of 5 cm using a rotary mower.

As one might expect, the undermanaged lawn was richer in species (22 species recorded in 0.7 ha) than was the highly managed one (11 species in 0.2 ha). What is surprising is the very similar values obtained for the total net primary productivity (below-ground production is included). For the neglected lawn this came to 1,669 $\text{kg m}^{-2}\text{yr}^{-1}$ (6,380 kcal) and for the well-managed lawn 1,649 $\text{kg m}^{-2}\text{yr}^{-1}$ (6,814 kcal). So all the extra management effort serves only to reduce diversity without increasing productivity. The amount removed in mowings is about 20 per cent of the total productivity, rather higher than that observed in California.

As Falk points out, the mowed lawn in temperate climes is a highly productive ecosystem, despite its low stature. The highest productivity of tropical grasslands (around 2,000 g $\text{m}^{-2}\text{yr}^{-1}$) and the productivity of maize or wheat in temperate environments (1,000–1,600 g $\text{m}^{-2}\text{yr}^{-1}$) are comparable to that of the suburban lawn. It is salutary to reflect, therefore, upon the energy harvest each year from such habitats in Britain alone. If these can match the productivity of their Washington counterparts (and anyone who has seen the lawns of Washington in August will have no hesitation in allowing this), then 332 kg m^{-2} (1,320 kcal m^{-2}) is harvested as mowings each year from our 3,800 km^2 of urban and suburban amenity grasslands. This amounts to 1.2×10^9 tons of dry matter, or 5×10^{12} kcal each year. Taking the original estimate of energy output : input ratio of 0.22, this implies that we expend a total of 2.27×10^{13} kcal on the harvesting of this herbage each year in Britain. Given the high energy investment in maintaining the British lawns and cricket pitches, the energy-from-biomass lobby must be tearing out its hair to see mowings being fed to the decomposer systems of the nations's compost heaps. □

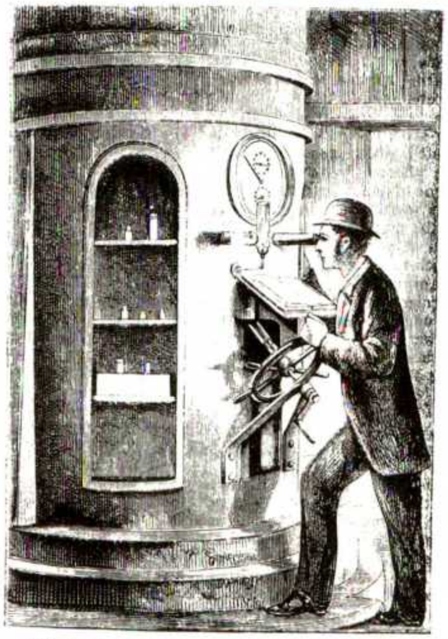
100 years ago

THE GREAT VIENNA TELESCOPE

THE political and social disturbances in Ireland have of late somewhat diverted attention from the literary and scientific work done in that country. Such work has nevertheless proceeded on its quiet way despite land agitation, failure of crops, or even commercial distress; and Ireland is to be congratulated on the completion of the fine 27-inch refracting telescope, designed and constructed by Mr. Howard Grubb of Dublin for the Imperial and Royal Observatory of Vienna. This telescope is the largest equatorial refractor at present in existence.

In the largest telescope until now in existence, the great 26-inch refractor at Washington, the oft-recurring operation of reading the circle involved the sending of an assistant with a hand-lamp to climb up some twenty feet of the instrument, and the vernier not being in a fixed place, but moving about with the telescope, the labour and difficulty of this operation are great. In the Vienna instrument Mr. Grubb has so contrived it that the observer sitting in his chair can read the right ascension and declination circles through one single reader, all being illuminated by one gas-lamp hung on the end of the declination axis.

Another wonderful convenience is enabling an assistant to easily turn and set the instrument to right ascension. This can be understood from the figure, which is from a photograph. In the case of an instrument of the size of the Vienna equatorial, the observer requires an elaborate stage or platform of variable height and position in order to reach the eye-end, and if he has to move to another object he must descend from his chair or platform and move *it* before he can move the instrument, and then he has not the facility of sighting objects, but must adopt a sort of tentative process, climbing up and down his stage and moving it and the telescope alternately. To avoid this labour and save time an arrangement is supplied by which the assistant from the ground floor can set the instrument in right ascension, and once set in one direction, the other (declination setting) can be readily managed by the observer.



We learn that M. Alphaud, the Director of Public Works in Paris, has in his hands the tender of Siemens and Co. for constructing an electrical railway from the Place de la Concorde to the interior of the Electrical Exhibition. M. Alphaud has given his adhesion to the request, which will be sent with his recommendation to the Commission of Sewers appointed by the Municipal Council, that when the Exhibition shall be closed, the railway will be kept running in the Champs Elysèes.

About twenty minutes to eleven on Monday night, owing to some accident at present unexplained, the electric lights on the Brush system, one of the three with which experiments are at present being made in the City, were suddenly extinguished, leaving a large portion of the City in total darkness. The area over which the Brush light has been placed extends from Blackfriars Bridge, up Ludgate Hill, to St. Paul's Churchyard, and down Cheapside as far as Queen Street and King Street. Fortunately the old gas-lamps remain in their places while the electric light experiments are being made, and orders were quickly given for these to be lighted. Every attempt was made by those in charge of the Brush light to restore the connection, and for a few minutes it seemed as though they had succeeded; but this only lasted for a very short time, and it was soon seen that something had gone hopelessly wrong.

Carbon in carbonaceous chondrites: carbyne or graphite?

from P. P. K. Smith

CARBON in carbonaceous chondrite meteorites has received much attention as a likely carrier of isotopically anomalous noble gases. Over the past year this has led to a difference of opinion concerning the structural form of the carbon in such meteorites. This problem was addressed by several contributors to the Twelfth Lunar and Planetary Science Conference, held in Houston, Texas, in March.

Carbonaceous material has been reported[1,2] as a carrier of part of the anomalous neon component, Ne-E, which is characterised by its extreme enrichment in the isotope ^{22}Ne. In 1969 Black and Pepin[3] argued that Ne-E is of presolar origin, having been trapped in interstellar dust grains that were subsequently incorporated into the solar nebula. A carbonaceous host phase also seems likely[1] for a presolar xenon component, s-process Xe, that was discovered by Srinivasan and Anders[4]. Thus if the carrier phases of these exotic noble gas components can be identified they may provide us with examples of interstellar dust grains.

Last year Whittaker and Watts of the Aerospace Corporation, in collaboration with Lewis and Anders of Chicago University, reported that 80 per cent or more of the carbon in the Allende carbonaceous chondrite is in the form of carbynes[5]. Carbynes are a relatively recently discovered series of polymorphs of elemental carbon, based on a chain structure with alternating single and triple bonds[6]. Whittaker *et al.* identified carbynes in Allende by means of electron diffraction, and also by the characteristic negative-ion mass spectrum that they produce in an ion probe. Carbynes were also detected in the Murchison carbonaceous chondrite, where they were found to be carriers of Ne-E and s-process Xe.

A different view of the structure of the Allende carbon has been presented by Smith and Buseck of Arizona State University, who used high-resolution transmission electron microscopy (HRTEM) to obtain images of the microstructure of the carbon[7,8]. Such images display prominent crystal lattice fringes with spacings between 3.4 and 3.9Å, corresponding to the interplanar spacings of poorly crystalline graphite. The individual graphite crystallites are only ~ 100Å in size, so that electron diffraction patterns obtained from areas 0.5 μm across (the smallest area that can be isolated by conventional selected-area electron diffraction) consist of diffuse rings. This may be contrasted with the sharp, single-crystal diffraction patterns that Whittaker *et al.* obtained from carbyne crystals which were up to 0.75 μm in size.

At the recent conference Smith and Buseck reported an attempt to resolve this discrepancy[9]. The Chicago/Aerospace group had provided a portion of their nearly pure carbon separate (BK) from Allende, together with an electron microscope mount that they had prepared from this material. Smith and Buseck located several grains on this electron microscope mount that gave carbyne-like diffraction patterns. However, chemical analysis of these grains by means of X-ray microanalysis demonstrated that they were all sheet silicates rather than elemental carbon. Examination of an electron microscope mount of BK that Smith and Buseck prepared themselves revealed only graphitic carbon. Thus Smith and Buseck inferred that some, and possibly all, of the diffraction patterns that Whittaker *et al.* obtained were actually due to contamination of their sample by sheet silicates. This would appear to account for one unexplained feature of the Chicago study: although BK was considered to be 80 per cent carbyne, only five carbyne crystals were found in it by electron diffraction.

Of course these observations do not have any direct bearing on the ion-probe results of Whittaker *et al.*, and in discussion of the Arizona study Anders emphasised the striking predominance of even-numbered carbon species (C_2, C_4, etc.) that they had found in the negative-ion spectrum of the Allende material. This pattern is believed to reflect the tendency of the . . . C–C≡C–C . . carbyne chain to cleave at the single bonds rather than at the triple bonds[10]. This feature is not in fact unique to carbynes — a predominance of C_{2n} species has been described previously for mass spectra obtained from both graphitic[11] and amorphous[12] carbon — but Whittaker *et al.* used reference spectra from graphite and from known carbynes to determine the carbyne content of their Allende carbon separate. The term graphitic carbon embraces a wide variety of microstructural forms, ranging from macroscopic single crystals to the extremely fine-grained tangled assemblage of ribbon-shaped crystallites that constitutes 'glassy' carbon[13]. Further work is perhaps needed to determine whether these varieties give rise to differing negative-ion spectra.

Electron diffraction observations of Allende carbon reported by Lumpkin[14] are consistent with the HRTEM observations of graphitic carbon. Lumpkin did find a small fraction (~ 3 per cent) of grains that gave carbyne-like diffraction patterns, but the chemistry of these grains has not yet been verified by microanalysis.

Dziczkaniec *et al.* described an investigation of the trapping of noble gases during the synthesis of carbonaceous material in a plasma discharge, an experiment designed to model the conditions under which the carbonaceous carrier phases in meteorites may have formed[15]. Although at an early stage, this study has shown that isotopic fractionation takes place during the trapping of xenon. It will be interesting to see whether the release temperatures for noble gases in this synthetic carbon follow a pattern similar to that found for meteoritic carbons. Interestingly enough, Dziczkaniec *et al.* found some crystalline grains amongst their run products that were very tentatively identified as carbynes. If this identification is confirmed, then this study would provide a new synthesis technique for carbynes, which have usually been prepared by laser heating of graphite.

Most recent studies of carbonaceous material in meteorites have centred on carbon-rich residues obtained by dissolving the bulk of the meteorite in concentrated acids, thereby destroying all information on the petrographical distribution of the carbon. An exception to this was the discovery by Scott *et al.* of aggregates of graphite and magnetite (Fe_3O_4) occurring as millimetre-size inclusions in several ordinary chondrite metoerites, and also in some more primitive unequilibrated ordinary chondrites[16]. The presence of this graphite–magnetite mixture in such primitive meteorites, which are thought not to have undergone appreciable heating in their asteroid parent bodies, indicates that graphite and magnetite may have been significant constituents of the early solar nebula. Textural relationships in these meteorites suggest that much of the

metallic iron present in them formed by the reduction of magnetite by carbon.

A previous report[17] of presolar Ne-E in a carbon-rich residue from one of the ordinary chondrites studied by Scott *et al.* led them to suspect that the graphite–magnetite inclusions might be the carrier, and hence be of presolar origin. Unfortunately the story is not that simple — they did not find any Ne-E in the graphite–magnetite intergrowths. Thus the Ne-E must either be contained in a different carbonaceous component, or in another minor phase in the residue. The identification of the carriers of such minor gas components is fraught with difficulties, but is providing us with valuable clues to the early history of the Solar System. □

Impact cratering

from Richard A.F. Grieve

The relative importance of cratering in planetary evolution was evidenced at the Twelfth Lunar and Planetary Science Conference* by numerous papers on impact craters and discussion, in sessions dealing with particular terrestrial planets and the icy satellites of Jupiter and Saturn, of their effects. The diversity of research reported in the sessions dealing directly with impact processes reflected the random nature of cratering with respect to specific geological environments and the involvement of many sub-disciplines of the physical science in providing information on cratering processes. As has been apparent in recent years, there was an increasing combination of theoretical and observational results, with each approach serving to constrain the other.

With respect to the evolution of the jovian and saturnian satellites, the results of impact experiments showed that the mechanical properties of ice differ from those of rock, even at the low temperatures of 70–80K existing on these bodies. In particular, the specific energy required to disrupt an icy body by impact appears to be ~ 20 per cent less than for a silicate body. Other impact experiments illustrated that extensive fracturing occurs around craters in ice but craters in ice-saturated sand targets exhibit more limited fracturing and are more like those in competent rock. It was noted, however, that ejection patterns appear to be similar for craters in icy and silicate targets.

Computational simulations derived from the solution of continuum mechanics equations continued to provide important insights into cratering processes. For example, they indicated that excavation dynamics and the physical state and radial distribution of ejecta are strong functions of impact velocity. Calculations also supported the interpretation that bowl-shaped cavities are produced by excavation plus the displacement of the cavity floor by impact-induced flow fields. Further confirmation of these displacements was proved by an analysis of the Cactus nuclear event. Similar conclusions on the formation of bowl-shaped craters were reached in a combined observational and theoretical treatment of the Brent Crater, Canada, which also provided an estimate of the initial impact conditions: a 113-m radius chondritic projectile impacting at ~ 27 km s^{-1}.

The important question of the detailed particle flow fields created in the target rocks by impact was addressed in a comparison of flow fields derived from continuum mechanics calculations and the 'Maxwell-Z' model. It was clear that this empirically derived model remains a powerful analytical tool. Similarities between the calculated flow fields for Meteor Crater, Arizona, and those of the Middle Gust III explosive event also suggested that the parametric codes derived from the latter may be applicable to impact events. However, the energy coupling differences suggest that explosive events are imperfect analogues to impact events in terms of scaling crater dimensions with energy.

It is known that the initial transient cavities formed by impact events generally modify rapidly to more stable final forms. In bowl-shaped craters, this modification is thought to occur by failure of the transient cavity walls. It was proposed at the meeting, however, that cavity modification may result from the centripetal motion of the entire rim area, in a manner similar to that suggested for the formation of larger, relatively shallow complex impact structures. The formation of these complex structures was addressed in a phenomenological model, ascribing central peak and ring formation to oscillatory motions of the transient cavity floor. These oscillatory motions require essentially plastic behaviour and viscosity of 10^9 P for the target rocks. Such viscosities may result from the effective fluidization of fractured target by an impact-generated acoustic field. Some support for the importance of two parameters, rock strength and gravity, in the phenomenological model may be found in the report that the 20-km Haughton impact structure on Devon Island, Canada, has a multi-ring form. Haughton was formed in sediments and its relatively small dimensions for a ring structure scale with gravity and rock strength when compared with similar crater forms on the Moon and in crystalline targets on Earth. Doubts were raised, however, over the universal concept of deep initial transient cavities by the results of impact experiments at high gravitational accelerations, which suggested that relatively shallow cavities may be produced directly without modification.

Several papers dealt with the mineralogical or shock metamorphic effects produced by impacts in various target media. Shock experiments in limestone indicated that incipient vapourization of carbonate occurs at pressures as low as 350 kbar. An analysis of effects in tectosilicates illustrated that planar deformation features are produced during shock compression. It was also reported that the reduction in refractive index of shocked quartz is due to lattice disordering. A high concentration of lattice defects, particularly non-bridging oxygens, is also the cause of the conversion of plagioclase to the solid-state glassy phase known as maskelynite at shock pressures of 300–350kbar.

The non-isochemical alteration of impact melt rocks was reported, as was evidence for extensive chemical exchange between feldspar clasts and enclosing impact melt matrix. This chemical exchange may account for some of the disturbances seen in the Rb–Sr systematics of melt rocks. ^{39}Ar–^{40}Ar systematics of shocked samples from the Ries, Germany, were also described and it appears that up to 99 per cent of radiogenic ^{40}Ar may be lost at shock pressures of 300 kbar or more. This observation should aid in the interpretation of Ar ages obtained on lunar impact breccias.

A report of siderophile abundances in the melt rocks at Strangways suggested that this 20–25 - km impact structure in Australia was formed by an olivine-rich achondrite. Siderophile enrichments were also discussed with reference to the Cretaceous–Tertiary boundary layer and extinctions. It was noted that several important geochemical problems with respect to the various sampled sections need to be resolved. Theoretical calculations were presented for the postulated extinction-causing impact and indicated that significant atmospheric heating could only be achieved indirectly through energy transfer from ejecta. The interpretation that the formation of the 20-km lunar crater Giordano Bruno is recorded in the Gervase of Canterbury chronicles as occurring on 19 June 1178 was reviewed. It appears that only an estimated 0.1 per cent of the ejecta might reach the Earth by direct trajectories and that the analytical problems associated with recognizing such material are formidable. □

ARTICLES

The structure of West Antarctica from geophysical studies

E. J. Jankowski & D. J. Drewry

Scott Polar Research Institute, University of Cambridge, Lensfield Road, Cambridge CB2 1ER, UK

The subglacial topographical and geological configurations of West Antarctica and the boundary zone between East and West Antarctica are poorly known, yet they are crucial to our understanding of the tectonic evolution of the Pacific–proto Atlantic margin of Gondwanaland. Preliminary results are presented of simultaneous airborne radio echo and magnetic sounding of $\sim 10^6$ km^2 of West Antarctica including detailed maps of ice sheet and bedrock surfaces. Magnetics, radio echo and other available geophysical data suggest interpretations of sub-glacial geology.

DURING the late 1950s and 1960s major US oversnow traverses in West Antarctica conducted altimetric, seismic, gravimetric and magnetic studies[1–4]. This work provided the first outline of ice sheet surface, subglacial topography and ice thickness. Many features were identified, including the principal ice divides, subglacial basins and mountainous blocks. Airborne magnetometry was also conducted, principally by the University of Wisconsin[5,6] the US Geological Survey[7] and US Project Magnet[8,9].

The oversnow traverses accomplished some 2,000 surface altitude determinations, ~250 seismic soundings and ~2,000 gravity observations in an area of $\sim 10^6$ km^2. Some interpolation and extrapolation was necessary for maps to be produced with a contour interval[10,11] of 500 m. Although the aeromagnetic data had high accuracy, they suffered from having no simultaneous ice thickness information and only dead reckoning navigation.

During the austral summers 1977–78 and 1978–79 the Scott Polar Research Institute (SPRI) undertook an airborne geophysical programme in West Antarctica which included radio echo sounding (by SPRI and Technical University of Denmark, TUD) and magnetometry (by Applied Physics Laboratory, APL, Johns' Hopkins University). The work was carried out in cooperation with the US National Science Foundation (NSF). In addition radio echo sounding (RES) alone was conducted during the austral summer 1974–75 in the area between Byrd Station and the Ross Ice Shelf[12] (see Fig. 1 for locations). The principal objective was to establish a grid for geophysical investigation of the complex structure of West Antarctica and its relationship to the East Antarctic craton. The available geophysical data combined with reconnaissance geology on scattered outcrops suggest West Antarctica possesses a complicated tectonic history[13,14].

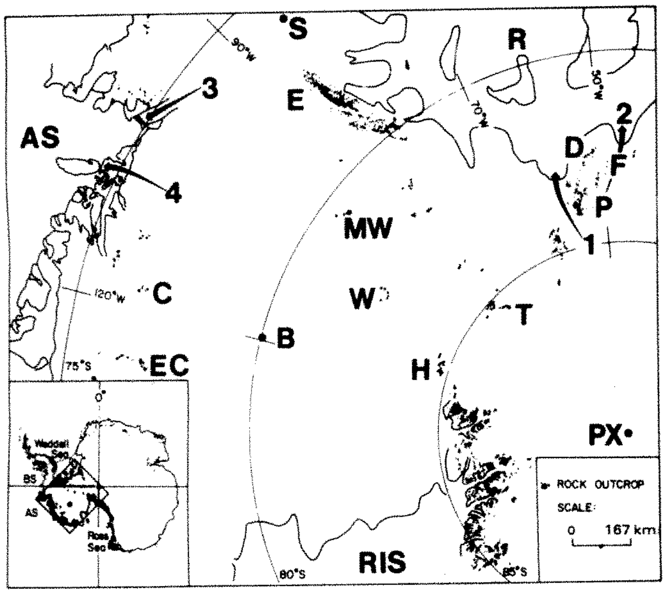

Fig. 1 Location map. AS, Amundsen Sea; BS, Bellingshausen Sea; R, Ronne-Filchner Ice Shelf; RIS, Ross Ice Shelf; B, Byrd Station; C, Crary Mountains; D, Dufek Massif; E, Ellsworth Mountains; EC, Executive Committee Range; F, Forrestal Range; H, Horlick Mountains; MW, Mount Woollard; P, Pensacola Mountains; PX, Pole Station; S, Siple Station; T, Thiel Mountains; W, Whitmore Mountains; 1, Foundation Ice Stream; 2, Support Force Glacier; 3, Pine Island Glacier; 4, Thwaites Glacier.

Equipment during both seasons comprised pulsed radar systems operating at centre frequencies of 60 and 300 MHz, designed and built by TUD in collaboration with SPRI[15,16]. Returned echoes were displayed in both *A*- and *Z*-modes and recorded on 35 mm film and dry-silver paper by a fibre-optic oscillograph. Equipment was mounted on pallets in a specially configured NSF C-130R Hercules aircraft, operated by US Navy Antarctic Development Squadron Six. An LTN-51 inertial system provided navigation data updated by photographic resections on known topographic points. Navigation and all other flight data were recorded on magnetic tape by an Airborne Research Data System (ARDS) constructed by US Naval Weapons Center, and operated since 1978 by APL. A proton precession magnetometer mounted in a tail stinger was installed by APL and operated by them simultaneously with RES. Coefficients compensating for the effect of the aircraft were determined by APL using a vector magnetometer and adopting the technique originally developed by Leliak[17–19]. The unreduced magnetic data, provided by the NSF, were then compensated, reduced and correlated with RES in Cambridge.

Aircraft pressure altitude was corrected to points of known surface elevation. The terrain clearance was determined from RES records and the aircrafts' radar altimeter. Navigation data were corrected for closure error, typically of the order of 3 km, and inflight fixes. Subsequent errors in altimetry from one flight to another were removed using a random walk technique. The mean error at crossover points before random walking was 46.5 m with a standard deviation of ±44 m. RES records were digitized at a spacing of between 1.5 and 1.8 km and concatenated with updated navigation and altimetry data. Maps were compiled to depict ice sheet surface and bedrock configuration. In the case of the ice-sheet surface some 70,000 RES data points were used. Additional elevations were obtained by using all data from oversnow traverses (refs 1–4, 20 and C. R. Bentley, personal communication). For the bedrock map we used ~56,000 RES determinations combined with bedrock elevations at some 250 seismic stations on the traverses. A contour interval of 100 m has been used for the ice surface and 250 m for

0028-0836/81/190017—05$01.00

bedrock. Shading has been applied to areas of bedrock below −1,000 m a.s.l. to assist with interpretation. No attempt was made to detail the contours in areas of outcrop.

Ice sheet surface

Although there is broad correspondance between Fig. 2 and previous maps based on oversnow traverse[20,21] or balloon data (tropical wind, energy conversion and reference level experiment, TWERLE)[22], the large amount of data now available from RES allows considerably better delineation of many features including the ice drainage basins of West Antarctica. A major ice divide runs from inland of the Transantarctic Mountains through a gap between the Horlick and Thiel Mountains towards the Ellsworth Mountains confirming previous studies. A further ice divide crosses from the Executive Committee Range (passing to the north-east of Byrd Station) to join the first divide in the vicinity of Mt Woollard (see Fig. 1 for locations). West Antarctica is thus effectively divided into a series of drainage basins feeding ice into the Ross Ice Shelf, Ronne–Filchner Ice Shelf and the Amundsen–Bellingshausen Seas. Drainage into the Ross Ice Shelf from West Antarctica has been fully described elsewhere[23].

Ice streams shown shaded in Fig. 1 have been delineated by the presence of surface crevassing detected on the RES records[23]. The Foundation Ice Stream, running along the west side of the Pensacola Mountains, is already known in general but additional detail shows it to be a much more significant feature of West Antarctic drainage. Another ice stream is located 250 km further to the north-west. Although a less pronounced feature with boundaries lacking strong definition, its crevassed, linear margins are, nevertheless, clearly visible on RES records and from the air. It extends inland only for a few hundred kilometres. The area between these two ice streams forms a peninsula and remains one of the least known margins of the Ronne–Filchner Ice Shelf. Elsewhere LANDSAT satellite imagery has allowed the grounding line and ice rises to be delimited with considerable accuracy[24,25]. RES records in this area reveal an undisputed ice–water interface indicating ice shelf. This is supported by ice thickness–surface elevation relationships. Further inland characteristic ice–rock reflections showing rapid fluctuations in instantaneous returned power are observed. Between the ice streams, however, a curious 'intermediate' zone has also been detected where received power is high and the echo return is smooth over considerable distances (tens of kilometres), yet ice thicknesses and surface elevations do not demonstrate hydrostatic equilibrium. Furthermore, high-resolution photographs from the Soviet 'Meteor' weather satellite show no clear grounding line shadow as exhibited elsewhere

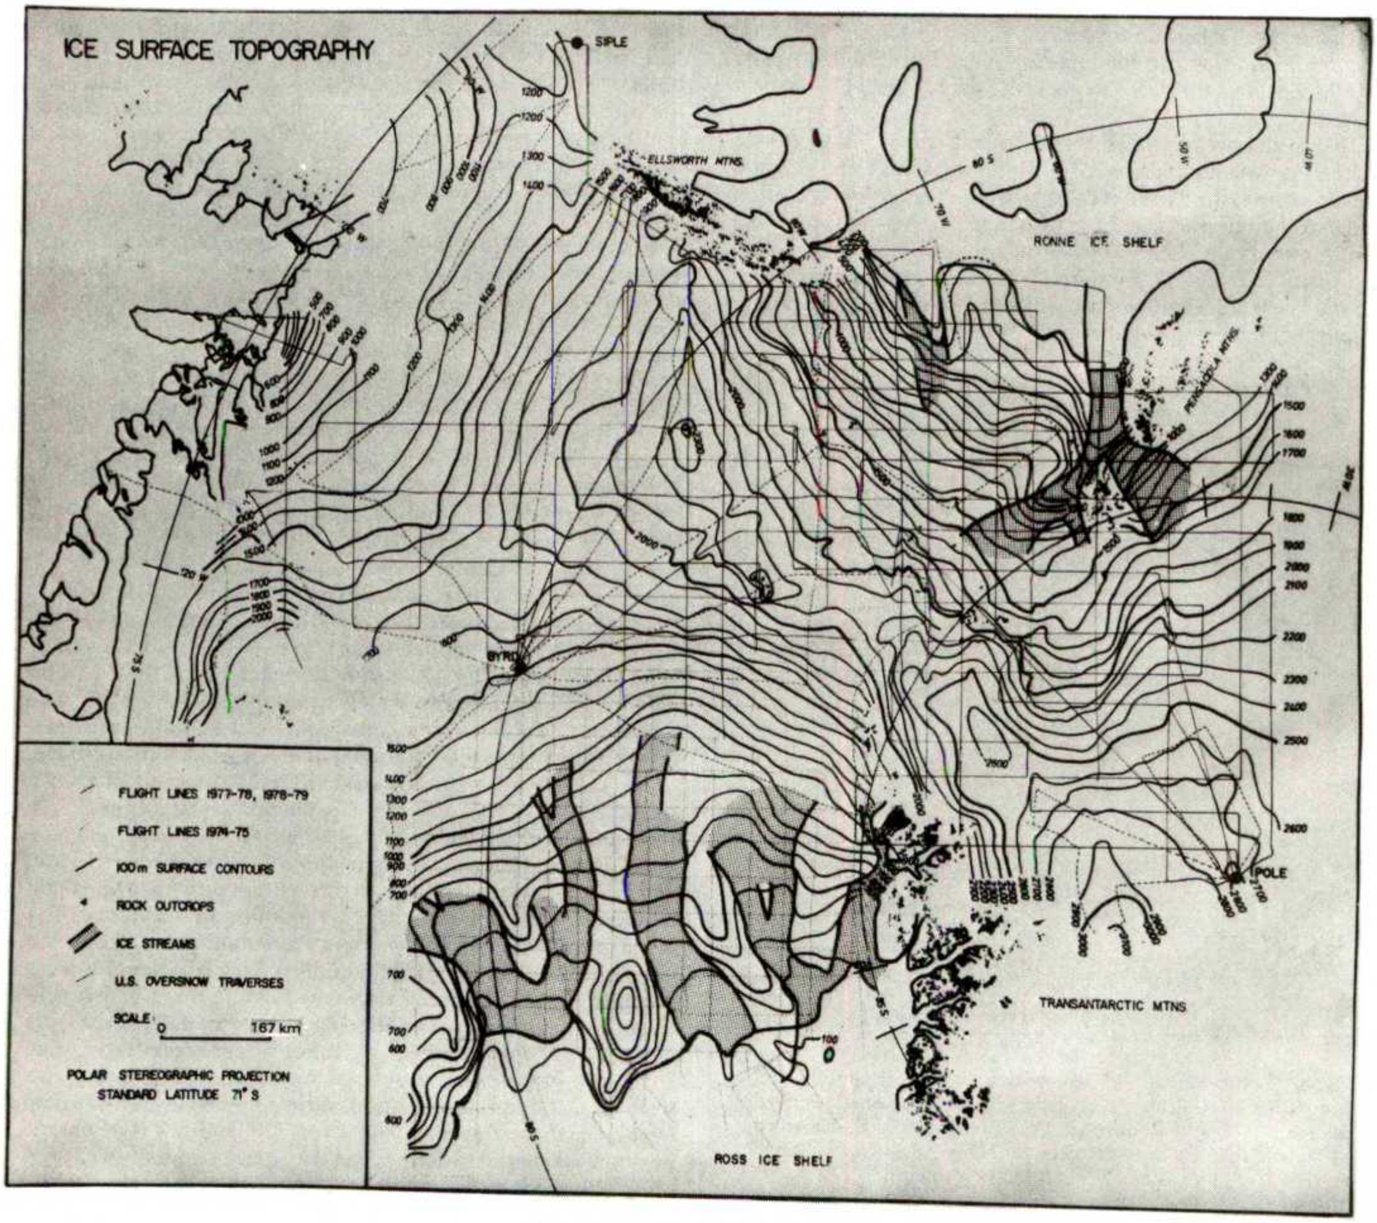

Fig. 2 Ice surface topography.

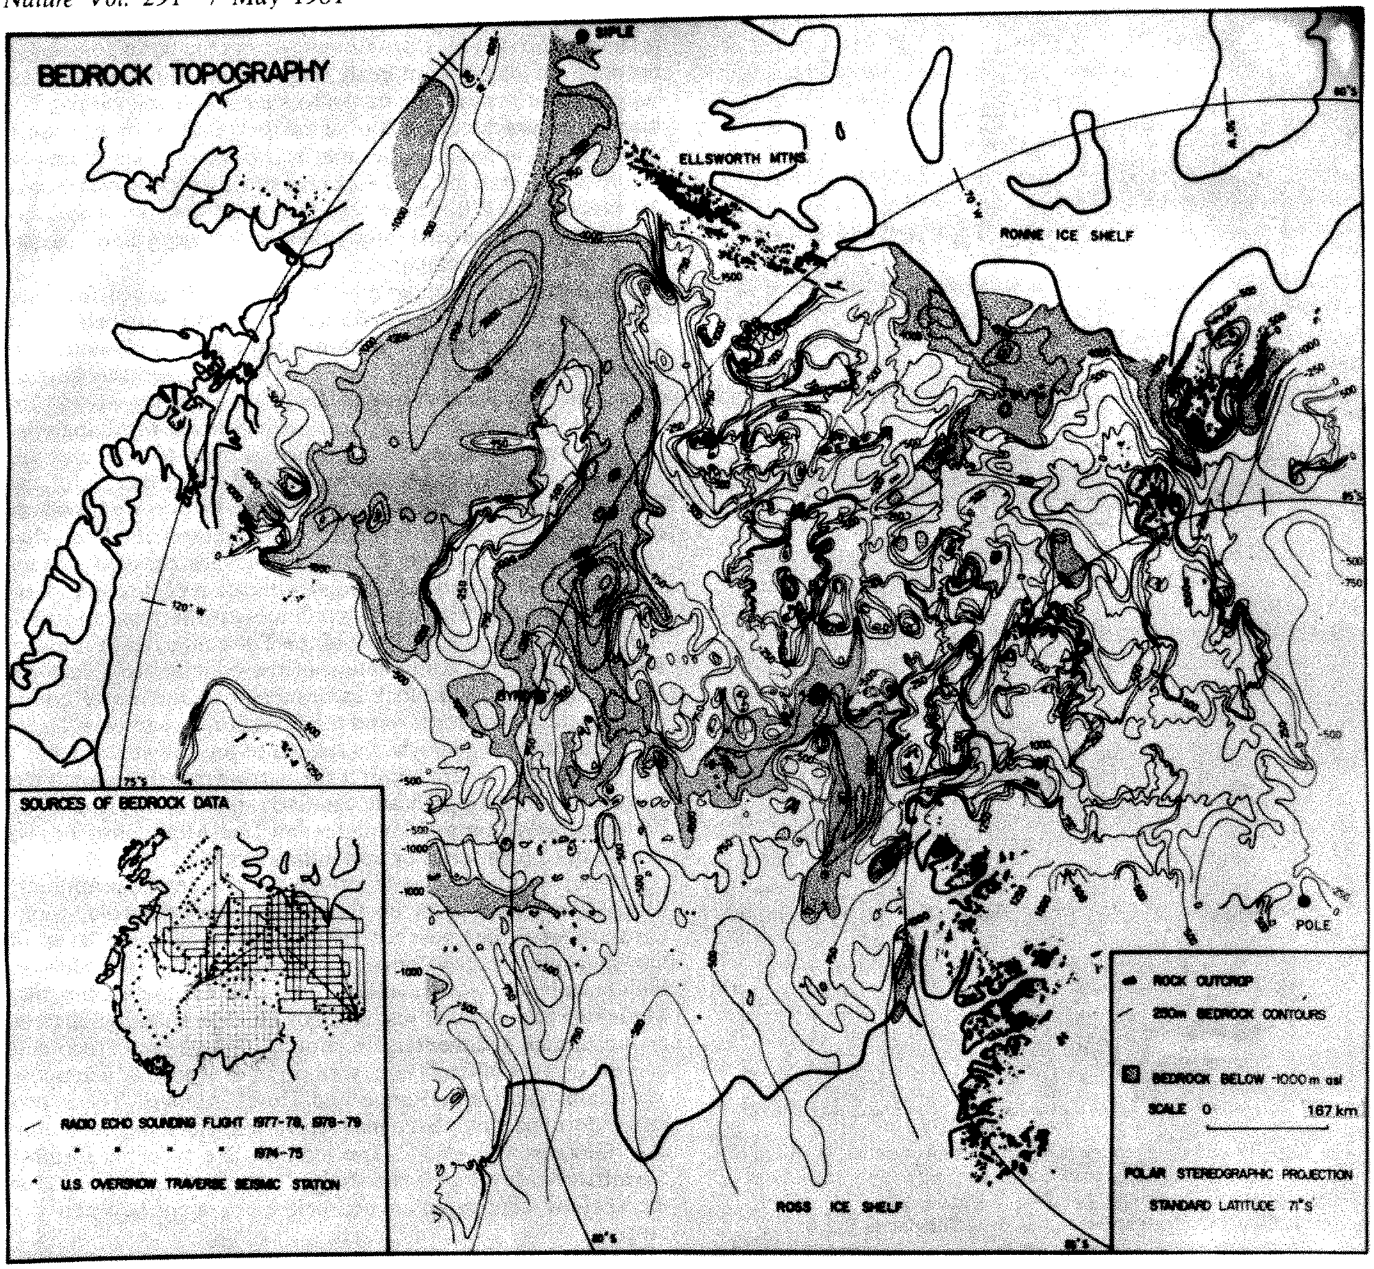

Fig. 3 Bedrock topography.

on the Ronne–Filchner Ice Shelf. The lack of relief–reflectivity further suggests that the area may possess an unusual and diffuse boundary[26]. We explain the 'intermediate' zone as ice shelf resting on sea floor composed of soft water-saturated sediments—a similar phenomenon to that observed by Soviet glaciologists on the Lazarev ice shelf in 1975[27].

Ice drains into the Amundsen Sea principally through the Thwaites and Pine Island glaciers. Unlike the ice streams flowing into the Ross and Ronne–Filchner Ice shelves these major outlets are not protected by large ice shelves and unless they flow over high bedrock sills may be in a finely balanced state of equilibrium[28] or may not even be in equilibrium at all[37]. RES suggests that Thwaites glacier does not have a high bedrock sill. There is, however, no pronounced erosional channel associated with the glacier which suggests that it may be a transient phenomenon. No data were collected on the Pine Island Glacier.

Bedrock configuration

The map presented in Fig. 3 is the first detailed and systematic study of bedrock using RES in West Antarctica. There is again a broad correspondance between major topographical features and previous maps based on seismic soundings and interpretation of free air gravity anomalies[10,11]. The location of all seismic stations used in this survey are shown in Fig. 3. Compared with previous work, however, the most striking feature of the map (and profiles) is the considerable improvement in topographical detail.

The area mapped can be divided into several parts some of which had been known from earlier work, and are briefly outlined here. (1) At the head of the Ross Ice Shelf the terrain is very smooth with subdued ridges and troughs marking the position of the ice streams draining into the ice shelf. This area is terminated to the north-east by (2) an extensive subglacial basin (Byrd Subglacial Basin). Insufficient data may account for its apparent smoothness. (3) A completely new feature is the sinuous ridge running across the centre of the basin. Near Byrd Station it is prominent on RES records, standing 1,000 m above the floor of the basin. (4) At the northern margin of the basin Cenozoic volcanic rocks crop out in the Crary Mountains and Executive Committee Range. RES records show these areas of outcrop to be steep sided and separated by deep narrow troughs. (5) A major highland region extends southwards from the exposed Ellsworth Mountains. The terrain is extremely rugged, possessing a relief amplitude of 2 km, a feature not previously apparent nor emphasized on the map due to spacing of flight lines and the contour interval. There is a very well defined boundary between this highland area and the Byrd Subglacial Basin. The Whitmore Mountains form a steep-sided upstanding

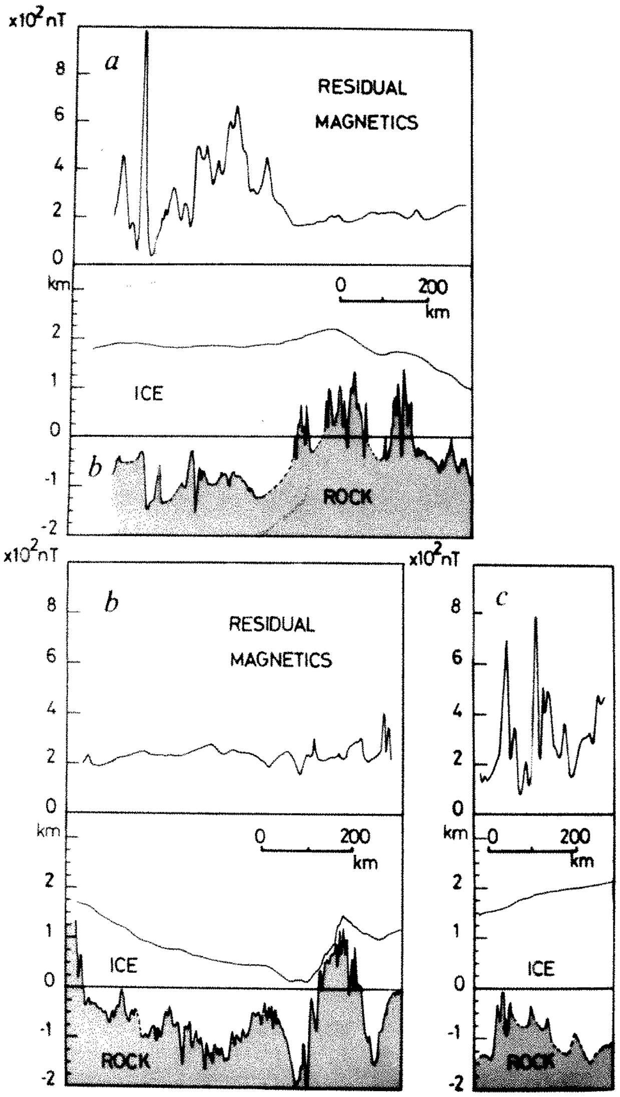

Fig. 4 RES and magnetic profiles in West Antarctica. *a*, Boundary between Byrd Subglacial Basin and Ellsworth Mountains block. *b*, Bedrock low at head of Ronne–Filchner Ice Shelf. *c*, Sinuous ridge cutting across Byrd Subglacial Basin.

massif separated from the Ellsworth Mountains block by a narrow trough. Other scattered outcrops to the south of the Ellsworth Mountains appear to be part of the same mountainous region. (6) The Transantarctic Mountains constitute a separate highland area and form a semi-continuous chain across Antarctica. Two deep valleys almost sever the Horlick Mountains from the rest of the Transantarctic Mountains, whereas the main part of the Pensacola Mountains is bounded on two sides by very deep narrow troughs occupied by Foundation Ice Stream and Support Force Glacier. At the northern end of the Pensacola Mountains there is a small depression between the exposed Forrestal Range and Dufek Massif. (7) At the head of the Ronne–Filchner Ice Shelf bedrock forms a deep depression which widens towards the ice shelf.

Geological interpretation

Bedrock at the head of the Ross Ice Shelf has been fully discussed elsewhere[12] where subdued topography and magnetic signatures are attributed to a substantial thickness of late Mesozoic–Cenozoic sediments extending the Ross Sea sedimentary basin beneath the grounded ice sheet. Further inland there is a significant change in magnetic character towards the volcanic outcrops in Northern Byrd Land and the Byrd Subglacial Basin, as noted in previous surveys[1,4–6]. Large anomalies (~1,000 nT) are here associated with outcrops and subglacial features. The sinuous ridge running across the basin possesses a pronounced magnetic anomaly (Fig. 4*c*): modelling in progress suggests that this feature may also have a volcanic origin. The magnetic character of the floor of the Byrd Basin shows a pattern of irregular anomalies. Seismic refraction studies from the centre of the basin indicate ~2 km of strata with P-wave velocity 4.1 km s^{-1} (ref. 29). These results suggest that the basin may constitute a sequence of interbedded sedimentary and volcanic strata overlying basement.

The pronounced topographical boundary between the Byrd Basin and rugged Ellsworth Mountains block is also marked by an abrupt change in pattern of magnetics from high-amplitude anomalies associated with the Basin to a magnetically quieter field with only isolated anomalies of wavelength ~40–50 km (Fig. 4*a*). The subdued magnetics are consistent with subglacial extension of a geological sequence similar to the exposed Ellsworth Mountains (Palaeozoic strata). This margin of the Ellsworth block becomes less well defined further west towards the Whitmore Mountains (south of Byrd Station); it is likely that sedimentation since the late Mesozoic has masked deeper structures and inhibits accurate identification of this boundary. A series of subglacial basins continues to the west and then trends south towards the front of the Transantarctic Mountains and may mark the continuation of the edge of the Ellsworth block. The Ellsworth block as described by the above boundaries includes an area around the Whitmore Mountains. These are thought to be geologically related to the Ellsworth chain[30], but may form a separate unit if the narrow trough between the two is structurally significant. Similarly, there is no clear break between the Whitmore Mountains and Thiel Mountains, the two being linked by a series of upstanding blocks.

Further south, magnetic profiles over the Transantarctic Mountains (except at the northern end of the Pensacola Mountains) suggest the presence of a significantly thick layer of non-magnetic rocks—possibly corresponding to Beacon Supergroup strata and older Precambrian metasediments. Modelling of anomalies just north of Thiel Mountains indicates a substantial sedimentary section[26]. The largest recorded anomalies (>1,000 nT) are seen in the northern Pensacola Mountains (Forrestal Range and Dufek Massif). These two ranges form part of a large mafic intrusion which has been fully described elsewhere[7,31,32]. The lopolith-like synclinal form of the intrusion, developed as a result of weak folding, accounts for the shallow depression in bedrock topography between the ranges[7].

The distinctive bedrock low at the head of the Ronne–Filchner Ice Shelf lies between the Transantarctic and Ellsworth Mountains, widening into the Weddell Sea. Hochstein calculated depth to MOHO at 83° S 70° W on the eastern edge of this basin, reporting thin crust of 24 km thickness[33]. Previous work has suggested that the Ellsworth Mountains and any associated subglacial block are out of place in West Antarctica based on their stratigraphy and structural trends[14,34–36]. The thin crust lying beneath the bedrock low may thus represent crust rifted during the displacement of the Ellsworth block. Magnetic records from this basin area show no significant anomalies and confirm earlier suggestions of a substantial section of sedimentary rock in the area[7] (Fig. 4*b*).

The present studies are being extended to provide quantitative estimates of rock magnetizations, depth of sedimentary cover, a detailed analysis of the structure and areal extent of the Dufek Massif (in collaboration with US Geological Survey), and to reconsider the position of West Antarctica in Gondwanaland.

This work was supported by NERC grant GR3/2291 and the NSF Division of Polar Programs. C. R. Bentley provided unpublished data from the Wisconsin traverse. We thank the NSF for aeromagnetic data, Dr J. C. Behrendt and the US Geological Survey Branch of Regional Geophysics for assistance in their reduction, and Drs G. de Q. Robin and D. H. Elliot for helpful discussions. TWERLE data were made available to SPRI by kind permission of N. Levanon and were plotted and contoured at SPRI for comparison with RES.

Parental liquids of the Skaergaard intrusion cumulates

C. E. Ford

Grant Institute of Geology, University of Edinburgh, West Mains Road, Edinburgh EH9 3JW, UK

Petrogenetic relationships between compositions advocated as possible liquids parental to the Skaergaard layered series cumulates have been investigated using equations for the prediction of liquidus temperature and liquid path followed during fractional crystallization. Given a suitably defined sequence of primocryst mineral assemblages, a variation of the fractionation scheme provides a new method for the calculation of the parent liquid composition.

IGNEOUS diversity may result from a combination of processes such as partial melting, magma mixing, contamination and fractional crystallization. However, the relative role of each process can only be accurately assessed if its effect can be separately predicted. This article considers the prediction of the compositions of evolving magmatic liquids, and complementary cumulus mineral assemblages, during fractional crystallization. The results are applied to the Skaergaard intrusion of east Greenland[1] which contains features expected of a cumulate sequence produced by fractional crystallization and also presents petrological problems.

Within an envelope of chilled marginal gabbros crystallization of the Skaergaard intrusion progressed inwards simultaneously from the roof, walls and unexposed floor where the upper and marginal border groups and the at least 2.5 km thick layered series were formed respectively. Segregation of cumulus minerals from liquid, with some sorting of minerals into layers, led to progressive evolution of the residual liquid composition and a complementary evolution of successive cumulus mineral assemblages. The early formed cumulates contain calcic plagioclases(An77/72) and magnesian olivines(Fo81) while the latest formed cumulates contain more sodic plagioclase(An30) and ferromagnesian minerals with extreme iron enrichment(Fo0). The points of appearance or disappearance of cumulus phases in the fractionation sequence have been used to subdivide the intrusion into zones. Particularly important are the point of appearance of cumulus clinopyroxene marking the base of lower-zone-b (LZb) and the points of disappearance, and subsequent re-appearance, of cumulus olivine marking the base and top of the middle-zone (MZ).

Composition of the Skaergaard parent liquid

The composition of the Skaergaard parent liquid is uncertain. Samples of the chilled marginal gabbro are heterogeneous[2] and may have been affected by wall rock contamination. Chill samples, which have been considered as possible parent liquids, cover a significant range of compositions. A parent liquid of the composition of the comparatively primitive chill EG4507 (Table 1) would require a 'hidden zone' of cumulates comprising some 70–80 wt% of the intrusion, based on estimates of the volume and composition of the exposed rocks and the proportion of trapped inter-cumulus liquid[1,3]. A hidden zone of this extent is consistent with calculations[4], based solely on arguments concerning olivine fractionation, which have suggested that 72

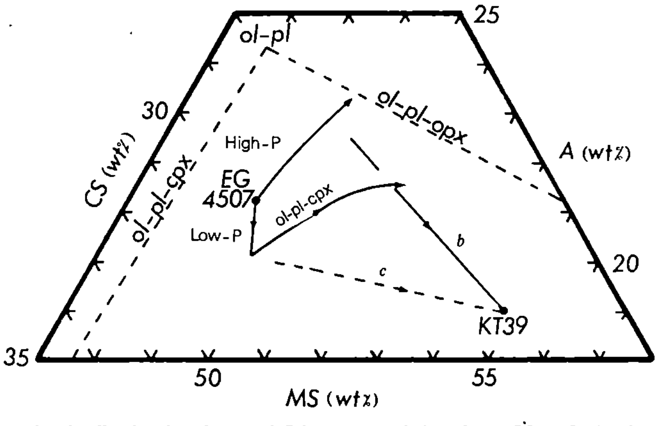

Fig. 1 Projection from M_2S into part of the plane $\dot{C}S$–MS–A of EG4507, KT39 and derived liquid compositions. At high pressure, crystallization of ol+pl+cpx from EG4507 drives the liquid composition away from the ol–pl–cpx tie-plane. At low pressure, crystallization of ol+pl precedes crystallization of ol+pl+cpx. Curve *b* represents negative fractional crystallization of ol+pl from KT39. This curve does not intersect those representing fractional crystallization of EG4507 at either low or high pressure—at the apparent points of intersection the mineral compositions are significantly different. Curve *c* is parallel to the liquid path followed in many cases of equilibrium crystallization of ol+pl+cpx.

KT39 from ref. 6, EG4507 from ref. 1. B1 = EG4507 + 50% olivine (Fo 86). B2 = EG4507 + 50% plagioclase (An 81). B3 = EG4507 + 15% olivine (Fo 86) + 35% plagioclase (An 81).

* Composition stated to be present in experimental charge.

cation% of fractional crystallization of chill EG4507 would be necessary to produce olivines of the composition observed at the exposed base of the layered series. However, geophysical evidence precludes the existence of such an extensive hidden zone immediately beneath the exposed layered series[5]. A parent liquid of the composition of the much more evolved, but less ubiquitous chill KT39 could perhaps produce the layered series with a minimal hidden zone[6]. The relationships between the various Skaergaard chill compositions and the layered series are thus not easily explained.

Evolving Skaergaard liquids and coexisting primocrysts

To calculate the extent of fractional crystallization required for a particular parent liquid to proceed to that which will precipitate a particular cumulus mineral assemblage the identity of the primary compositions of the cumulus minerals (primocrysts) are needed as the latter may have changed in composition during equilibrium crystallization of trapped liquid.

The Skaergaard layered series cumulus plagioclase crystals consist of homogeneous cores and zoned rims. The cores have been interpreted as primocryst compositions with the rims representing the crystallization product of trapped inter-cumulus liquid[1,7]. However, olivine crystals are virtually homogeneous[8] and must have continuously re-equilibrated, and become less magnesian, during further crystallization of trapped liquid. The extent of the change in primocryst mineral compositions during re-equilibration depends on the proportions of primocrysts and trapped liquid. This may be illustrated by considering chill EG4507 which has olivine(Fo86) and plagioclase(An81) as liquidus phases[9]. In Table 1 compositions B1, B2 and B3 are the result of accumulation of 50% of olivine, 50% of plagioclase and 50% of olivine(15%) + plagioclase(35%) into the original liquid. The ratio of olivine to plagioclase incorporated into EG4507 to form composition B3 is that in which they are predicted to crystallize during fractional crystallization. For these bulk compositions the equilibrium mineral compositions at the solidus can be approximated by the CIPW norm with the anorthite and albite contents recast to indicate plagioclase composition and the Fe–Mg distribution between the ferromagnesian minerals reset using measured cation exchange reaction coefficients[10,11]. Note that the olivine in the bulk composition buffered by the 50% of previously crystallized cumulus olivine is significantly more magnesian than the olivine in the composition buffered by 50% of cumulus plagioclase. Similarly, plagioclase is much more calcic in the bulk composition equilibrated with 50% of cumulus plagioclase. Such variations in mineral composition do occur in layers as narrow as 10 cm (refs 8, 12).

A critical point in the fractional crystallization sequence of the Skaergaard parent liquid is that at which clinopyroxene first appears as a cumulus phase at the base of LZb. Identification of the primocryst mineral compositions at this point could constrain the composition of the coexisting liquid and thus of the range of liquids in the fractionation sequence. From this discussion, and the fact that plagioclases are zoned, the best assumption is that the coexisting primocryst compositions are the most calcic plagioclase and most magnesian ferromagnesian minerals observed at this structural height, not necessarily from the same sample: olivine(Fo64), plagioclase(An63) and clinopyroxene(Di71 = $Mg/(Mg+Fe^{2+})$)[1,6]. The problem is then to identify which of the possible parent liquids would precipitate this mineral assemblage at the point where clinopyroxene joins olivine and plagioclase as fractionating phases.

Theoretical fractional crystallization

To predict magmatic evolution based on known phase equilibria we need to predict liquidus temperatures, liquidus phase compositions and the change in liquid composition produced by perfect fractional crystallization of the liquidus phases. Nathan and Van Kirk[11] presented a generalized method incorporating these features but the accuracy of liquidus temperature equations, relating mineral phase liquidus temperature to liquid composition at atmospheric pressure, have been criticized[17]. Applied to a data set consisting of microprobe analyses of glasses produced in experiments at atmospheric pressure in this laboratory, and for which experiment temperature and oxygen fugacity were known, the equations produce systematic discrepancies of up to 40 °C. The data set has been compiled from experiments on 24 terrestrial basaltic rocks, 5 komatiites and 10 achondritic meteorite and lunar basalts. At present, the data set contains 336 olivine saturated glasses, 296 spinel–magnetite saturated glasses, 160 plagioclase saturated glasses, 116 clinopyroxene saturated glasses and 67 low Ca-pyroxene saturated glasses. With the equation compositional coefficients revised based on this data set, liquidus temperatures for olivine, plagioclase, clinopyroxene and magnetite fit the equations with a standard deviation of error of <6 °C (refs 18, 19). With this degree of accuracy in liquidus temperature prediction it is possible to be much more accurate in the calculation of fractionation paths and more specific in the interpretation of petrogenetic relationships.

The revised coefficients for the orthopyroxene liquidus temperature equation, derived from the orthopyroxene–glass pairs in the data set, give a standard deviation of error of <5 °C (all structural modifications of low-Ca pyroxene are referred to as orthopyroxene). However, the resulting equation predicts that orthopyroxene would be the liquidus phase in glass compositions which did not coexist with orthopyroxene. This anomaly probably results from the limited range of liquid compositions in the data set for orthopyroxene–glass pairs and illustrates the possible consequences of undue extrapolation of the liquidus temperature equations. During fractional crystallization in a multi-component system the extent of extrapolation may not be readily apparent. Until this anomaly is resolved the quantitative application of the mineral temperature equations will be restricted to equilibria not involving orthopyroxene.

The predicted and experimentally determined liquidus temperatures for EG4507 and KT39, neither of which were included in the data set, are presented in Table 2. For KT39 the equations predict that orthopyroxene would be close to the liquidus although in the experiments this phase was not detected after 55 °C of equilibrium crystallization[6]. Apart from this, the rather small discrepancies between predicted and experimentally determined liquidus temperatures may be accounted for by known experimental and analytical problems. The liquidus temperature equations are, therefore, considered sufficiently accurate to demonstrate possible petrogenetic relationships between Skaergaard chill compositions before the appearance of orthopyroxene. It could even be argued that the predictions for KT39 fit the observed petrography[6] better than the experiments.

In many pressure–temperature (*P–T*) phase diagrams of basic rocks clinopyroxene becomes the liquidus phase at elevated pressure. The possible consequences of the involvement of clinopyroxene in fractionation equilibria at high pressure can be considered after assessment of the effects of total pressure on the liquidus temperature equations. The effects of total pressure can be estimated approximately from the experimentally determined slopes of liquidus surfaces on *P–T* phase diagrams of rocks[21–25]. Average values of +4 °C kbar^{-1} for olivine, plagioclase and magnetite and +9 °C kbar^{-1} for clinopyroxene and orthopyroxene have been adopted. Similarly the effects of small quantities of dissolved water can also be estimated from data in the systems albite–water and diopside–anorthite–water[13]. Values of −250 °C × H^+ (cation fraction) for felsic minerals and −80 °C × H^+ for mafic minerals have been adopted.

Using the mineral temperature equations to identify the liquidus phase the liquid path followed during fractional crystallization can be approximated by repeated removal of a small amount of the current liquidus phase using equations for exact fractionation[14]. For olivine, clinopyroxene and orthopyroxene these are of the form

$$\mathrm{Fe} = (\mathrm{Fe}_0/\mathrm{Mg}_0^{K}).\mathrm{Mg}^{K}$$

where the element values are absolute cation quantities in the liquid before (Fe_0, Mg_0) and after (Fe, Mg) each fractionation step and K is the appropriate cation exchange reaction coefficient[10,11]. The latter may also be used to determine the composition of the liquidus phase. The amounts of other components to be removed from the liquid are determined by the stoichiometry of the phase in question. For plagioclase and magnetite the equations for exact fractionation can be solved by numerical approximation:

Plagioclase:

$$\mathrm{Na}^{((\mathrm{K.Ca.Al})/\mathrm{Si})} = (\mathrm{Ca}.\mathrm{Na}_0{}^{((\mathrm{K.Ca_0.Al_0})/\mathrm{Si_0})})/\mathrm{Ca}_0$$

Magnetite:

$$\mathrm{Ti}^{((\mathrm{K.Fe^{3+}})/(\mathrm{Fe^{2+}.Ti}))} = (\mathrm{Fe}^{3+}.\mathrm{Ti}_0{}^{((\mathrm{K.Fe^{3+}}_0)/(\mathrm{Fe^{2+}}_0.\mathrm{Ti}_0))})/\mathrm{Fe}^{3+}{}_0$$

At a phase boundary, crystallization of one phase results in the liquid moving into the primary phase volume of one of the other phases present. This then becomes the liquidus phase for the next fractionation step. A cotectic is thus followed by a zig-zag approximation path which is almost independent of the size of the crystallization increment provided that the increments are sufficiently low. At a reaction boundary the phase in reaction fails to become a liquidus phase and ceases to fractionate. Specification of a negative increment allows a liquid fractionation path to be followed back to higher temperature, more primitive compositions. This process can be described as negative fractional crystallization to avoid conflict of terminology with melting processes.

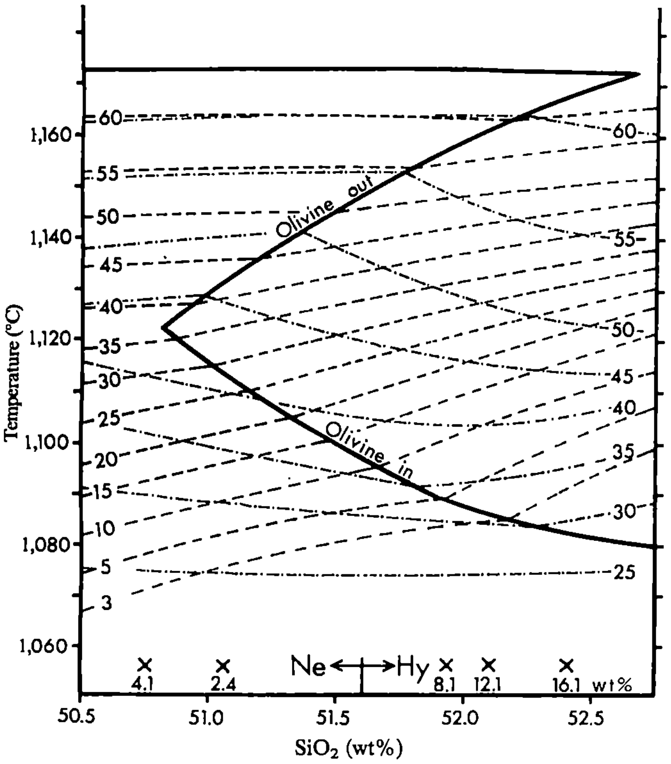

Fig. 2 Fractional crystallization diagram based on the liquidus-temperature equations from ref. 11 for the univariant range of liquids in the system SiO_2–Al_2O_3–FeO–MgO–CaO–Na_2O which all have olivine(Fo64), plagioclase(An63) and clinopyroxene(Di71) as simultaneous liquidus phases. Vertical lines illustrate the changing primocryst compositions and assemblages which would be produced by fractional crystallization. Dashed lines are isopleths of Fo content of olivine, shown with metastable continuation through the field in which olivine is absent, but orthopyroxene is present, while dashed-dotted lines are isopleths of An content of plagioclase. The nepheline and hypersthene scales are not linear.

The liquidus temperature and fractionation equations have been incorporated into a computer program. Given a parent liquid composition the program has been designed to list the compositions and proportions of crystallizing phases and the evolved liquid composition at regular intervals during the fractionation process. The compositions of crystallizing phases correspond to the primocryst mineral compositions of cumulate sequences.

Crystallization of Skaergaard chills

At atmospheric pressure, 37% of fractional crystallization of olivine and plagioclase from EG4507 is predicted to occur before the appearance of clinopyroxene. Only 3% of fractional crystallization of olivine from KT39 is predicted to occur before plagioclase and clinopyroxene appear almost simultaneously. In both cases the ferromagnesian minerals are more magnesian and plagioclases more calcic than the quoted primocryst compositions at the base of LZb. Neither composition could apparently be directly parental to the layered series by fractional crystallization at low pressure unless re-equilibration of primocrysts with trapped liquid has resulted in an incorrect identification of the primocryst compositions.

EG4507 and KT39 are shown in Fig. 1 as an M2S projection into the plane CS-MS-A (ref. 15). The liquid path followed during fractional crystallization of EG4507 at low pressure does not pass through, or even close to, the composition of KT39. Note specifically the orientation of the liquid path followed during fractional crystallization of olivine + plagioclase + clinopyroxene. This is significantly different from the path followed during equilibrium crystallization of these phases. Least squares mixing calculations using the method of Wright and Docherty[16] demonstrate that KT39 could be combined with the olivine, plagioclase and clinopyroxene compositions present close to the liquidus to produce EG4507 (45.1%KT39 + 12.6% olivine(Fo74) + 35.6% plagioclase(An73) + 6.7% clinopyroxene(Di79) = EG4507 sum $r^2 = 0.5$). KT39 could thus be a liquid produced during equilibrium crystallization of a liquid such as EG4507 before separation of crystals from liquid. However, this is not an essential relationship.

Cumulate sequence parent liquids

Although it might be possible to find a chill composition able to produce the observed layered series primocryst assemblages during fractional crystallization it is possible to adopt a radically new approach to the calculation of parent liquid compositions.

Let an olivine–gabbro mineral assemblage consist of primocrysts of olivine (Fo64), plagioclase (An63) and clinopyroxene

Table 2 Comparisons of experimentally determined and calculated liquidus temperatures (°C) for Skaergaard chills at atmospheric pressure

Mineral	EG4507 (fO_2 = iron/wustite)*			KT39 (fO_2 = magnetite/wustite)*		
	XP†	F‡	N & V§	XP‖	F‡	N & V§
Olivine	1,230–1,248	1,225	1,241	1,171–1,179	1,179	1,187
Plagioclase	1,230–1,248	1,219	1,220	1,171–1,174	1,167	1,165
Magnetite	<1,174	1,193	—	1,171–1,179	1,154	1,142
Clinopyroxene	1,188–1,208	1,173	1,213	1,134–1,140	1,157	1,181
Orthopyroxene	<1,174	1,181	1,166	<1,115	1,176	1,170

The liquidus-temperature predictions for phases which would not actually be the liquidus phases cannot be compared with the temperature of appearance of these phases during equilibrium crystallization. They are given for comparison and to give an approximate indication of the possible effect of total pressure (see text).

* Fe_2O_3 and FeO contents recalculated using an equation given in ref. 11.

† From ref. 9. Upper temperature is that at which phase was absent, lower temperature is that at which phase was present.

‖ From ref. 6, magnetite liquidus may be too high.

(Di71), the assemblage marking the base of LZb. In the system SiO_2–Al_2O_3–FeO–MgO–CaO–Na_2O one liquid which would precipitate this assemblage would lie in the pseudo-ternary plane olivine(FoX)–plagioclase(AnY)–clinopyroxene(DiZ), where X, Y and Z represent the mineral compositions which form the plane end-members. Values for X ($=Z$) can be calculated from crystal–liquid iron–magnesium cation exchange reaction coefficients[10,11] and the identified primocryst ferromagnesian mineral compositions. The value of Y depends on the proportions of plane end-members contributing to the liquid composition at the piercing point where the three crystalline phases are in equilibrium with liquid. It is easy to estimate Y, use the liquidus temperature equations to generate the pseudo-ternary phase diagram, observe the composition of the plagioclase in equilibrium with the ferromagnesian minerals of the selected composition, and refine Y accordingly. The liquid composition is represented by the plane end-members at the piercing point determined to closer than 0.1 wt%.

The resulting liquid composition is not unique. In a six-component system the phase rule is uniquely satisfied by the coexistence of four phases and the specification of pressure and the compositions of three of the phases. However, in this instance the compositions of olivine and both pyroxenes are determined by the Mg/(Mg+Fe) ratio of the liquid. Therefore, this mineral assemblage could be precipitated from a univariant range of liquid compositions in the six-component system. The extent of this range can be determined by altering the concentration of any one of the components of plagioclase in the parent liquid. For convenience SiO_2 has been chosen because the effect of varying the concentration of this component is easily expressed in terms of normative nepheline, olivine, hypersthene or quartz.

Figure 2 is a fractional crystallization diagram in which the specified mineral assemblage is crystallized at the liquidus over a range of nepheline and hypersthene normative compositions. Note that different liquids would produce progressively differing primocryst assemblages as illustrated by the mineral composition isopleths and the location of the boundaries defining the field in which olivine is absent. This is the key to the interpretation of natural igneous cumulate assemblages. The extent of the orthopyroxene field and its extension into nepheline normative compositions are almost certainly erroneous, resulting from extrapolation of the orthopyroxene liquidus temperature equation. Note also that the extent of the 'olivine gap' is a function of the SiO_2 content of the parent liquid.

Adding more components to the system will produce a greater range of liquids capable of precipitating the same mineral assemblage. However, it should be possible to restrict element abundances in parent liquids from consideration of crystal–liquid partition coefficients or from element abundances in extrusive rocks. The one liquid which is best able to reproduce the observed sequence can be obtained by adjustment of the minor components by trial and error. To promote the appearance of cumulus magnetite at the correct point in the fractionation sequence in relation to the compositions of the coexisting primocrysts at the base of LZc there is comparatively little room for adjustment of the contents of K_2O, TiO_2 and Fe_2O_3 in the parent liquid. However, as shown in Fig. 2, it is the point of disappearance and reappearance of olivine, as a result of reaction relationships with orthopyroxene, and the compositions of primocrysts in the later stages of fractional crystallization which identify more clearly the most probable parent liquid composition. Refinement of the liquid composition present at the base of LZb should, therefore, await additional experimental data on orthopyroxene–liquid equilibria.

Negative polybaric fractional crystallization

For any given liquid composition a range of parental compositions can be generated by negative fractional crystallization. For EG4507, for example, parent liquids may lie some way back along the olivine–plagioclase cotectic and then even further back towards olivine alone. Alternatively at high pressure, parent liquids may lie along cotectics involving olivine+plagioclase+clinopyroxene, or olivine+clinopyroxene and ultimately olivine alone.

Two particular features emerge from these general considerations. (1) Provided that the same phases are involved at all stages, negative fractional crystallization of a range of compositions tends to produce convergence of their parental compositions. The small but significant differences in composition which would be amplified by subsequent positive fractional crystallization are more easily produced in converged parental compositions. For example, Ca/Al ratios are very sensitive to crystallization, or otherwise, of clinopyroxene. For this reason some of the range of Skaergaard chill compositions might be more easily related to each other by equilibria at very high pressure. (2) Polybaric fractional crystallization of a particular assemblage of phases from a particular liquid, accomplished by lowering pressure by a small selected amount after each increment of crystallization, may produce residual liquid compositions significantly different from the liquid compositions produced by isobaric fractional crystallization of the same phases. For example, positive isobaric fractional crystallization of olivine+plagioclase+clinopyroxene from EG4507 at 10 kbar produces residual liquids with Al_2O_3 contents rising to over 20% whereas polybaric fractional crystallization of these phases from 10 to 1 kbar produces residual liquids with Al_2O_3 contents falling to below 16%.

Conclusions

The integration of data from phase equilibrium experiments on a range of bulk rock compositions by means of a set of mineral-phase liquidus-temperature equations is sufficiently accurate to allow some quantitative modelling of crystal–liquid fractionation processes. The accuracy of this approach and the scope for extending its range of applicability to higher pressures and to equilibria involving additional phases such as garnet and amphibole are being examined. This approach should be able to test for possible relationships between associated igneous rocks; to determine the conditions of formation of phenocryst assemblages; and to constrain cumulus sequence parental liquid compositions in cases for which no appropriate chilled liquid sample is available. It is also easy to incorporate trace elements into the fractionation scheme.

I thank Drs K. G. Cox and G. M. Biggar for valuable comments and D. G. Russell for his unpublished glass analyses.

Chloroplast protein phosphorylation couples plastoquinone redox state to distribution of excitation energy between photosystems

John F. Allen[*†], **John Bennett**[†], **Katherine E. Steinback**[*‡] **& Charles J. Arntzen**[*‡]

In photosynthetic membranes isolated from pea leaves, the redox state of the plastoquinone pool controls both the level of phosphorylation of the chloroplast light-harvesting pigment–protein complex (LHC) and distribution of absorbed excitation energy between the two photosystems. Phosphorylation of LHC polypeptides is proposed as the regulatory mechanism by which photosynthetic systems adapt to changing wavelengths of light.

In chloroplasts, non-cyclic photosynthetic electron transport generates ATP and NADPH by the operation of photosystem I and photosystem II acting in series. The energy that drives this process is derived partly from light absorbed by antenna chlorophylls associated closely with each photosynthetic reaction centre and partly from the more peripheral light-harvesting pigments[1] which are organized into specific chlorophyll–protein complexes[2–4]. The most abundant of the chlorophyll-binding proteins in green plants is a 25,000 molecular weight (MW) polypeptide known as the light-harvesting chlorophyll *a/b* protein (LHCP).

In non-cyclic electron transport, the two photosystems must operate at the same rate. If absorbed radiant energy is distributed between the photosystems in such a way that one photosystem is excited more than the other, the excess excitation energy is dissipated, with a consequent loss of photosynthetic quantum efficiency. However, it is clear from studies with algal cells exposed to red and far-red light that chloroplasts can detect such an imbalance in the excitation of the photosystems and at least partially correct it by increasing the proportion of absorbed excitation energy that is distributed to the rate-limiting photosystem[5–8]. These adaptive changes are referred to as state 1–state 2 transitions. State 1 is the adaptive state which results from over-excitation of photosystem I (as, for example, by far-red light) and is characterized by an increase in the proportion of total absorbed excitation energy that is transferred to photosystem II relative to photosystem I. State 2 results from over-excitation of photosystem II by red light and is characterized by increased energy transfer to photosystem I.

The biochemical events underlying state 1–state 2 transitions are poorly understood. However, a related phenomenon that has been extensively studied at the biochemical level is the ability of metal cations to affect the distribution of absorbed excitation energy in isolated thylakoids[9–11]. In the presence of salts of monovalent and divalent metal cations[12], the light-harvesting chlorophyll–protein complexes that contain LHCP are structurally and functionally associated with photosystem II, whereas in the absence of salts the association between the light-harvesting apparatus and the photosystems is altered and excitation energy transfer to photosystem I increases.

A major factor governing the response of thylakoids to cations *in vitro* is the LHC itself. Experiments using thylakoids have shown that trypsin can selectively remove a surface-exposed segment of the LHCP and that this removal is concomitant with the loss of the ability of cations to affect the distribution of excitation energy[13]. In addition, antibodies raised against isolated, purified LHC were found to react with surface-exposed segments of the membrane-bound complex and to prevent such cation effects[14]. These studies indicate that the regulatory mechanism controlling the distribution of absorbed excitation energy in chloroplasts involves a surface-exposed segment of the LHCP.

It has recently been established that the LHCP is reversibly phosphorylated on a threonyl residue located within this surface-exposed segment[15–18]. The LHCP belongs to a group of thylakoid polypeptides shown to be phosphorylated by a membrane-bound, light-activated protein kinase[19,20] and dephosphorylated by a membrane-bound phosphatase[17]. Bennett *et al.*[21] have demonstrated that the reversible phosphorylation of LHCP changes the light-harvesting properties of isolated thylakoids: phosphorylation increases (and dephosphorylation decreases) the proportion of absorbed excitation energy transferred to photosystem I.

This article shows that the activity of the protein kinase is regulated by the redox state of plastoquinone. We propose a molecular mechanism for state 1–state 2 transitions *in vivo* that

0028–0836/81/190025—05$01.00

is consistent with these data and we argue that the presence of cations is merely a prerequisite for these transitions rather than a decisive regulatory factor in itself.

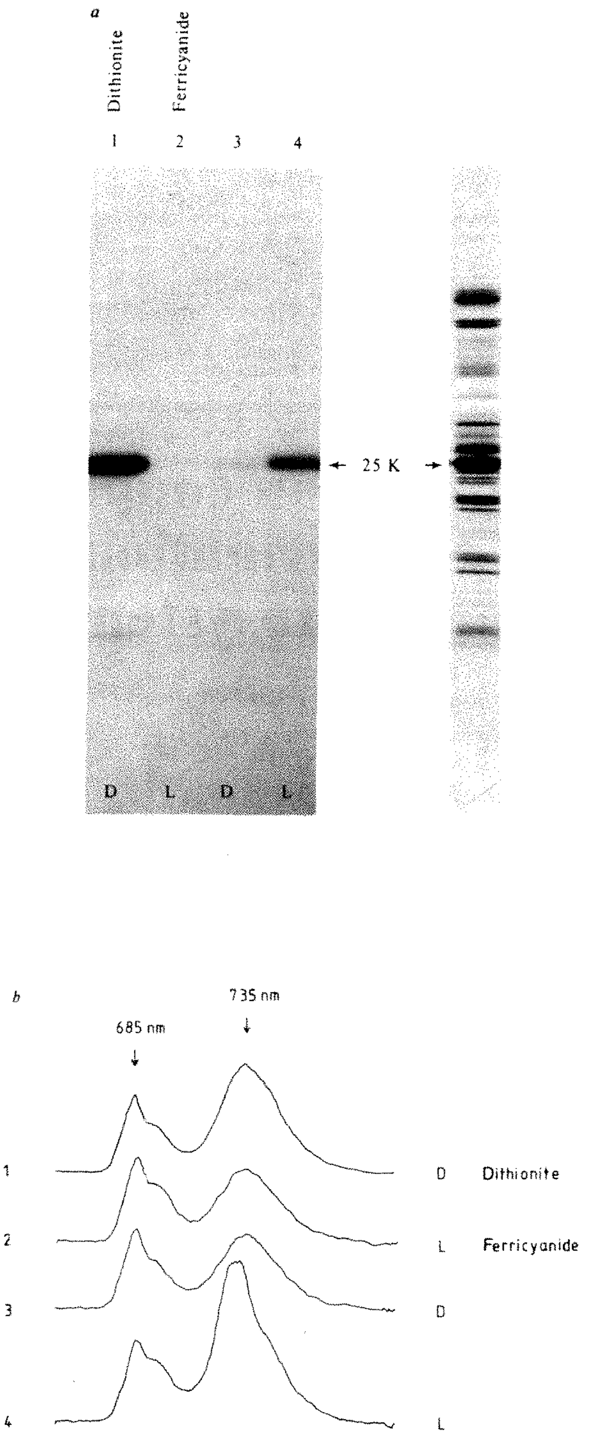

Fig. 1 Effects of light, dithionite and ferricyanide on phosphorylation of LHCP (*a*) and on 77 K fluorescence emission spectrum of thylakoids (*b*). *a*, Thylakoids that had been pre-equilibrated with or without dithionite (10 mM) in darkness and with or without ferricyanide (2 mM) in the light were incubated with [γ-^{32}P]ATP as described in Table 1 legend. Total ^{32}P incorporation into acid-insoluble material was determined and then each sample was subjected to SDS-polyacrylamide gel electrophoresis, followed by staining (lane 5) and autoradiography (lanes 1–4). The identities of the lanes (together with total protein kinase activity of the thylakoids, expressed as a percentage of the light control) are: lane 1, dark + dithionite (124%); lane 2, light + ferricyanide (33%); lane 3, dark (16%); lane 4, light (100%). The position of the 25,000 MW LHCP is indicated (25 K). *b*, Thylakoids were pre-equilibrated and incubated as described above except that the dithionite concentration was 20 mM and the ATP was not radioactive. After incubation, thylakoids were quickly diluted 10-fold with a medium containing 50 mM Tricine-NaOH (*p*H 7.6), 30% (v/v) glycerol and 10 mM $MgCl_2$ and then frozen to 77 K. Fluorescence emission spectra were obtained as described previously[21] using 440 ± 10 nm light for excitation. Spectra were normalized to give equal relative fluorescence at 685 nm using a Hewlett-Packard 9825 computer.

Activation of the thylakoid protein kinase by light and reducing agents

The protein kinase activity of isolated thylakoids was assayed by measuring the transfer of ^{32}P from [γ-^{32}P]ATP to total membrane protein (Table 1). Light stimulated the kinase about fourfold compared with a dark-incubated control. The herbicide 3-(3′,4′-dichlorophenyl)-1,1-dimethylurea (DCMU), which blocks electron transport between the primary acceptor (Q) of photosystem II and plastoquinone, completely abolished the stimulatory effect of light. The stimulation could not be restored by addition of 2,6-dichlorophenolindophenol (DCPIP) in the reduced form ($DCPIPH_2$), which donates electrons to the intersystem chain after plastoquinone. Thus, the kinase seemed to be stimulated by reduction of certain intersystem electron carriers. This idea was supported by the effects of oxidizing and reducing agents on kinase activity (Table 1). Ferricyanide and methyl viologen accept electrons from photosystem I and consequently tend to oxidize the intersystem carriers. These oxidants inhibited light-activation of the kinase. In contrast, the low-potential reductant dithionite[22] activated the kinase in the dark, as did tetramethylhydroquinone ($TMQH_2$, a specific donor to plastoquinone in the intersystem electron transport chain[23,39]). Although dithionite was a somewhat more effective activator than light, their effects were equivalent rather than additive or synergistic. It is likely, therefore, that light and dithionite activated the kinase by the same basic mechanism, that is, by reduction of the intersystem carriers.

When activated by light, the protein kinase of the thylakoid phosphorylates predominantly the 25,000 MW LHCP[16]. Figure 1*a* shows that the same protein was phosphorylated when the kinase was activated in the dark by dithionite. Dithionite also stimulated phosphorylation of the 8,000 MW polypeptide reported to be the proton channel of the thylakoid ATP

Table 1 Activation of thylakoid protein kinase by light and reducing agents

Incubation conditions	Kinase activity (%)
Light	100
Dark	28
Light + DCMU	21
Light + DCMU + $DCPIPH_2$	18
Dark + dithionite	111
Light + dithionite	112
Light + DCMU + dithionite	121
Dark + $TMQH_2$	101
Light + methyl viologen	27
Light + ferricyanide	17

Thylakoid membranes were prepared from 12–20-day-old peas (*Pisum sativum* L. var. Progress no. 9) grown as previously described[3]. Shoots (25 g) were homogenized for 5 s in a blender at low speed in 100 ml of 50 mM Tricine-NaOH (*p*H 7.8), 0.4 M sorbitol and 5 mM $MgCl_2$. The homogenate was filtered through cheesecloth, and centrifuged at 1,000*g* for 5 min. The pelleted chloroplasts were osmotically shocked in 50 ml of 10 mM Tricine-NaOH (*p*H 7.8) and 5 mM $MgCl_2$. The suspension was centrifuged at 2,800*g* for 5 min and the thylakoid pellet was resuspended to a final chlorophyll concentration of 1 mg ml^{-1} in 50 mM Tricine-NaOH (*p*H 7.8), 100 mM sorbitol and 10 mM $MgCl_2$. Portions (100 μl) of the thylakoid suspension were equilibrated at 20 °C in a final volume of 1 ml of the same buffer containing the indicated additions: 3-(3′,4′-dichlorophenyl)-1,1-dimethylurea (DCMU) at 10 μM; 2,6-dichlorophenolindophenol (DCPIP) at 50 μM, maintained in the reduced form ($DCPIPH_2$) by sodium ascorbate (2 mM); sodium dithionite (20 mM); tetramethylhydroquinone ($TMQH_2$, 500 μM) reduced with sodium borohydride as described elsewhere[23]; methyl viologen (50 μM); potassium ferricyanide (2 mM). Equilibration took place either in the light (15 μE m^{-2} s^{-1}) or darkness, and, where dithionite was included, reaction mixtures were made anaerobic by bubbling them with nitrogen gas before the addition of thylakoids. Phosphorylation reactions were started by addition of [γ-^{32}P]ATP (10 Ci mol^{-1}) to a final concentration of 100 μM. The reaction was stopped after 4 min by addition of 0.5 ml of cold trichloroacetic acid (30%, w/v). Acid-stable, precipitable radioactivity was counted by Cerenkov spectrometry. The extent of protein phosphorylation was calculated from the mean activity of duplicated samples. Results are expressed as a percentage of the rate obtained in the light in aerobic conditions (5 nmol phosphate incorporated per mg chlorophyll in 4 min).

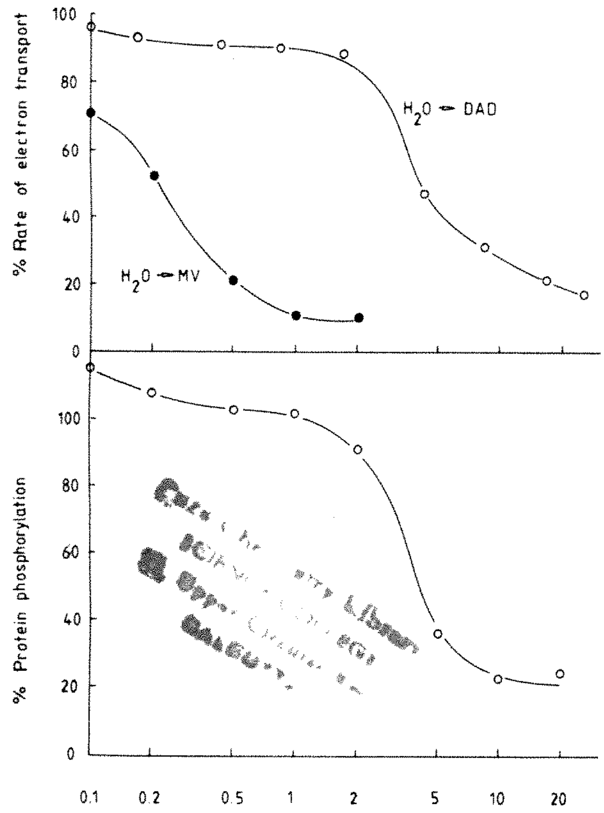

Fig. 2 Inhibition of electron transport and protein kinase activity by 2,5-dibromo-3-methyl-6-isopropyl-*p*-benzoquinone (DBMIB). Whole chain electron transport was measured as oxygen uptake in the presence of methyl viologen (MV, 100 μM), sodium azide (5 mM) and ATP (100 μM). The control rate in the absence of DBMIB was 23 μmol (mg chlorophyll h)$^{-1}$. Photosystem II-mediated electron transport was measured as oxygen evolution in the presence of $K_3Fe(CN)_6$ (2.5 mM), diaminodurene (DAD, 1.2 mM) and ATP (100 μM). The control rate was 97 μmol (mg chlorophyll h)$^{-1}$. All electron transport measurements were carried out at saturating light intensity (1 mE m^{-2}s^{-1}) in a reaction medium (2 ml) containing 50 mM Tricine (*p*H 7.8), 100 mM sorbitol, 10 mM $MgCl_2$ and chloroplasts equivalent to 200 μg chlorophyll. Protein kinase activity was measured as described in Table 1 legend. DBMIB was present during the equilibration period before the addition of [γ-^{32}P]ATP. Values for phosphorylation were calculated by subtraction of the activity of a dark control and are expressed as a percentage of the activity in the light in the absence of DBMIB.

synthase[20]. In contrast, ferricyanide completely inhibited phosphorylation of these thylakoid polypeptides.

Changes in the distribution of absorbed excitation energy

Bennett *et al.*[21] reported that light-induced protein phosphorylation altered the 77 K chlorophyll fluorescence emission spectrum of isolated thylakoids. The finding that emission at 735 nm (F_{735}; derived mainly from the chlorophylls of photosystem I) was increased relative to emission at 685 nm (F_{685}; derived mainly from light-harvesting chlorophylls associated with photosystem II[1]) was one of several lines of evidence[21] indicating that protein phosphorylation changed the distribution of excitation energy within the pigment bed of the membrane in such a way as to favour distribution to photosystem I at the expense of photosystem II.

If the above conclusion is correct, changes in the distribution of absorbed excitation energy should occur whenever the level of protein phosphorylation is altered regardless of how the latter is brought about. Figure 1*b* shows that the 77 K chlorophyll fluorescence emission spectrum of isolated thylakoids was changed by ferricyanide and dithionite in accordance with the effects of these reagents on protein phosphorylation. Ferricyanide inhibited the light-dependent increase in F_{735} while dithionite increased F_{735} in darkness, thus providing evidence for the control of excitation energy distribution by the redox state of the electron transport chain.

Although the dithionite-induced fluorescence change occurred in the presence of ATP, the data in Fig. 1 do not in themselves indicate that the change required ATP or involved protein phosphorylation. To explore this point in more detail, thylakoids were incubated in various conditions in the presence and absence of ATP and dithionite. Values for the ratio F_{735}/F_{685} were calculated from the resulting 77 K fluorescence emission spectra (Table 2). An ATP-dependent increase in the ratio was observed only in conditions which also permitted protein phosphorylation. Thus, there was no significant effect of ATP on fluorescence in the dark or in the light in the presence of DCMU, unless dithionite was also present. It is also clear from Table 2 that dithionite exerted two effects on the F_{735}/F_{685} ratio, one depending on the presence of ATP and the other not. The effect which required both ATP and dithionite represented the change in the distribution of excitation energy that could be attributed to dithionite-activated protein phosphorylation. The effect of dithionite in the absence of ATP may result from a direct alteration in fluorescence yield.

Activation of protein kinase by reduced plastoquinone

The above data raised the possibility that plastoquinone was the electron transport component whose reduction led to kinase activation. This possibility was tested by the use of 2,5-dibromo-3-methyl-6-isopropyl-*p*-benzoquinone (DBMIB), which inhibits electron transport at two sites—it inhibits oxidation of plastohydroquinone at a high-affinity site[24] and reduction of plastoquinone at a secondary, low-affinity site[25]. Figure 2 illustrates both inhibitory activities. At a concentration of 1 μM,

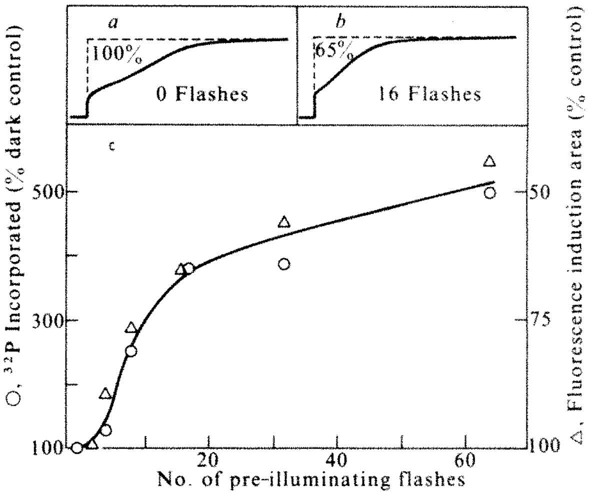

Fig. 3 Thylakoid protein phosphorylation and redox state of plastoquinone as functions of the number of pre-illuminating single-turnover flashes. Thylakoids were diluted with a medium containing 50 mM Tricine (*p*H 7.8), 100 mM sorbitol, 10 mM $MgCl_2$ and 10 mM NaF to a chlorophyll concentration of 50 μg ml^{-1} for protein kinase assays or 5 μg ml^{-1} for room temperature chlorophyll fluorescence induction transients. The dilution medium had been bubbled with nitrogen before the addition of thylakoids. The samples were pre-illuminated with a flashlamp (General Radio 'Stroboslav', type 1539A) delivering one intense, 8-μs flash per s. A fibre-optics bundle carried light from the flash-lamp directly into either cuvettes (for the induction transients) or polyethylene microcentrifuge tubes (for kinase assays). After the indicated number of flashes, fluorescence induction was measured in the cuvettes as previously described[3]. *a,b*, Direct tracings of oscillographic recordings; broken lines delimit the area above the induction curve, a measure of the proportion of the plastoquinone pool that is in the oxidized state. *c*, [γ-^{32}P]ATP was added to the microcentrifuge tubes for a 2-min, dark, anaerobic incubation which was terminated by addition of trichloroacetic acid to a concentration of 10%. Protein phosphorylation was then measured as described in Table 1 legend. Fluorescence measurements and additions of [γ-^{32}P]ATP were made within 5 s of the final pre-illuminating flash.

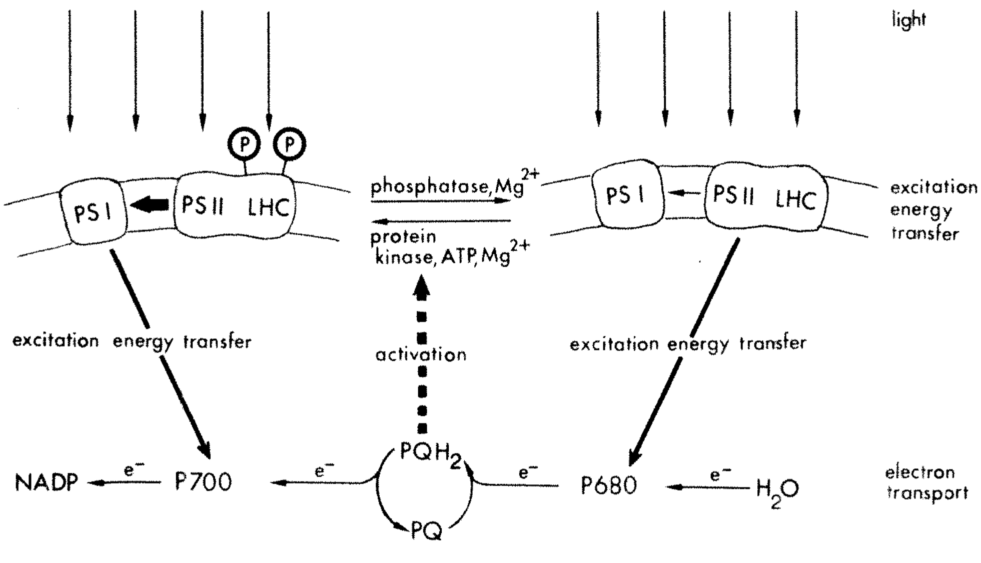

Fig. 4 A model for control of distribution of excitation energy in photosynthesis, in which reversible phosphorylation of LHC couples the redox state of plastoquinone (PQ) to the distribution of excitation energy between the photosystems. The mechanism we propose ensures maximal quantum efficiency of non-cyclic electron transport from water to NADP, mediated by P680 and P700, the reaction centres of photosystem II (PSII) and photosystem I (PSI), respectively. Reduction of plastoquinone by photosystem II leads to kinase activation and LHC phosphorylation, and hence to increased excitation of photosystem I. Conversely, oxidation of plastohydroquinone (PQH_2) by photosystem I inactivates the kinase; the phosphatase then dephosphorylates LHC and hence excitation of photosystem II is increased relative to that of photosystem I. Since the redox state of plastoquinone will be determined in part by the distribution of excitation energy between the two photosystems, reversible LHC phosphorylation completes a feedback loop by means of which any imbalance in this distribution will tend to be self-correcting.

DBMIB inhibited whole chain electron transport (from water to methyl viologen) by 90%, whereas photosystem II-mediated reduction of diaminodurene (DAD) was strongly inhibited only at concentrations greater than about 10 µM (DAD accepts electrons at or before plastoquinone[26]). When light-dependent kinase activity was measured as a function of DBMIB concentration (Fig. 2), strong inhibition was obtained only at concentrations equal to or greater than 10 µM. Thus, the electron transport component that links the activity of the protein kinase to the redox state of the intersystem carriers is situated between the primary and secondary sites of action of DBMIB; the most obvious candidate is plastoquinone itself.

To characterize further the possible relationship between the redox state of plastoquinone and kinase activation, we subjected a series of thylakoid samples to short, intense flashes of light. The redox state of the plastoquinone pool was assessed by recording chlorophyll fluorescence induction transients (Fig. 3). The area above the curve of the transient is proportional to the fraction of the plastoquinone pool that is in the oxidized state[27]. As shown in Fig. 3*a* and *b*, pre-illuminating flashes decreased the area above the curve of the transient, indicating that the plastoquinone pool had accumulated reducing equivalents. In parallel measurements, [γ-^{32}P]ATP was injected in the dark into preflashed samples which were then incubated for 4 min to permit kinase activity assay. As shown in Fig 3*c*, there was a striking similarity between the extent of kinase activation and that of reduction of the plastoquinone pool, as measured by the decrease in the area above the curve of the transient. Thus, the activity of the kinase is linked to the redox state of plastoquinone.

The previous observation[19] that NADPH and ferredoxin could together activate the protein kinase in darkness may now be explained as an indirect effect, resulting from the ability of reduced ferredoxin to reduce plastoquinone[28,29]. We do not believe that activation of the thylakoid-bound protein kinase is mediated by either the thioredoxin system[30] or the 'LEM' system[31], both of which have been implicated in the control of stromal enzyme activity and require electron transport via components on the reducing side of photosystem I.

Table 2 Effects of light, dithionite, DCMU and ATP on the ratio of 77 K fluorescence emissions at 735 nm and 685 nm

Incubation conditions*	F_{735}/F_{685} +ATP (*a*)	−ATP (*b*)	(*a*)/(*b*)†
Dark	1.00	0.95	1.05
Light	1.90	1.20	1.58
Dark + dithionite	1.45	1.10	1.32
Light + dithionite	1.85	1.30	1.42
Light + DCMU	0.85	0.90	0.94
Light + DCMU + dithionite	1.90	1.30	1.46

* As described in Fig. 1*b*; DCMU concentration, 10 µM.

† Values greater than 1 indicate an ATP-dependent change in excitation energy distribution in favour of photosystem I.

Regulation of photosynthetic efficiency by reversible protein phosphorylation

The involvement of plastoquinone in the activation of the thylakoid protein kinase is probably of fundamental importance in the regulation of photosynthesis, for it provides a physiological mechanism for an adaptation which will correct any imbalance in the distribution of excitation energy between the two photosystems (Fig. 4).

The operation of this mechanism may be illustrated by reference to state 1–state 2 transitions. In green algae and higher plants, that is, in photosynthetic organisms containing LHCP, exposure to red light (of wavelength <680 nm) will excite photosystem II to a greater extent than photosystem I, and thereby lead to reduction of plastoquinone. The protein kinase will then be activated, LHCP will become phosphorylated and an increased proportion of absorbed excitation energy will be transferred from the light-harvesting complex to photosystem I at the expense of photosystem II. Thus, the biochemical event underlying the transition to state 2 is phosphorylation of the LHCP. Conversely, under far-red light (of wavelength >680 nm), photosystem I will be excited to a greater extent than photosystem II, plastoquinone will be oxidized and the kinase will be inactivated. Any phosphorylated LHCP will be dephosphorylated by the thylakoid phosphatase and excitation energy transfer to photosystem I will be decreased. Thus, the biochemical event underlying the transition to state 1 is dephosphorylation of the LHCP.

It has often been suggested that state 1–state 2 transitions reflect changes in the cation content of the stroma surrounding the thylakoids[9–11,32], a suggestion based on the effect of cations on the distribution of excitation energy in isolated thylakoids[9–11]. One problem with this idea is that state 2 transitions would have to be correlated with a massive loss of cations from the stroma (to either the thylakoid or the cytoplasm), but there is no reason to believe that the cation concentration of the stroma changes greatly when higher plants or algae are transferred from far-red light to red light or vice versa. However, it should not be assumed that cations are not involved in the regulation of excitation energy distribution *in vivo*. Two roles need to be emphasized. First, cations such as Mg^{2+} ions are required to establish the pattern of excitation energy distribution seen in dephosphorylated membranes, including the close structural and functional association between the LHCP complex and photosystem II[10,12,33]. The second role for Mg^{2+} ions derives from the fact that these cations are cofactors of both the kinase and the phosphatase (Fig. 4)[17,19,20]. Thus, the presence of cations should be thought of as a prerequisite for state 1–state 2 trasitions rather than as a regulatory factor *per se*.

The mechanism depicted in Fig. 4 provides an explanation for the original results of Bonaventura and Myers[5] and of Murata[6] and also for more recent contributions to the study of state 1–state 2 transitions. Several authors have drawn attention to the involvement of the high energy state of the membrane in these transitions[9,34,35]. This would certainly be required for the generation of ATP consumed in protein phosphorylation (transition to state 2). Duysens[36] suggested that the redox state of a component of the intersystem electron transport chain controls these transitions. Plastoquinone would clearly fulfil this role. Horton and Black[37,38] have recently established state 1–state 2 transitions *in vitro*. The transition to state 2 required ATP and was controlled by a membrane-bound factor with the redox potential of plastoquinone. The idea that protein phosphorulation might provide the connection between plastoquinone and ATP is fully in agreement with our present results.

It is important to recognize that state 1–state 2 transitions are also observed in organisms that lack LHCP. For example, Murata[6] and Ried and Reinhardt[8] have shown that these transitions occur in red algae, which contain phycobiliproteins instead of LHCP complexes. Ried and Reinhardt[8] conclude from their studies that the transitions are controlled by the redox state of a component of the intersystem electron transport chain. It will be interesting to discover whether state 1–state 2 transitions in the red algae are brought about by a mechanism analogous to that shown in Fig. 4; that is, a mechanism in which reversible phosphorylation of the phycobiliproteins is controlled by the redox state of plastoquinone.

This study was supported in part by NSF grant PCM 77-18953 to C.J.A. and by SRC grant GR/B11660 to J.B. DBMIB was synthesized and provided by Dr Don Ort. We thank Mrs J. Watson for technical assistance.

Note added in proof: Another piece of evidence for the mechanism in Fig. 4 has now been obtained. Potentiometric redox titrations of plastoquinone, of LHCP phosphorylation and of ATP-dependent chlorophyll fluorescence quenching give identical results[40].

IgG antibodies to phosphorylcholine exhibit more diversity than their IgM counterparts

Patricia J. Gearhart
Department of Embryology, Carnegie Institution of Washington, 115 W. University Parkway, Baltimore, Maryland 21210, USA

An amino acid sequence analysis of the N-terminal immunoglobulin heavy and light chain variable regions (V_H and V_L) from 16 hybridoma proteins which bind phosphorylcholine as well as the complete sequence analysis of 9 of these V_H regions is presented. There seem to be more V_H regions participating in the phosphorylcholine response than can be encoded directly by germ-line V_H gene segments. Moreover, the V regions from IgG antibodies are considerably more variable than those from their IgM counterparts. These observations raise the possibility that a somatic mechanism for V region diversification produces greater diversity in IgG than in IgM antibodies.

ONE goal in molecular immunology is to understand the mechanisms responsible for antibody gene diversification. Insight into antibody diversity has been obtained by comparing sequence information from both immunoglobulin genes and proteins[1–8], and our present level of understanding may be summarized as follows. (1) Antibody molecules are composed of heavy (H) and light (L) chains, each of which contain variable (V) and constant (C) regions. (2) Comparative analyses of many variable regions have demonstrated that amino acid sequence variability is unevenly distributed throughout the V region. The antigen-binding site is composed of extremely variable sections termed hypervariable regions (three for each chain), whereas

0028-0836/81/190029—06$01.00

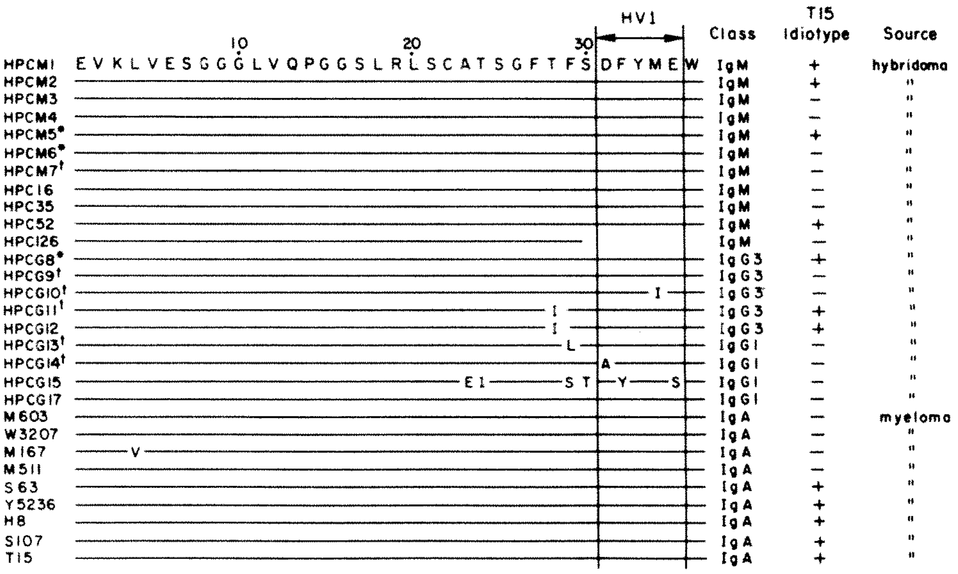

Fig. 1 V_L regions of anti-phosphorylcholine antibodies. The hybridomas were made by the following procedure. BALB/cJ mice (Jackson Laboratory) were immunized intraperitoneally with 0.1 mg of phosphorylcholine–haemocyanin[53] in complete Freund's adjuvant, and 1–2 months later (4 days before cell fusion), injected intraperitoneally with 0.1 mg of phosphorylcholine–haemocyanin in complete Freund's adjuvant. The cells from individual spleens were fused to non-secreting SP2/0-Ag14 cells[54] according to Kennett *et al.*[55]. The heavy chain class of anti-phosphorylcholine antibodies was determined by radioimmunoassay[32], and antibody with the T15 idiotype was detected by binding to A/J anti-T15 serum as described[53]. The HPCM7(1F8), HPCG10(1B6), HPCG13(2F5), HPCG9(2B4), HPCG14(2C5), HPCG15(1B10), HPCG17(24B5) and HPCG12(1D8) hybridomas were obtained from J. Hurwitz[56]. The HPCM3(63b4) and HPCM4(64a5) hybridomas were obtained from B. Clevinger and J. Davie, and were generated from adult mice which were suppressed for expression of the T15 idiotype by treatment with anti-T15 serum at birth. The numbers in parentheses refer to the nomenclature of the donor laboratory. The antibodies were purified and chain separated as previously described[57,58]. The amino acid sequence analysis was carried out on a modified Beckman 890B sequenator as previously described[59]. Amino acids are noted by the one-letter code of Dayhoff[60]. HV1 designates the first hypervariable region which ends at residue 40 (ref. 35). All * proteins come from one mouse, and the + proteins from a second mouse. Other proteins each come from separate individuals. The V_L sequences are categorized according to the T15, M603 and M167 groups with the most typical protein of each group used as the prototype. A solid line indicates identity with the prototype sequence. The sequence of HPC16 is written assuming Asx residues are identical to prototype asparagine or aspartic acid residues. The sequences of HPC52, HPC126, HPC19, HPC104 and HPC16 are from ref. 61; H8, S107, T15 and M603 from ref. 22; S63, W3207 and M511 from ref. 62; and M167 is from ref. 63. Y5236 sequence is from J. Hubert (personal communication).

non-binding portions, termed the framework regions, are more highly conserved[9–12]. The hypervariable regions fold to constitute the walls of the antigen-binding site. (3) The V regions fall into sets of closely related sequences termed groups (formerly called subgroups)[13–15]. The minor variation within the V regions of a particular group has afforded special insight into mechanisms of diversity[2,3,5–8,16,17]. (4) The antibody molecules are encoded by three unlinked families of genes—two light chain families, lambda (λ) and kappa (κ), and a heavy chain family. (5) The V region of the light chain (V_L) is encoded by two distinct gene segments—V_L and J_L (joining)[18], and the V region of the heavy chain (V_H) is encoded by three distinct gene segments—V_H, D (diversity) and J_H (ref. 8). The J_L gene segments encode only a small portion of the third hypervariable region of the light chain, whereas the D and J_H gene segments encode most of the third hypervariable region of the heavy chain. (6) There are at least 100 germ-line V_L and V_H gene segments[17,19], indicating that germ-line diversity is extensive. (7) There are four functional J_κ and J_H gene segments[6–8,20], and it seems that any J_κ gene segment may be joined with any V_κ gene segment[5]. Likewise, the combinatorial joining of V_H, D and J_H gene segments is an important mechanism for amplifying diversity in the third hypervariable region of the heavy chain[3]. (8) The site-specific recombination mechanism which joins the V_L and J_L, or the V_H, D and J_H gene segments, may join particular gene segments at different points in their sequences, thus generating hybrid codons as well as codon insertions or deletions. Thus, alternative joining points generate somatic variation at these junctions during the act of gene segment joining[4,6–8]. (9) The V_L regions seem to exhibit somatic variation in hypervariable and framework regions beyond that which can be explained by the germ-line V gene repertoire and the junctional diversity of V–J joining. In the V_λ region, this diversity appears exclusively in the hypervariable regions[1], but in V_κ regions, diversity is seen in framework regions as well[5].

Table 1 Affinity of antibodies for phosphorylcholine

Antibodies	Class	T15 idiotype	$K_a \times 10^5\ M^{-1}$
T15-V_H, T15-V_L groups			
HPCM2	IgM	+	3.5
HPCM5	IgM	+	2.4
HPCM7	IgM	−	3.2
HPCG8	IgG3	+	1.3
HPCG14	IgG1	−	4.4
T15	IgA	+	4.3
T15-V_H, M603-V_L groups			
HPCM3	IgM	−	0.34
HPCG15	IgG1	−	0.13
W3207	IgA	−	2.5
T15-V_H, M167-V_L groups			
HPCG10	IgG3	−	0.25
HPCG13	IgG1	−	1.8
HPCG17	IgG1	−	1.0
M167	IgA	−	1.9

The affinity of antibodies for phosphoryl[*Me*-^{14}C]choline (NEN) was measured by equilibrium dialysis in a buffer containing 0.17 M boric acid, 0.03 M sodium borate, 0.15 M sodium chloride, *p*H 8.0. Equilibrium dialysis was performed at 25 °C in 0.1-ml compartments at an antibody concentration of 1.5–3.5 mg ml^{-1}. Protein molarity was determined by absorbance at 280 nm using $E^{0.1\%}_{1\,\mathrm{cm}} = 1.37$, and a molecular weight of 150,000 for IgG and IgA, and 170,000 for IgM. The data were plotted by the method of Scatchard[67] to calculate number of sites and by the Sips distribution function[68] to calculate K_a. A least-squares fit was used to obtain the best line. The Scatchard plots were linear, and the number of binding sites ranged from 1.7 to 2.0 for monomeric forms. Values of α, the heterogeneity index, were calculated by the Sips distribution function and ranged from 0.9 to 1.06, indicating homogeneity of binding sites. Binding constants were accurate to ± 10%.

To assess the patterns of variable region diversity to a simple hapten, we have used the hybridoma technique of Köhler and Milstein[21] to obtain homogeneous antibodies from BALB/c mice immunized against phosphorylcholine. Antibodies binding to phosphorylcholine were studied for the following reasons. First, the variable regions of a closely related set of myeloma proteins and serum antibodies that bind phosphorylcholine have been sequenced[15,22–24], and these data can be compared with the sequences obtained from hybridoma antibodies. Second, anti-idiotypic sera raised against several of the myeloma proteins have revealed that the majority of anti-phosphorylcholine antibodies from BALB/c mice have the variable region idiotype of the myeloma protein T15 (refs 25, 26); this is denoted the T15 idiotype. A variety of interesting analyses have subsequently been carried out on the developmental expression[27], genetic mapping[28,29] and regulation[30–32] of this predominant idiotype.

We report here the N-terminal amino acid sequences for the V_H and V_L regions of 16 hybridoma antibodies which bind phosphorylcholine. In addition, we have determined the complete V_H region sequences for nine of these hybridoma antibodies. The most striking observation is that the IgG antibodies exhibit far more diversity than their IgM counterparts. The data also suggest that somatic variation may be involved in V region diversification.

Hybridoma and myeloma immunoglobulins belong to the same V_L and V_H groups

The N-terminal amino acid sequences of 30 V_L regions from hybridoma and myeloma proteins binding phosphorylcholine are given in Fig. 1. Immunoglobulin V_L regions which differ by two or less amino acids over the first 23 residues are classified as members of a single group[15]. The data indicate that the 30 V_L regions fall into three groups. These groups are the same as those initially delineated by analysis of light chains from myeloma proteins and are known as the T15, M603 and M167 groups[33]. Light chains derived from antibodies to phosphorylcholine generated in mouse strains other than BALB/c also fall into these same three V_L groups[34]. Each V_L group has a prototype sequence that is repeated identically many times (Fig. 1). Within a group, each V sequence that differs from the prototype will be denoted a nonprototype sequence.

Of 15 V_L regions in the T15 group, 14 are identical and the 15th differs by a single residue substitution which can be explained by a single nucleotide change. Three of six V_L regions in the M603 group are identical and the other three differ by two, two and five residues, respectively. All these substitutions can be accounted for by single nucleotide changes. Four of nine V_L regions in the M167 group are identical and the others differ by a single residue. Three of these substitutions require two nucleotide changes (HPCG10, HPCG9 and HPC16). Seven of the 15 substitutions noted in these groups fall outside the first hypervariable region as defined by Kabat *et al.*[35]. There seems to be more diversity in the M603 and M167 V_L groups than in the T15 group.

The N-terminal amino acid sequences of the V_H regions from 11 IgM hybridomas, 9 IgG hybridomas and 9 IgA myeloma proteins that bind phosphorylcholine are shown in Fig. 2. Immunoglobulin V_H regions which differ by two or less amino acids over their N-terminal 27 residues belong to a single V group[15]. As seen in Fig. 2, all 29 V_H regions fall within a single V_H group. Twenty-two of the V_H sequences are identical, and six of the remaining seven V_H regions differ by a single residue from the prototype T15 sequence. The remaining V_H region, HPCG15, differs by six residues. Eleven of 12 substitutions can be explained by single nucleotide substitutions, and 8 of 12 substitutions lie outside the first hypervariable region.

The complete V_H region sequences from 10 hybridoma antibodies and 9 myeloma proteins are compared in Fig. 3. The hybridoma and myeloma V_H regions exhibit similar diversity patterns by several criteria. (1) Three hybridoma and four myeloma V_H regions are identical to the T15 prototype V_H sequence. (2) The variant hybridoma V_H sequences differ by 1–6 substitutions and the variant myelomas differ by 1–13 substitutions. (3) In both the hybridoma and myeloma V_H regions, insertions and deletions occur only in the third hypervariable region. (4) In the hybridoma V_H regions, 20 of 25 (80%) variant residues are found in the three hypervariable regions, and similarly, in the myeloma V_H regions, 21 of 28 (75%) variant residues are located in the three hypervariable regions. Since the hybridoma and myeloma V_H regions exhibit the same basic patterns of variation, we will consider both sets of data together in analysing diversity in the V_H segments (residues 1–101), the D segments (residues 102–108) and the J_H segments (109–125), which are encoded respectively, by the V_H, D and J_H gene segments[8].

The V_H segments demonstrate diversity in both framework and hypervariable regions

Ten V_H segments are identical and nine others differ by one to eight substitutions (Fig. 3). Generally, the variant V segments differ by two or more widely scattered substitutions. Note that each variant V segment is distinct from all the others. Twenty-four variant residues are present at 16 different positions. Four positions show variation in more than one V_H region: position 56 has four different amino acid substitutions, position 55 has two different substitutions, position 28 has two identical substitutions and position 40 has three substitutions, two of which are identical. Twelve of 24 substitutions (50%) fall outside the two hypervariable regions contained in the V segment. Single base changes can account for 22 of 24 amino acid substitutions, and two substitutions require two base changes. Thus, any diversification mechanisms must account for diversity outside as well as within hypervariable regions[22].

D segment diversity is extensive

Figure 3 demonstrates that the D segment diversity is extensive and falls into three categories: isolated single base changes (for example, position 106 in M167 and 107 in H8 and HPCG8), substitutions, insertions or deletions at either end of the D segment (as in HPCG13, HPCG14, M603, M511 and M167), and blocks of amino acid substitutions (for example, W3207, HPCM4 and HPCM6). The single base substitutions could arise

Fig. 2 The V_H regions of anti-phosphorylcholine antibodies. See Fig. 1 legend for an explanation of the symbols. from the presence of multiple germ-line D gene segments or from somatic variation. The insertions or deletions of codons associated with either end of the D segment as well as the junctional codon substitutions probably arise from the site-specific recombinational mechanism that joins the V_H and D as well as the D and J_H gene segments (Fig. 4). This diversity arises because the actual DNA splice points may occur at different sites on each of these three gene segments, in each case generating insertions, deletions and/or hybrid codons at the junctional boundaries[6-8]. Figures 3 and 4 suggest that there are probably multiple germ-line D gene segments and that variable boundaries of recombination may occur for any of the V region gene segments—V_H, D or J_H. The blocks of substitutions may arise from multiple germ-line D segments, from the splicing together of two germ-line D gene segments or from a variety of other diversification mechanisms[4,17,36,37].

The number and diversity of germ-line D gene segments are not known, as the D gene segments have only recently been isolated from germ-line DNA (P. Early and L. Hood, personal communication). As a result of D segment variability, the third hypervariable region of the heavy chain is the most diverse portion of the antibody V regions[38]. This can be clearly seen in the V_H regions of immunoglobulins binding phosphorylcholine as well as those binding dextran[3].

The J_H segments are encoded by one germ-line J_H gene segment

The J_H segments of mouse heavy chains are encoded by four different J_H gene segments[8,20]. In the 16 V_H regions from immunoglobulins binding phosphorylcholine that can be compared, all seem to have J_H segments coded by the J_{H1} gene segment (Figs 3, 4). Five J_H segments (HPCM6, HPCM4, HPCG14, M603 and W3207) have N-terminal substitutions or deletions at position 108. As discussed before, this diversity can be explained by variability in the DNA splice point for joining the D and J_H gene segments (Fig. 4). In addition, two J_H segments (W3207 and M167) have additional substitutions when compared with the T15 sequence. At first glance, these data suggest that a particular J_H gene segment may be selected by antibody specificity. However, this selection is not always the rule, for in the 19 V_H regions derived from hybridoma antibodies binding dextran, all four J_H gene segments are expressed[3] (J. Schilling, personal communication).

Antibodies binding phosphorylcholine demonstrate combinatorial association between light and heavy chains

Among the IgM immunoglobulins binding phosphorylcholine, some use the same heavy chain in conjunction with two very different light chains (such as HPCM2 and HPCM3 in Figs 1 and 3). The T15- and M603-like V_L regions associated with these V_H regions differ by more than 50% of their amino acid sequence over their N-terminal 38 residues and belong to two different groups (Fig. 1). Moreover, this combinatorial association of two different light chains with the same heavy chain changes the nature of the antigen-binding site because the affinities of the HPCM2 and HPCM3 antibodies for phosphorylcholine differ by 10-fold (Table 1). It has long been assumed that one heavy chain may pair with many different light chains[39]. Indeed, if 1,000 light and 1,000 heavy chains could be associated combinatorially, 10^6 different antibodies could be produced. Although it has not been formally demonstrated that every light chain can pair with every heavy chain, these data suggest that combinatorial association may occur in some antibodies to increase diversity.

The T15 idiotype is present on immunoglobulins with sequence heterogeneity in V_H and V_L regions

Antisera recognizing the T15 idiotype have been used to identify a restricted group of antibodies that bind to phosphorylcholine. The immunoglobulin class and idiotype classification of antibodies are given in Figs 1–3, and show that antibodies with the T15 idiotype are found among proteins of the IgM, IgG3 and IgA classes. These data also show that antibodies with the T15 idiotype can have different amino acid sequences in their V regions. Four hybridoma antibodies (HPCM1, HPCM2, HPCM5 and HPC52) and four myeloma proteins (S63, Y5236, S107 and T15) exhibit the T15 idiotype and have identical N-terminal V_H and V_L sequences. However, hybridomas HPCG8, HPCG11 and HPCG12 express the T15 idiotype but differ from the proteins described above by one or more residues either in the V_H (HPCG8, HPCG11 and HPCG12) or the V_L (HPCG8) region. These data clearly indicate that antibodies with the same idiotype comprise a

family of closely related but distinct V regions, and, in this regard, are similar to immunoglobulins which bind nitrophenyl[40], dextran[3] and arsonate[41,42].

Does somatic variation occur in the V_H and V_L segments derived from immunoglobulins binding phosphorylcholine?

The protein sequences presented here demonstrate that the V_H (amino acids 1–101) and V_L (amino acids 1–97) segments are very diverse. The question arises whether this V segment diversity can be generated entirely from multiple germ-line genes, or whether some somatic diversification must occur. We have approached this question by analysing the protein and nucleic acid data for the proteins and genes encoding the phosphorylcholine response.

To determine a minimal estimate of the number of V genes in the T15 V_H group, a cloned V_H probe was used to analyse undifferentiated (embryo) DNA by Southern blot analysis[19]. This V_H probe was derived from a full-length cDNA copy of the heavy chain mRNA from the S107 myeloma tumour[43]. (The S107 and T15 V_H regions have identical protein sequences [Fig. 3].) The S107 V_H probe hybridizes strongly to four restriction fragments. Experiments have demonstrated that the S107 V_H probe cross-reacts strongly with mRNAs from M167 and M603[43]. Because these are among the most different V_H regions from phosphorylcholine-binding immunoglobulins (Fig. 3), the S107 cDNA probe should detect most, if not all, of the V_H genes in the T15 group. If each of the DNA restriction fragments that hybridize to the S107 cDNA probe contains one T15-like V_H gene segment, there are approximately four V_H genes in the T15 V_H group. However, more than four different phosphorylcholine-specific myeloma and hybridoma proteins have already been sequenced. Among the nine myeloma V_H regions that are completely sequenced, four differ in their V segments from the T15 V_H region by one to eight residues (Fig. 3). Among the 20 hybridoma V_H regions that have been examined over their N-terminus, seven differ from the T15 V_H segment and from the myeloma V_H variants (Figs 2, 3). Thus, in the 29 V_H regions derived from immunoglobulins binding phosphorylcholine, 12 different V_H protein segments are present. The four germ-line DNA restriction fragments hybridizing to the S107 V_H probe may each contain more than one V gene segment. However, even if each band contained three V_H gene segments—the number necessary to explain the protein V_H segment data—one would expect, in 29 V_H segments analysed at the protein level, to see several examples of the same germ-line V_H gene being expressed two or three times. Instead, each nonprototype sequence is unique, and with two exceptions, every variant amino acid is different from other amino acids found at that position. Hence, we conclude that the pool of distinct V_H regions is very large and somatic variation must account for at least a portion of the nonprototype V_H sequences reported here. Interestingly, as judged by the data in Figs 2 and 3, variation occurs as frequently outside as within the hypervariable regions (16 of 31 V_H segment substitutions lie outside the hypervariable regions). Therefore, either the framework variants arise from distinct germ-line V_H gene segments or the presumptive mechanism for somatic variation is not confined to the hypervariable regions.

Somatic variation also may occur in anti-phosphorylcholine light chain genes. In the M167 V_L group, there is only one germ-line gene[44] (I. Weissman and U. Storb, personal communication). Six different protein sequences have already been identified (Fig. 1). Thus, somatic diversification also generates V_L variants.

An alternative explanation for this V region diversity is the possibility of genetic polymorphism in V gene segments among BALB/c mice. Although this possibility cannot be ruled out, it seems unlikely. BALB/c mice have been inbred for hundreds of generations, and mice obtained from a single source should be greater than 99% homozygous[45], although admittedly, some polymorphisms do exist in inbred strains[46]. However, the extent of variation seen in the V_H and V_L regions from immunoglobulins binding phosphorylcholine far exceeds any known types of polymorphism including those noted in the globins and haptoglobins. For example, it is striking that four of the V_H and three of the V_L variants analysed in this study are derived from a single mouse (Figs 1, 2). Accordingly, individual mice are capable of generating extensive V segment diversity.

IgG antibodies binding phosphorylcholine exhibit more diversity than their IgM counterparts

The V_H segments from 11 IgM hybridomas do not show any diversity in their N-terminal 36 residues (Fig. 2). In contrast, the corresponding portions of the V_H regions from IgG hybridomas vary in six of the nine examples studied. The same pattern is seen in the corresponding V_L segments (Fig. 1). Of 12 light chains from IgM antibodies, 11 are identical in sequence to the prototype sequence of their respective groups while five of nine V_L regions from IgG antibodies vary. Thus, eight out of nine of the IgG antibodies vary from the V group prototype sequences in either their V_H or V_L regions, whereas only one of the 12 IgM antibodies varies.

One possible explanation for the observed differences in diversification between IgG and IgM proteins is that both do arise from the same population and the differences are the result of sampling errors. We used Fisher's exact method to demonstrate that it is very unlikely that these differences came from sampling error. The probability that the V_L segments of the IgM molecules and the V_L segments of the IgG molecules were selected from the same population is less than 0.05; likewise, the probability that the V_H segments from the IgM and IgG molecules were drawn from the same pool is 0.01; finally, the probability that both the V_L and the V_H segments were drawn from common V_L and V_H populations is less than 0.005. Thus, it is likely that the IgG polypeptides are significantly more diverse than their IgM counterparts. The complete V_H segment sequences strongly support this conclusion (Fig. 3) in that every V_H segment from the IgM group is identical to T15 and every V_H segment from the IgG shows one or more substitutions.

Cellular and recombinant DNA studies have suggested that B cells initially produce IgM and then switch to produce IgG or IgA after antigen stimulation[20,47–49]. Thus, the greater diversity of the IgG hybridomas must arise either from infrequent nonprototype V_H gene segments in IgM-producing B cells, which are selectively expanded and expressed in IgG-producing cells, or from nonprototype V_H gene segments that are generated in

IgG-producing cells. Two important questions arise. First, how and when are the nonprototype sequences generated? Second, what selective pressures could give rise to the differences between IgM and IgG diversity?

The nonprototype sequences could be produced by one of two general mechanisms. (1) The nonprototype V regions may be encoded by germ-line V gene segments. We think this unlikely because there are apparently more protein sequences than germ-line genes in the T15 V_H group and M167 V_L group. (2) The nonprototype V regions may arise by somatic diversification. If so, B cells that express variant antibodies must be amplified by selection after the class switch from IgM to IgG production. Somatic diversification may occur by any one of three distinct mechanisms: ordinary somatic mutation[37], somatic recombination[39], or a special hypermutational mechanism[36,50]. Two points are of special interest with regard to mechanisms of somatic mutation. First, activation of the somatic diversification mechanism may occur in conjunction with the switching of heavy chain classes. If so, the antibodies in secondary immune responses should be far more diverse than their primary immune response counterparts[51]. As the somatic diversification mechanism must generate variants in V_L as well as V_H gene segments, it must be activated in a *trans* fashion on different chromosomes. Second, somatic mutation may occur throughout the lifetime of individual B cells. Accordingly, the oldest B cells (those having undergone most clonal expansion) accumulate the most mutations. To explain our observations by this model, one would suggest that on the average B cells that had undergone a class switch were older than those which had not switched[52].

Two types of selection may operate on infrequent germ-line or somatic variants which could result in the observed IgM–IgG differences. (1) Antigen-driven selection. B-cell clones expressing variant antibodies may be expanded because they have a higher affinity for antigen than B cells expressing prototype antibodies. As IgG-producing cell populations may have undergone more antigen-driven selection than IgM populations, IgG antibodies should show more variability than IgM antibodies. At first sight, the data presented in Table 1 seem to argue against this possibility. The range of affinity constants seen in the IgM and IgG antibodies is not significantly different. However, these data do not exclude the possibility that the affinity constant of antibody for free hapten could be significantly different from the affinity constant of antibody for the hapten–carrier conjugate. Selection for variants in non-binding site regions may occur whenever framework residues modify the positions of binding-site residues. (2) Idiotype selection. Selection of infrequent variants may occur by idiotype-specific regulation. For example, if idiotype-specific suppression controls the level of predominant clones expressing the prototype sequences, B cells with altered sequences may be selectively expanded.

The IgA antibodies also are more diverse than their IgM counterparts ($P<0.05$). However, the IgA V_H regions from immunoglobulins binding phosphorylcholine fall into two categories—those which have diversified (5/9) and those which are identical to the T15 prototype sequence (4/9) (Figs 1, 3). We propose that the V_H and V_L segments of IgG3, IgG1, IgA and probably IgG2a and IgG2b antibodies generally will be significantly more diverse than the V_H and V_L segments of IgM antibodies. Thus, increased diversity seems to be associated with the class switch from IgM to other isotypes. The increased variability in V segments is in part due to the somatic diversification of germ-line V genes. It will be interesting to compare the amino acid sequences of the protein variants with the nucleic acid sequences of the germ-line genes to determine which amino acid residues are encoded in the germ-line DNA and which result from somatic variation.

A radiochemical technique has been used to determine the primary structure of a murine H–2K^b molecule, a 346-residue glycoprotein subunit attached to a 99-residue β_2-microglobulin subunit. Comparison of this structure with those available for other murine H–2 antigens and human HLA molecules suggests an evolutionary origin of MHC products.

THE antigens encoded within the tightly linked major histocompatibility complex (MHC)[1–4] are a diverse group of membrane-bound molecules intimately involved in various aspects of immune function. This genetic region, which has been characterized in several species, encodes a series of integral cell membrane glycoproteins with a high degree of polymorphism. Although the details of their function remain unknown, it is clear that MHC-encoded molecules are involved in the self–self recognition required for cellular cooperation[1,2] and in the recognition of altered cells by cytolytic T lymphocytes[5,6]. An extensive list of traits, including susceptibility to specific diseases in humans, has also been linked to this complex locus[7,8]. Although the MHC has been studied extensively by immunogenetic methods[3,4], only recently have details of primary structure been elucidated for human and murine MHC gene products[9,10].

Biochemical studies have shown that three major classes of molecules are encoded by the MHC, each having a different role

Fig. 1 Summary of information used to deduce the amino acid sequence of the H–2K^b glycoprotein[12,13,20,21]. The sequence is given in single letter code where A is Ala; C, Cys; D, Asp; E, Glu; F, Phe; G, Gly; H, His; I, Ile; K, Lys; L, Leu; M, Met; N, Asn; P, Pro; Q, Gln; R, Arg; S, Ser; T, Thr; V, Val; W, Trp; Y, Tyr. CHO indicates a carbohydrate moiety. Peptides are designated by letters indicating method of chain cleavage (In, intact molecule; CN, cyanogen bromide; TO, tryptic peptide obtained from the intact molecule used to overlap CNBr peptides; T*, trypsin after blockage of Lys with citraconyl groups; Θ, thrombin; V8, staphylococcal V8 protease; CT, chymotrypsin). TC refers to tryptic core, that is, tryptic peptides that were precipitated from the digestion mixture by 5% (v/v) acetic acid, collected by centrifugation, dissolved in 65% acetic acid and isolated by subsequent chromatographic procedures[12]. When multiple designations are used, the order indicates the sequence in which the digestions were performed. For example, TO2 was obtained by tryptic cleavage of the intact chain whereas CN-Ib-V8-2 was produced by V8 treatment of the isolated cyanogen bromide fragment Ib. Fragment CN-Vc results from a reproducible but inappropriate CNBr cleavage. Dotted lines indicate peptide regions for which sequence data were incomplete. The strategy used for determining the complete sequence of the H–2K^b molecule relied on initial isolation of fragments obtained by CNBr cleavage (CN) at Met residues. Subsequent amino acid sequence analyses and use of tryptic overlap (TO) peptides permitted the alignment of these fragments. The only portion of the molecule not recovered as a CNBr fragment was the membrane-associated region (residues 284–307), which was obtained as a tryptic fragment from the intact molecule[56]. The amino acid sequences of the small CNBr fragments IIIn, IIIa, Va, Vb and Vc were determined on the intact fragments. The largest CNBr fragments, Ia and Ib, were reduced to smaller fragments by thrombin cleavage in order to effect their sequence determination. The thrombin fragments were overlapped by isolating fragments obtained by staphylococcal V8 protease digestion and chymotryptic digestion of the appropriate CNBr fragments. Small peptides from CNBr fragment Ic were obtained by trypsinization after blocking of the Lys residues by citraconylation; after removal of the citraconyl groups, the large peptide was redigested with trypsin. Similarly, trypsin digestion after citraconylation was used to obtain fragments for overlapping the COOH-terminal CNBr fragments (IIIc, Vc, Va).

in the immune response[7,11]. The class I molecules, which include the classical transplantation antigens, are composed of two noncovalently associated polypeptide chains, a 45,000-molecular weight polymorphic chain encoded by the MHC and a non-MHC-encoded 11,500-molecular weight polypeptide, β_2-microglobulin (β_2M)[9,11]. Studies in our laboratories have concentrated on determining the primary structure of murine class I molecules[12–18], and we report the complete primary structure of one of these, H-2K^b, a molecule which has recently been intensively studied[12,13,18–22]. The membrane-bound heavy chain of this glycoprotein is 346 amino acids long, and has two intra-chain disulphide linkages and two carbohydrate prosthetic groups linked to asparagine residues, whereas the associated β_2M is 99 residues long, contains one intra-chain disulphide bond and is nonglycosylated. All our structural analyses of H-2K^b and several other murine class I antigens have been accomplished by the use of radiochemical methodology[9,23].

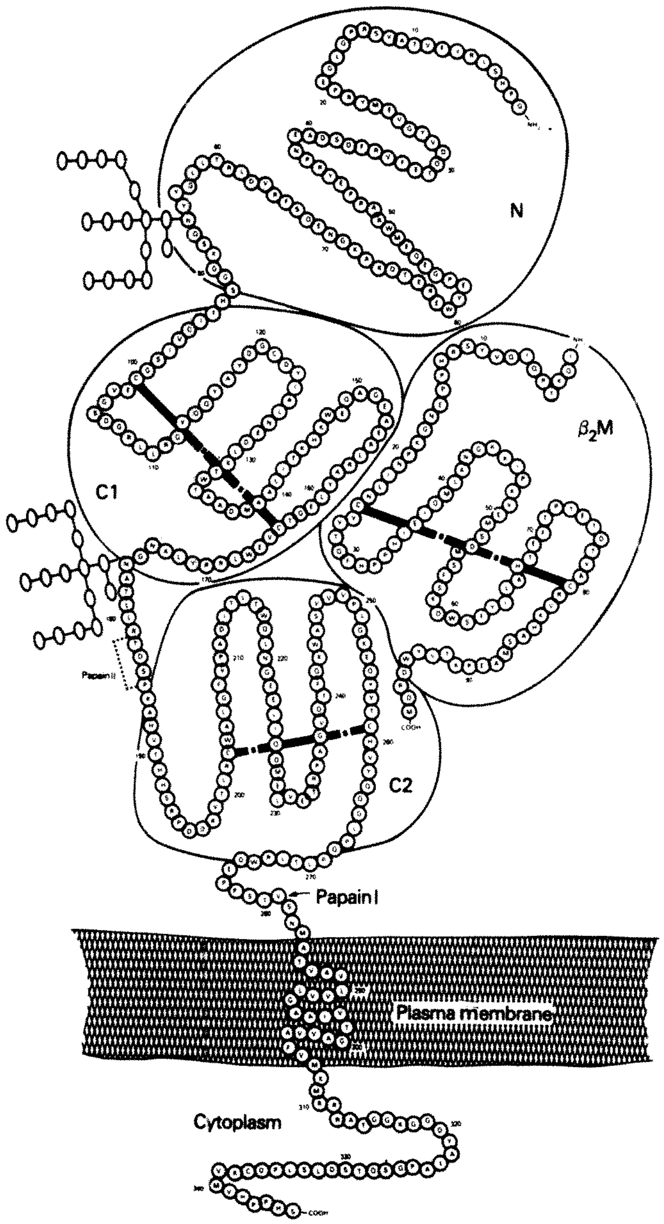

Fig. 2 A schematic representation of the complete amino acid sequence of the murine major transplantation antigen H-2K^b including the associated β_2M and showing putative features of the molecule deduced from primary structure and other properties. The amino acids are identified within the circles in the single letter code detailed in Fig. 1 legend. The Cys–Cys bonds are depicted as black bars. The sequence shown for β_2M is that for the variant found in C57BL/6 mice which has Ala at position 85 (ref. 22). The molecule may be considered to consist of three functional segments: the extracellular segment (~1–281), the membrane-bound segment (~282–308) and the cytoplasmic segment (~309–346). Cleavage by papain at the major site (papain I) yields a soluble antigenically active molecule lacking the hydrophobic and intracellular portions. Division of the extracellular portion of the molecule into three approximately equal subregions is based on homology of the CHO units 90 residues apart (N and Cl) and the presence of two intra-chain disulphide linkages (C1 and C2). The globular nature of the N, C1 and C2 subregions is suggested by limited susceptibility of the molecule to papain digestion; the only fragments yielded are the intact extracellular segments and, in lower yield, a fragment designated papain II that includes the N and C1 subregions[15,57,58]. The dotted box at positions 182–185 shows the approximate location of the papain cleavage yielding papain II. The β_2M is not altered by papain treatment.

Isolation of radiolabelled H-2 alloantigens

There were two major obstacles to the study of the primary structure of H-2 alloantigens. First, because H-2 alloantigens are integral membrane proteins, they possess a hydrophobic region which associates with the membrane lipid bilayer, rendering them insoluble in common aqueous buffers, and thereby preventing the use of conventional biochemical purification techniques. This difficulty has been circumvented by using buffers containing a nonionic detergent (Nonidet P40) which solubilize H-2 antigens in high yield[24]. Second, because only small amounts of H-2 alloantigens can be isolated from tissues[25] or from cultured cells[26,27], our primary structure determinations used H-2 alloantigens biosynthetically labelled with radioactive amino acids[18,28,29].

The procedure for obtaining radiolabelled H-2 antigens has been described previously[14,30]. Briefly, appropriate cells are cultured in the presence of radioactive amino acids and the plasma membranes are then solubilized with Nonidet P40. The detergent-soluble extract is passed over a lentil lectin affinity column to obtain a glycoprotein fraction enriched in H-2 alloantigens. The H-2 molecules are isolated from this fraction by immune precipitation with monospecific alloantisera[17] or monoclonal antibodies[31]. The H-2 heavy chain is dissociated and separated from the light chain (β_2M) by gel filtration in 1 M formic acid.

For radiosequence studies, tumour cell lines are preferred as a source of material because they are metabolically more active than normal cells and thus incorporate greater amounts of the radiolabelled amino acids into cell protein; also tumour cell lines expressing increased amounts of the H-2 molecules under study can usually be obtained[14].

In addition to the increased sensitivity gained in the detection of peptides and phenylthiohydantoin (PTH) amino acids, a major advantage of using radiolabelled material is that the H-2 molecules can then be purified rapidly by immune precipitation[18,28–30] as there is no risk of the radiolabelled H-2 molecules being contaminated with unlabelled proteins (in fact, it is helpful to have additional protein to prevent losses). Also, because the original radiolabelled glycoprotein fraction remains essentially intact, several different molecules can be isolated from the same cell extract by sequential immunoprecipitation steps[31,32].

Sequence determination of radiolabelled proteins

The sequence of radioactive proteins and peptides is determined by stepwise degradation using the automated Beckman sequencer followed by analysis of PTH amino acid derivatives by HPLC, in much the same manner as used for sequencing unlabelled peptides. An obvious difference, however, is that instead of detecting the PTH amino acid derivatives directly on the HPLC, the radioactive PTH derivatives are analysed by co-chromatography with a mixture of unlabelled PTH amino acid derivatives. Peaks are collected and the radioactive amino acid residue is identified by liquid scintillation counting[33].

An important consideration in radiochemical sequence determination concerns the number of amino acids used in a given radiolabelled H-2 preparation. Although this can vary from 1 to 20, difficulties in detecting low specific activity amino acids in the presence of high specific activity amino acids make it practical to use groups of two to six amino acids[14,21]. The radioactive amino acids which become incorporated into cell protein at similar specific activities are grouped together. In determining such groups of amino acids and the amount of each to be incorporated, metabolic interconversions of certain amino acids must be considered[14,33]. For example, radiolabelling cells with glutamine results in radioactive glutamine, glutamic acid and proline in the cell protein in an approximate ratio of 7 : 2 : 1 (ref. 20). This and other interconversions of amino acids have been consistently observed in two murine tumour cell lines[14,33] and a rabbit cell line[34]. Once known, the interconversions present no special difficulty. All amino acids except aspartic acid have been incorporated at sufficient levels for radiosequence analysis. Aspartic acid residues are assigned indirectly after concluding that a given position does not contain one of the other 19 possible amino acids[12,13,21]. (Recent improvements in methods of radiolabelling cells will make possible the direct assignment of Asp residues[35].)

Structural features of H–2K^b

The primary structure of the H–2K^b glycoprotein was determined as outlined in Fig. 1. The primary structure of the β_2M was investigated using radiolabelled protein separated from the H–2K^b, K^d and D^d heavy chains by gel chromatography in 1 M formic acid. Figure 2 depicts schematic representation for the structure of the H–2K^b transplantation antigen suggested from the amino acid sequence and other ancillary data. The 99-residue subunit (β_2M) contains no carbohydrate unit, exhibits limited strain-related polymorphism[22,36–38], is noncovalently associated with the H-2-encoded chain, and shows no indication that it is bound to the cell membrane. The larger of the two chains contains two carbohydrate units and two intra-chain disulphide linkages and exhibits the high degree of polymorphism that characterizes H–2 alloantigens.

A major feature of the molecule is the ease with which the intact extracellular region can be cleaved from the cell surface with the proteolytic enzyme papain[39,40]. Comparison of the structure of the papain-derived molecule (papain I) with that of the intact form has defined the COOH-terminus of the papain-derived molecule as residue 281 (ref. 13). This site coincides with the beginning of a stretch of uncharged and hydrophobic amino acids of approximately 25 residues, thought to be a membrane-binding subregion. (Twenty-five residues in the conformation of an α-helix could span 35 Å, the approximate thickness of the hydrocarbon core of a lipid bilayer[41].) At the carboxy-terminal end of the membrane-binding region there is a cluster of basic amino acids (positions 308 and 310–312) that may serve to anchor the H–2 molecule in the membrane through interaction with the negatively charged phosphate groups of the membrane phospholipids. Glycophorin[42], membrane-bound IgM[43] and HLA[44] have similar clusters of basic residues at the end of the membrane-binding portion of the molecules. That portion of the molecule beginning at the inner face of the membrane and stretching to the C-terminus is apparently located inside the cell[45] and possible functions in the communication of signals to the cell interior following interactions of the exposed extracellular region of the molecule. Whether the phosphoserine residues purported to be present in this portion of H–2[46] and HLA[47] molecules is involved in such processes remains to be demonstrated.

As depicted in the schematic model (Fig. 2), the molecule divides neatly into three functional segments: the extracellular portion which includes the noncovalently bound β_2M and contains the alloantigenic determinants, the membrane segment that penetrates the lipid bilayer and allows the molecule to span the plasma membrane, and the intracellular segment that possibly serves in the communication of signals to the interior of

Fig. 4 Comparison of the H–2 and HLA amino acid sequences for the NH_2 terminal 100 residues. The residues indicated by single letter code (see Fig. 1 legend) are amino acids shared by at least one H–2 and one HLA molecule. At positions where more than one amino acid residue is common to H–2 and HLA, the predominant residue is listed. Asterisks indicate positions where no residues common to H–2 and HLA molecules have been found, but where shared residues could be created by single base changes in the DNA coding sequences. Boxed asterisks are those positions which require a double case change for the generation of shared residues. × indicates positions in H–2 or HLA where multiple substitutions occur but which only require single base changes in the DNA coding sequences for the generation of observed substitutions: ×′ indicates those positions which require multiple base changes for the generation of observed differences.

the cell. Division of the extracellular portion of the molecule into subregions analogous to immunoglobulin-like domains is prompted by primary structural homologies of HLA and β_2M to IgG constant region domains[48,49]. The division (Fig. 2) is supported by the location of the two points where the molecule is susceptible to cleavage by the proteolytic enzyme, papain, which suggest an interruption of a domain-like structure of a globular protein. The subregions (domains) are designated N for the NH_2-terminal portion, C1 and C2 for Cys-containing segments.

Relationship of H-2 and immunoglobulin

The model of the H–2K^b molecule showing domain-like subregions suggests a certain kinship to immunoglobulins. This relationship is supported by weak but significant amino acid sequence homologies between HLA, β_2M and IgG constant regions[48–50], and by the facts that the histocompatibility and immunoglobulin molecules both consist of two chains encoded by unlinked genes and that both the 'heavy' chains are products of complex genetic loci. However, there are some very basic differences. For example, there is no evidence for hypervariable regions or extensive somatic diversification in the H–2K^b molecule as has been found in immunoglobulin variable regions. Whereas pooled immunoglobulin would show heterogeneity in amino acid sequence[51], no evidence of microheterogeneity was found in material isolated from E1–4 tumour cells. Furthermore, when compared by peptide mapping, no differences were observed between H–2K^b isolated from C57BL/6 splenocytes[52] and that isolated from E1–4 tumour cells. In addition, analyses of K^b molecules isolated from splenocytes of mutant mice have revealed sequences identical to those found for the H–2K^b molecules isolated from E1–4[53]. Only discrete differences (one or two amino acids) were found between the H–2K^b molecules isolated from splenocytes from 10 mutant strains of mice and that from E1–4, and they undoubtedly related to the mutations which allowed detection of these molecules in biological assays[53]. Furthermore, examination of the data presented below (Fig. 3) reveals that sequence differences among the H–2 molecules from a given haplotype occur in all parts of the molecule and not just in their NH_2-terminal portions, thus precluding extrapolation of the analogy between H–2 and immunoglobulin molecules to include their having in common structures with clearly delineated variable and constant regions.

Comparison of H–2 and HLA

Although H–2K^b is the only major mouse histocompatibility antigen for which a complete structure is known, extensive areas of several other murine H–2 molecules have been determined and nearly complete primary structures have been reported for the human HLA-B7 and HLA-A2 molecules as well as for a pool of human HLA antigens (Fig. 3). Structural features apparently conserved by all these molecules include the two intra-chain disulphide loops which span positions 101–164 and 203–259 in H–2K^b (ref. 54), and the carbohydrate moiety which is linked to an Asn residue at position 86 (refs 10, 32). Important for the structural studies, which are based on obtaining peptides by CNBr cleavage, is the highly repetitive occurrence of Met residues at identical positions among the different H–2 molecules[32].

Comparison of the amino acid sequence of the NH_2-terminal 100 residues from three H–2, two HLA molecules and the pool of HLA molecules, reveals a high degree of primary structural homology among these molecules. The homology of K^b to D^b, K^b to K^d and K^d to D^b is 85%, 75% and 76%, respectively, and the homology between the HLA molecules is 85%. Comparison between H–2 and HLA molecules yields about 70% homology in all cases. Further examination of the NH_2-terminal sequence data indicates that 63 residues are common to all H–2 molecules (Fig. 3). (These data include the partial sequence data available for K^k, D^d and L^d.) Of these 63 residues, 54 (or 86%) are also common to HLA. Even more remarkably, at 86 of the 100 positions at least one H–2 and one HLA molecule share a common amino acid (Fig. 4). In addition, at only 1 of the 14 positions where common amino acids are not shared would the substitutions observed require a multiple base change in the DNA-coding sequences for common amino acids to occur.

Examination of the NH_2-terminal 100 residues of the H–2 molecules reveals that there are 37 positions where at least two different amino acid residues occur in the sequence; most of these differences are nonrandomly distributed. Small clusters of differences are evident at positions 18–24, 30–32, 41–45 and 95–100, and a large concentration of differences is found between positions 61 and 83, these clusters being interspersed with stretches of conserved amino acid residues (Fig. 4). All these regions represent areas of diversity between the murine and human molecules; however, only the large cluster of differences (61–83) represents an area of diversity when only the human molecules are compared. It is tempting to speculate that the amino acid interchanges observed at positions 61–83 represent an important region of diversity among these alloantigens. In support of this possibility, the homology in this region is strikingly lower than the overall NH_2-terminal homology: only four of the 23 positions (17%) are common to the five molecules for which extensive NH_2-terminal sequence data are available, whereas 50 of the remaining 77 residues (65%) are identical. Likewise, only 10 residues (43%) are shared among the three H–2 molecules in region 61–83 whereas 53 (69%) are shared for the remaining 77 residues. Furthermore, 7 of the 10 amino acid conversions which require two base changes at the nucleic acid level for interconversion occur in this region (Fig. 4).

The extensive sequence data available for H-2K^b and HLA-B7 allow comparisons to be made over the entire length of these molecules. Thus, although the overall homology between these molecules is 71% for positions 1–281 (extracellular portion), the homology for the stretch after position 281 drops to 34%. Comparison of K^b and HLA-A2 in positions available for comparison in this region shows 28% homology. In contrast, the homology between the human molecules (87%)[10] is similar to that observed for the extracellular region of the molecule. In addition to the striking degree of sequence difference between the murine and human molecules, the K^b molecule is 10 residues longer than the human molecules. To achieve maximum alignment of the K^b and B7 molecules, a deletion must be placed at position 307 of the B7 molecule. Also, the second carbohydrate chain present at position 176 in K^b is not detected in HLA-B7.

The finding that there is significantly less homology between K^b and K^d (presumed alleles) than between K^b and D^b is intriguing; it agrees with previous conclusions from peptide mapping data[30] and is difficult to reconcile with the concept that the multiple histocompatibility gene loci arose by gene duplication in a common ancestor. In such a model, divergence of the allelic genes would arise through mutations occurring after speciation. The present data suggest that the gene duplication event occurred subsequent to speciation.

Finally, a major goal of the primary structural studies on H-2 molecules is the localization of sites involved in recognition by alloantibodies and by activated T lymphocytes. It is tempting to speculate that the regions of diversity, especially that found between residues 61 and 83, are involved in such processes. However, although the differences outlined above between the H-2 molecules are quite dramatic, recent data on the structural characterization of H-2 mutants suggest that only small numbers of amino acid differences between antigens are required for immune recognition. Differences between parental and mutant molecules at one or two positions are sufficient to elicit a highly responsive and specific immune recognition, both in alloaggression and in 'associative recognition'[53,55]. Therefore, the multiple differences among the H-2 molecules shown above provide a potentially vast repertoire of recognition determinants for both T-cell allorecognition and serological distinctions.

Parts of this study were supported by NIH grants AI 07289 and AI 10702.

Major rearrangement in the human β-globin gene cluster

R. W. Jones, J. M. Old, R. J. Trent, J. B. Clegg & D. J. Weatherall

MRC Molecular Haematology Unit, Nuffield Department of Clinical Medicine, John Radcliffe Hospital, Oxford OX3 9DU, UK

A form of $\delta\beta$-thalassaemia results from a major chromosomal rearrangement involving the β-globin gene cluster which includes an inversion of the entire sequence between the ${}^A\gamma$- and δ-globin genes and two deletions.

IN MAN the ε, ${}^G\gamma$-, ${}^A\gamma$-, δ- and β-globin genes that code for the embryonic, fetal and adult β-like globin chains of haemoglobin are closely linked on chromosome 11[1–6]. The hereditary disorders which result in their altered expression include forms of pancellular hereditary persistence of fetal haemoglobin (HPFH) and $\delta\beta$-thalassaemia which are characterized by an absence of δ- and β-chain production and a variable persistence of ${}^G\gamma$-, ${}^A\gamma$-, or ${}^G\gamma$- and ${}^A\gamma$-chain synthesis into adult life.

0028-0836/81/190039—06$01.00

We describe here the analysis of the ε–γ–δ–β gene cluster in DNA of an Indian patient (FB) who has previously been shown by haematological, haemoglobin and family studies to be homozygous for $^{G}\gamma$-$\delta\beta$-thalassaemia[7]. Restriction endonuclease analysis indicates that the disorder results from a previously undescribed chromosomal rearrangement involving two deletions totalling 8.5 kilobases of DNA and an inversion of 15.5 kilobases of DNA in the γ–δ–β gene cluster. Unlike the deletions previously described in $\delta\beta$-thalassaemia[4,8–10] or HPFH[4,11,12], the entire sequence between the $^{A}\gamma$- and δ-globin genes is retained but is inverted. This is the first example of a major inversion as the basis for a human hereditary disease.

Table 1 Size of restriction enzyme fragments

Enzyme	Size in normal DNA (kb)	Size in $^{G}\gamma$-$(\delta\beta)^{\circ}$-thalassaemia DNA (kb)
a Detected with γ-cDNA probe		
*Bam*HI	2.6+5.1+15.5	2.6+5.1
*Bgl*II	13	10.5
*Eco*RI	7.2+1.6+2.7	7.2+1.6+4.2
*Hpa*I	24+5.1+14	24+4.4
*Pst*I	4.0+5.1	4.0+5.1
*Xho*I	5.1	5.1
b Detected with β-cDNA probe		
*Bam*HI	15.5+4.4+1.8+8.1	20
*Bgl*II	7.7+5.0	10.5+6.6
*Eco*RI	2.2+1.7+5.4+3.6	4.2+3.6
*Hpa*I	1.9+1.4+7.0	1.9+17

DNA was isolated from peripheral blood of a patient (FB) homozygous for $^{G}\gamma$-$(\delta\beta)^{\circ}$-thalassaemia and from a normal human spleen by phenol chloroform extraction[29]. DNA samples were digested with restriction endonucleases as indicated and fractionated in a vertical 0.8% agarose gel by electrophoresis for 15 h at 1.5 V cm^{-1}. The DNA fragments were transferred to a nitrocellulose filter by the gel blotting technique of Southern[30] and the nitrocellulose filter hybridized[31] to a cloned γ- or β-cDNA probe labelled with ^{32}P by nick translation[32]. After hybridization at 42 °C for 48 h the filter was washed in 0.1 × SSC at 52 °C as described elsewhere[33] and the bands detected by autoradiography[34]. The γ-cDNA probe was the γ-globin cDNA plasmid JW151 (ref. 35); the β-cDNA probe was β-globin cDNA plasmid JW102 (ref. 35). The 3.6-kilobase *Eco*RI fragment hybridizing with the B-cDNA probe did not have a place in the final structure of FB DNA. This was probably due to hybridization of the β-cDNA probe to the ε gene[1].

An abnormal $^{A}\gamma$ gene, and abnormal δ- or β-globin sequences

Hybridization of several single (Table 1*a*) and double (not shown) restriction enzyme digests of FB DNA to a cloned γ-cDNA probe showed a normal arrangement of restriction sites on the 5′ side of the $^{A}\gamma$ gene up to the *Pst*I site in that gene (A in Fig. 1). Restriction enzymes producing DNA fragments which span this point in normal DNA produced abnormal fragments when used to digest FB DNA, which suggested that DNA on the 3′ side of A (Fig. 1) had been deleted. However, hybridization of a cloned β-cDNA probe to single enzyme digests of FB DNA (Table 1*b*) showed a number of DNA fragments, most of which differed in size from those seen in normal DNA. Among these were a 4.2-kilobase *Eco*RI and a 10.5-kilobase *Bgl*II fragment, both of which were the same size as abnormal fragments found in digests with the same enzymes hybridized to the γ-cDNA probe (Table 1*a*). This suggested that there was one abnormal DNA fragment generated by each enzyme which spanned the remaining 5′ half of the $^{A}\gamma$ gene and also included some part of either the δ or β genes.

To test this hypothesis, the 4.2-kilobase *Eco*RI and 10.5-kilobase *Bgl*II fragments were digested with *Xho*I. The latter cuts once in the $^{G}\gamma$ gene and once in the $^{A}\gamma$ gene very close to A (Fig. 1) but nowhere else in the whole ε–γ–δ–β region. Thus the

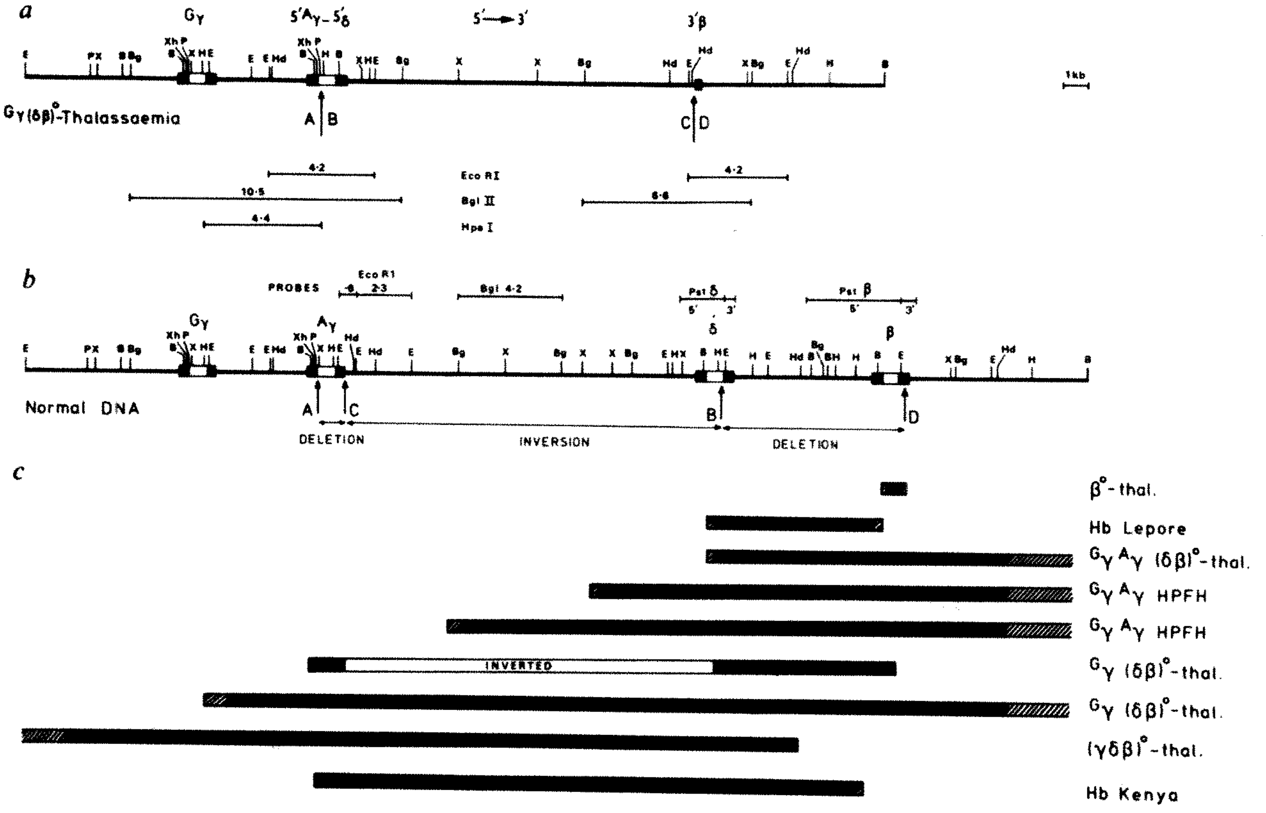

Fig. 1 A map of restriction endonuclease sites in and around the β-like globin gene region of $^{G}\gamma$-$(\delta\beta)^{\circ}$-thalassaemia DNA compared with normal DNA. *a*, Restriction map of DNA from a patient with $^{G}\gamma$-$(\delta\beta)^{\circ}$-thalassaemia. The brackets below the map indicate the locations of some of the abnormal fragments listed in Table 1. *b*, Restriction map of normal DNA derived from refs 4, 24 and 25, except for the *Hin*dIII site on the 5′ side of the δ-globin gene, which was located by hybridization of the 2.3-kilobase *Eco*RI fragment to FB DNA (Fig. 5) and to normal DNA (data not shown). A, B, C and D mark the boundaries of the normal sequences which have been deleted and inverted in the $^{G}\gamma$-$(\delta\beta)^{\circ}$-thalassaemia DNA. The brackets above the normal DNA map indicate the positions of the *Eco*RI 0.6, *Eco*RI 2.3, *Bgl*II 4.2, *Pst* δ and *Pst* β fragments. *c*, Schematic map of the deletions in the β-like globin region in various diseases. The deletions are shown by solid boxes and the end points are located within the hatched boxes where known. The maps are from the following refs: β°-thalassaemia, ref. 26; Hb Lepore, 2,27; $^{G}\gamma^{A}\gamma$-HPFH, 4,11,12; $^{G}\gamma^{A}\gamma$-$(\delta\beta)^{\circ}$ thalassaemia, 4,8,9; $^{G}\gamma$-$(\delta\beta)^{\circ}$ thalassaemia, 4,10; $(\gamma\delta\beta)^{\circ}$-thalassaemia, 21. Different locations of the 3′ end of the $^{G}\gamma^{A}\gamma$-$(\delta\beta)^{\circ}$-thalassaemia deletion have been proposed[4,8,9] and its precise location is unknown. Hb Kenya has not been proved to be a deletion by restriction enzyme mapping. Restriction enzyme sites are: B, *Bam*HI; Bg, *Bgl*II; E, *Eco*RI; Hd, *Hin*dIII; H, *Hpa*I; P, *Pst*I; X, *Xba*I; and Xh, *Xho*I.

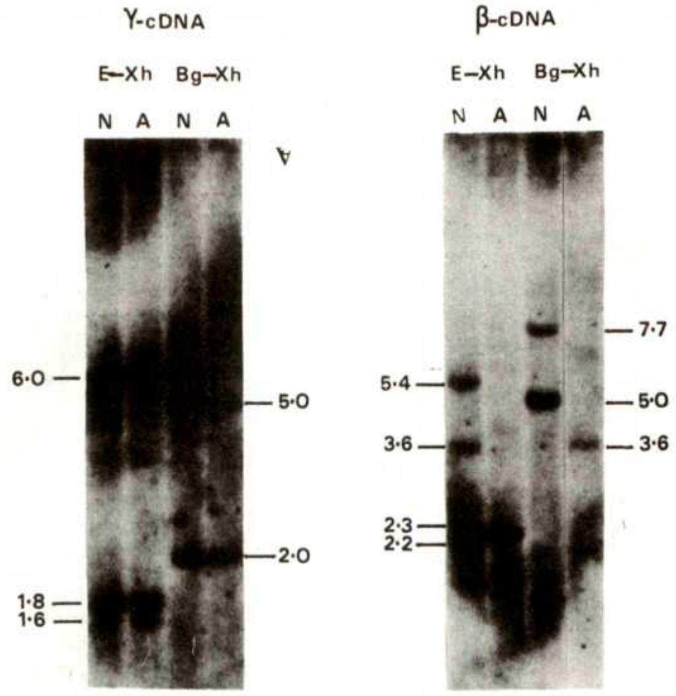

Fig. 2 Hybridization of double digests of normal and FB DNA to cloned γ- and β-cDNA probes. Normal (N) and FB DNAs (A) were digested with either *Xho*I and *Eco*RI (E-Xh) or with *Bgl*II and *Xho*I (Bg-Xh), and duplicate filters were hybridized to cloned γ- and β-cDNAs as described in Table 1 legend. Although a proportion of *Xho*I sites in DNA from some tissues are modified by methylation and therefore are resistant to digestion, there was no evidence of this in the DNA digested here. The size in kilobases of each fragment is shown.

4.2-kilobase *Eco*RI fragment should be cleaved by *Xho*I to give one γ gene fragment and one β-like gene fragment. Double digests of FB DNA with *Eco*RI and *Xho*I (Fig. 2) generated a 1.8-kilobase fragment which hybridized only to the γ-cDNA probe and a 2.3-kilobase fragment which hybridized only to the β-cDNA probe. The sum of these two fragments is 4.1 kilobases, which is close to the expected sum of 4.2. Similarly, *Xho*I cut the *Bgl*II 10.5-kilobase fragment twice to give fragments of 5.0 and 2.0 kilobases which hybridized to γ-cDNA, but only one fragment of 3.6 kilobases on hybridization with β-cDNA (Fig. 2). The sum of these three fragments is 10.9 kilobases, again in close agreement to the predicted value of 10.5.

Both these double digests can therefore be interpreted as showing that in FB DNA, the normal $^{A}\gamma$-gene sequence changes to one containing either all or part of either the β or δ gene, or parts of both. Some β-like sequence must lie within 2.3 kilobases of the *Xho*I site in the $^{A}\gamma$ gene to account for the presence of a DNA fragment of that size in *Eco*RI/*Xho*I digests hybridized to cloned β-cDNA probe.

Inversion of DNA sequence

The relative positions of several new restriction sites, including those of *Bgl*II and *Eco*RI, appeared to be the reverse of those on the 5′ side of the δ-globin gene in normal DNA. An inversion of the normal DNA sequence between A and B (Fig. 1*b*) would place the 5′ half of the δ gene next to the 5′ half of the $^{A}\gamma$ gene, and generate 3.9-kilobase *Eco*RI and 10.7-kilobase *Bgl*II fragments which would hybridize to both γ- and β-cDNA probes (Fig. 1*a*). To determine which β-like sequence lay close to A, 5′- and 3′-δ and β probes were hybridized to *Eco*RI and *Bgl*II digests (Fig. 3). Neither the 3′-δ nor 5′-β probes hybridized to FB DNA, suggesting that these DNA sequences had been lost in the rearrangement. The 5′-δ probe hybridized to 4.2-kilobase *Eco*RI and 10.5-kilobase *Bgl*II fragments supporting the presence of the 5′-δ sequence close to the 5′ half of the $^{A}\gamma$ gene. However, the 3′-β probe hybridized to a 4.2-kilobase *Eco*RI fragment as well. As it also hybridized to a 6.6-kilobase *Bgl*II fragment, rather than one of 10.5 kilobases, it seemed likely that the 3′-β sequence was involved in some further rearrangement of the normal DNA sequence such as the point of reattachment of an inverted sequence to the chromosome (junction C/D, Fig. 1*a*).

The *Eco*RI 2.3- and 0.6-kilobase probes are generated from the normal DNA sequence close to the 3′ end of the $^{A}\gamma$ gene (Fig. 1*b*). Both these probes, as well as the 3′-β probe, hybridized to the 6.6-kilobase *Bgl*II fragment from FB DNA (Fig. 4), showing that this fragment contains sequences complementary to those at both C and D in Fig. 1*b*. The 4.2-kilobase *Eco*RI fragment that hybridized with the 5′-δ probe contains no *Bgl*II site, distinguishing it from the *Eco*RI fragment of the same size to which both the *Eco*RI 0.6-kilobase and 3′-*Pst* β probes hybridized (Fig. 4).

This confirms the separate identities of the two abnormal 4.2-kilobase *Eco*RI fragments, and demonstrates that the relative positions of *Eco*RI and *Bgl*II restriction sites around the junction C/D (Fig. 1*a*) are consistent with the proposed DNA rearrangement.

Linkage of γ, δ and β sequences

To establish the overall arrangement of the sequences in FB DNA, single and double digests with *Hin*dIII and *Xba*I were hybridized to a series of probes complementary to DNA sequences spanning the $^{A}\gamma$ and δ genes (Fig. 5). Hybridization of these digests to the γ–cDNA probe supported the normal location of *Hin*dIII and *Xba*I restriction sites on the 5′ side of the $^{A}\gamma$ gene. The same digests also demonstrated the presence of abnormal 7.2-kilobase *Xba*I and 18.5-kilobase *Hin*dIII fragments which must include the 5′ half of the $^{A}\gamma$ gene, and extend

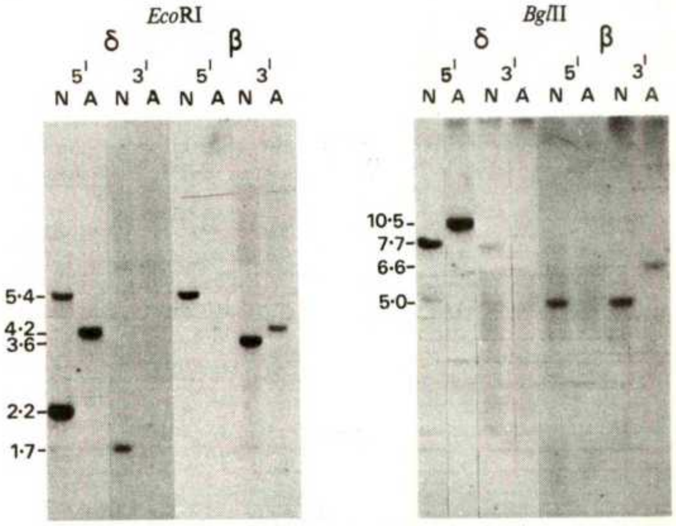

Fig. 3 Hybridization of *Eco*RI and *Bgl*II digests of normal and $^{G}\gamma$-($\delta\beta$)-thalassaemia DNA to 5′- and 3′-*Pst* δ and 5′- and 3′-*Pst* β probes. Normal and FB DNAs were digested with either *Eco*RI or *Bgl*II and duplicate filters hybridized with each of these probes as described in Table 1 except that the hybridization buffer contained 10% dextran sulphate; hybridization was for 12 h, and the filters were finally washed in 0.1 × SSC at 65 °C (ref. 28). The probes were prepared by agarose gel electrophoresis of *Eco*RI digests of the cloned *Pst* β or *Pst* δ fragments. The DNA fragments containing the sequence on either the 5′ or 3′ side of the *Eco*RI site within the δ-globin gene and the β-globin gene were identified after staining with ethidium bromide and eluted electrophoretically from the agarose gel. The size in kilobases of each fragment is shown. *Eco*RI cuts inside the normal δ-globin gene to give a 2.2-kilobase fragment containing 5′ sequences and a 1.7-kilobase fragment containing 3′ sequences; inside the normal β-globin gene it gives a 5.4-kilobase fragment containing 5′ sequences and a 3.6-kilobase fragment containing 3′ sequences. *Bgl*II cuts outside the normal δ- and β-globin genes to give a 7.7-kilobase fragment containing both 5′ and 3′ δ-globin sequences and a 5.0-kilobase fragment containing both 5′ and 3′ β-globin sequences. In *Eco*RI digests of normal DNA there is no significant cross-hybridization of the 5′ probes to 3′ sequences, or vice versa. There is limited cross-hybridization between two 5′ probes, and between the two 3′ probes, but the absence of any significant hybridization of the 5′-*Pst* β or 3′-*Pst* δ probes to FB DNA eases any problems of interpretation. N, normal DNA; A, FB DNA; δ, *Pst* δ probe; β, *Pst* β probe.

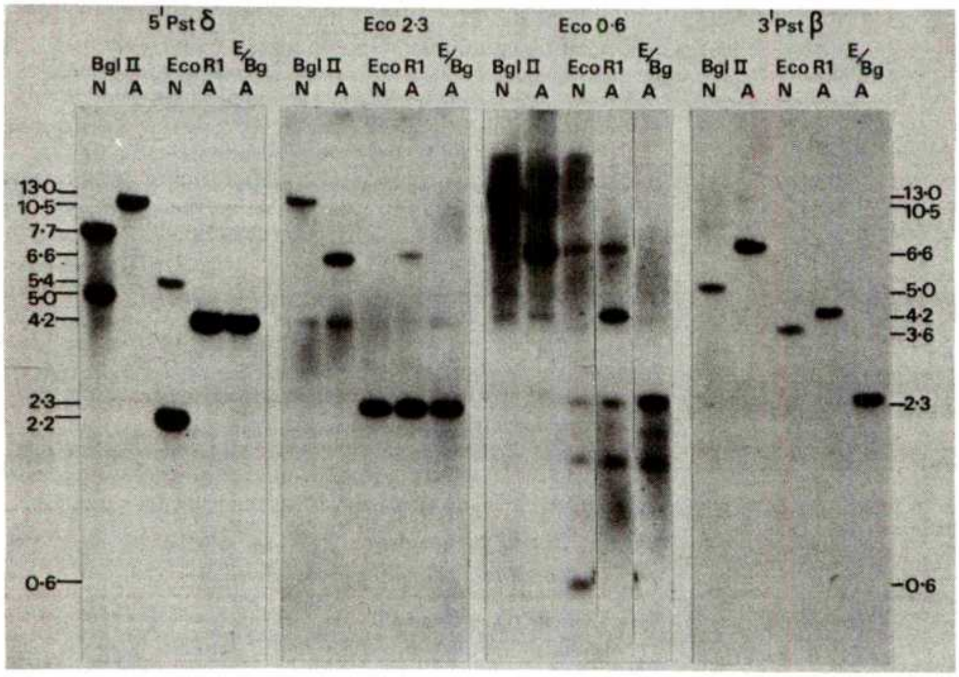

Fig. 4 Hybridization of FB DNA with 5'-*Pst* δ, *Eco*RI 2.3, *Eco*RI 0.6 and 3'-*Pst* β probes. The 3'- and 5'-*Pst* probes were prepared as described in Fig. 3, and the *Eco*RI 0.6 and 2.3 probes in the same way after digestion of λ HγG4[5] with *Eco*RI. The normal (N) and FB (A) DNAs were digested with *Eco*RI, *Bgl*II, or with both enzymes (E/Bg), and duplicate filters were hybridized to each of these probes as described in Fig. 3 legend. The sizes of DNA fragments in kilobases are indicated. The *Eco*RI 0.6-kilobase probe hybridizes to part of the 3' coding sequence of both γ genes. Thus in *Eco*RI digests of normal and FB DNA, it hybridizes to a 1.6-kilobase fragment containing the 3' end of the $^{G}\gamma$ gene as well as to a 0.6-kilobase fragment containing the 3' end of the $^{A}\gamma$ gene (normal DNA) and a 4.2-kilobase fragment (FB DNA). In *Bgl*II digests, as well as hybridizing to a 6.6-kilobase fragment in FB DNA, this probe hybridized to the abnormal 0.5-kilobase fragment containing the intact $^{G}\gamma$ gene. In addition, cross-hybridization occured with a number of unidentified fragments present in both normal and FB DNA.

downstream from it. Both of these fragments were seen when these digests were hybridized with the 5'-*Pst* δ probe, but only the 18.5-kilobase *Hin*dIII fragment also hybridized with the 4.2-kilobase *Bgl*II and 2.3-kilobase *Eco*RI probes (Fig. 5). The sequences hybridizing to these two probes must therefore lie downstream from the $^{A}\gamma$ and δ sequences. Because the 2.3 *Eco*RI probe hybridized with a 0.9-kilobase *Hin*dIII fragment, as well as with the 18.5-kilobase *Hin*dIII fragment, the sequence hybridizing with this probe must straddle the *Hin*dIII site at the 3' end of the large *Hin*dIII fragment. As we already know the relative orientation of the 5'-$^{A}\gamma$ and 5'-δ sequences, we can order the sequences hybridizing to the 18.5-kilobase *Hin*dIII fragment as: 5'-$^{A}\gamma$; 5'-*Pst* δ; 4.2-kilobase *Bgl*II; 2.3-kilobase *Eco*RI.

In digests with *Xba*I, the 4.2-kilobase *Bgl*II, 2.3-kilobase *Eco*RI and 3'-*Pst* β probes all hybridized to an abnormal 9.0-kilobase *Xba*I fragment. Double digests with *Xba*I and *Hin*dIII produced a 5.6-kilobase fragment which hybridized with the first two probes, but not with the 3'-*Pst* β probe. Therefore the 9-kilobase *Xba*I fragment overlaps the 3' end of the 18.5-kilobase *Hin*dIII fragment by 5.6 kilobases, and the 3'-*Pst* β probe must hybridize to a sequence downstream from this overlap, on the 3' side of the sequence hybridizing with the 2.3-kilobase *Eco*RI probe.

More precise information about the relative positions of the sequences hybridizing to the 4.2-kilobase *Bgl*II, 2.3-kilobase *Eco*RI and 3'-*Pst* β probes was provided by these single and double digests. The *Bgl*II probe hybridized to a 2.0–kilobase *Xba*I fragment as well as to the 9.0–kilobase *Xba*I fragment, showing that this sequence straddled the 5' end of the latter fragment. The sequence hybridizing to the 2.3–kilobase *Eco*RI probe must lie near the middle of the 9.0-kilobase *Xba*I fragment straddling one of the two *Hin*dIII sites. The 3'-*Pst* β probe hybridized with a 4.7–kilobase *Hin*dIII fragment which, as shown by a *Hin*dIII–*Xba*I double digest, overlaps the 3' end of the 9.0-kilobase *Xba*I fragment by 2.4 kilobases, with all the sequence hybridizing with this probe contained in this last fragment.

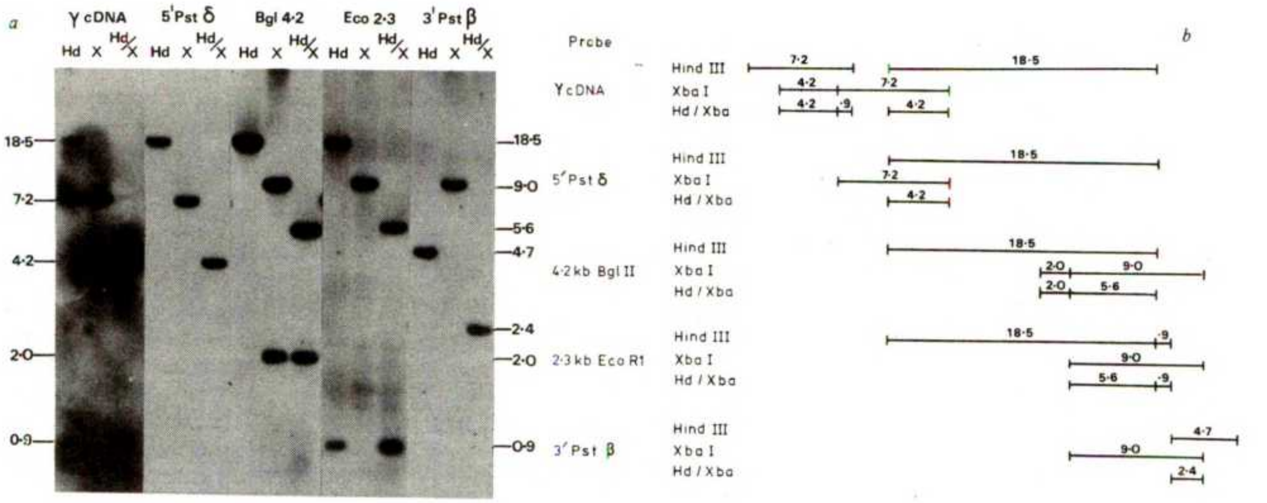

Fig. 5 *a*, Hybridization of FB DNA with the cloned γ-cDNA, 5'-*Pst* δ, 4.2 *Bgl*II, 2.3 *Eco*RI and 3'-*Pst* β probes. The 5'-*Pst* δ, 3'-*Pst* β and 2.3 *Eco*RI probes were prepared as described in the legends to Figs 3 and 4, and the 4.2-kilobase *Bgl*II fragment was prepared in the same way after digestion of HγG4 (ref. 5) with *Bgl*II. FB DNA was digested with *Hin*dIII (Hd), *Xba*I (X), or with both enzymes (Hd-X) and duplicate filters hybridized to each of these probes as described in Fig. 3 legend. *b*, The interpretation of the hybridization data is shown as a series of overlapping fragments spanning the region between the 5' end of the $^{A}\gamma$ gene and the 3' β sequence (see Fig. 1). The size of each fragment is shown in kilobases (kb).

The order of these sequences in FB DNA is therefore 5'-$^{A}\gamma$; 5'-*Pst* δ; 4.2-kilobase *Bgl*II; 2.3-kilobase *Eco*RI; 3'-*Pst* β. In this context it is unlikely that the 0.6-kilobase *Eco*RI probe (Fig. 4) which is contiguous with the 2.3-kilobase *Eco*RI probe in normal DNA, lies anywhere else but between the 2.3-kilobase *Eco*RI and 3'-β sequences. The relative position of these sequences, and of the *Xba*I and *Hin*dIII sites, in this region of FB DNA is entirely consistent with the proposed structure (Fig. 1*a*).

The completed map allows the points A, B, C and D (Fig. 1) to be localized quite precisely; A lies between *Pst*I and *Xba*I sites near the 5' end of the major intervening sequence in the $^{A}\gamma$ gene, and B is between *Hpa*I and *Eco*RI sites at the 3' end of the δ major intervening sequence. C lies in a 0.6-kilobase *Eco*RI fragment at the 3' end of the $^{A}\gamma$ gene, and, as a cloned β-cDNA probe detected abnormal fragments containing the 3' end of the β gene, D must lie between an *Eco*RI site in the 3' coding sequence of the β gene and the end of the gene.

Mechanism of rearrangement of the non-α gene cluster

The form of δβ-thalassaemia described here seems to result from a major rearrangement of the non-α globin gene cluster which has involved the inversion of 15.5 kilobases of DNA between the $^{A}\gamma$ and δ genes and deletions of approximately 1 kilobase from the $^{A}\gamma$ gene and 7.5 kilobases from between the δ and β genes. This is quite unlike previous findings for δβ-thalassaemia[4,8-10] and HPFH[4,8,11,12] which have been shown to result from simple deletions of varying sizes. The rearrangement found in the present case must have resulted from a more complicated mechanism.

It has been suggested that inversions are created between inverted repeat sequences[13-15]. The present arrangement must have involved at least one inversion, but computer analysis of the known sequences close to points A, B, C and D[16-18] (Fig. 1) does not reveal any extensive inverted repeat sequences. Nevertheless, the most economical models for the generation of this rearrangement exclusively involve recombination events of the same kind as would occur between one pair of inverted repeats at A and B, and between a second pair at C and D.

In the case of an intrachromosomal rearrangement, a cross-over between A and B (Fig. 1*b*) in the $^{A}\gamma$ and δ genes of a single chromosome leads to the inversion of the sequence between these points. This inversion brings the sequence between A and C into continuity with that between B and D, and in the process inverts the repeat sequence at C. C and D are now direct repeats and a second cross-over between C and D deletes the sequences between A and C and B and D, producing the abnormal sequence found here. Alternatively, an inversion between C and D is followed by a deletion between A and B. In this model, both cross-overs are of the same kind and each could have occurred independently giving rise to an inversion within a monocentric chromosome.

An alternative explanation is that the cross-overs were between two chromosomes. The repeat sequences at A and D in the $^{A}\gamma$ and β genes of one chromosome are aligned with those at B and C, respectively, in the δ and $^{A}\gamma$ genes of a second. A cross-over between either A and B or D and C leads to an inversion with the products consisting of one bicentric and one acentric chromosome, preventing the formation of viable daughter cells. A second cross-over between the second pair of inverted repeat sequences is therefore obligatory, generating two monocentric chromosomes, one with the arrangement found here.

Despite their economy, these intra- and inter-chromosomal mechanisms still pose problems. Whatever the probability of a single cross-over, the likelihood of two occurring within 20 kilobases of DNA must be smaller. In the case of two cross-overs between chromosomes the probability is even less because they must both be of the same kind and occur at the same time. One solution is that both cross-overs were closely linked as coincident events in a single chromosome (Fig. 6). In this model both cross-overs involve a single $^{A}\gamma$ gene, and are therefore separated by no more than 1 kilobase of DNA. This degree of proximity might allow either cross-over to promote the second, or conceivably both may have been part of a single process—this would account for the fact that they are of the same kind.

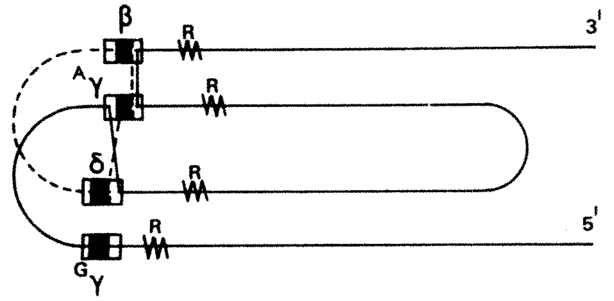

Fig. 6 An intrachromosomal mechanism for the generation of an inversion and deletion. The γ-, δ- and β-globin genes on a single chromosome are aligned so that the cross-overs necessary to generate the inversion and deletion are facilitated. The alignment is brought about by arranging the DNA in a series of loops. The repeat sequences[5] (R) which lie on either side of the pair of γ genes, and at similar distances on either side of the δ and β genes, might interact and serve to stabilize this looped structure. The distances between the repeats and the nearest gene on the left are to scale. If either cross-over occurs alone, an inversion results. When both occur in conjunction, an inversion and deletion as described in this case of $^{G}\gamma$-$(\delta\beta)^{\circ}$-thalassaemia (continuous line) and an acentric fragment (broken line) are formed.

Regulation of γ- and β-chain synthesis

δβ-Thalassaemia and HPFH constitute a spectrum of conditions in which there is significant γ-chain synthesis in adult life[19]; in δβ-thalassaemia this is insufficient to compensate for the absence of δ- and β-chain production, whereas in HPFH γ-chain synthesis is more efficient so that there is less imbalance of globin-chain production.

The deletion which gives rise to $^{G}\gamma^{A}\gamma$-δβ-thalassaemia leaves the 5' end of the δ-globin gene intact whereas the differently sized deletions that produce $^{G}\gamma^{A}\gamma$-HPFH all include the 5' end of the δ-globin gene and variable regions upstream from it (Fig. 1*c*). It has been suggested, therefore, that there may be a region of DNA upstream from the δ-globin gene which is involved in the regulation of the switch from γ- to β-chain synthesis[4,8-12,20]. Loss of this region in the various deletions which produce HPFH might result in failure of the neonatal switch from γ- to β-chain production and hence persistent activity of the $^{G}\gamma$ and $^{A}\gamma$ loci at a level approaching that which occurs in fetal life. In the case of $^{G}\gamma$-$(\delta\beta)^{\circ}$-thalassaemia, a single γ-globin gene does not compensate completely for absent δ- and β-chain production, but there is a high level of $^{G}\gamma$-chain synthesis which must be related to the underlying molecular lesion.

In the one previously reported case of $^{G}\gamma$-$(\delta\beta)^{\circ}$-thalassaemia that has been characterized by restriction enzyme analysis there is a deletion involving all the sequences downstream from a point between the $^{G}\gamma$ and $^{A}\gamma$ genes[4,10] (Fig. 1*c*). The phenotypes of this and the present case of $^{G}\gamma$-$(\delta\beta)^{\circ}$-thalassaemia are very similar but of the sequences missing from the first, those between the $^{A}\gamma$ and δ genes, and downstream from the β gene, are intact in our case. If the loss of putative regulatory sequences in either of these regions is responsible for persistent $^{G}\gamma$-globin synthesis in the first case of $^{G}\gamma$-$(\delta\beta)^{\circ}$-thalassaemia, then the inversion of the sequence between the $^{A}\gamma$ and δ genes, or the interposition of this rearranged sequence between the $^{G}\gamma$ gene and the region downstream from the β gene, must have the same effect in ours. Any regulatory sequences in these regions must therefore be inactivated by the rearrangement of DNA around them, which implies that they are acted on, or act, in *cis*. This comparison does not rule out the existence of regulatory sequences in these regions, but it does place constraints on their nature.

The observation that an intact β-globin gene is inactive in a case of $(\gamma\delta\beta)^{\circ}$-thalassaemia as the result of a major deletion on its 5′ side suggests that the expression of genes in the ε-γ-δ-β cluster is influenced through some form of interaction in *cis*[11,21]. The sequential arrangement of the ε, γ, δ and β genes parallels ontogenesis, and there is recent evidence that γ-globin synthesis precedes δ- and β-globin synthesis in the maturing erythrocyte[22,23]. This suggests the possibility that these genes are sequentially activated and inactivated by a mechanism, such as a progressive change in chromatin structure, acting only within the chromosome. It would then be expected that at least some of the genetic lesions affecting globin gene activity would be polar in nature, exerting their effect by blocking the progress of gene activation. Thus the common feature in both kinds of $^G\gamma$-$(\delta\beta)^\circ$-thalassaemia would be that the deletions start in a similar place, and the precise form of genetic rearrangement downstream from this site would be largely irrelevant. This idea could also be applied to the non-deletion forms of HPFH in which varying proportions of γ- and β-globin chains are present in the mature adult erythrocyte. Here genetic lesions undetectable by restriction enzyme analysis could, because of their position in the ε-γ-δ-β globin cluster, delay the progress of gene activation during erythrocyte maturation so that the mature erythrocyte would contain a higher than normal proportion of γ-globin.

We thank A. B. Amin for providing the $^G\gamma$-$(\delta\beta)^\circ$-thalassaemia blood samples, T. Maniatis for the clone HγG4 and the *Pst* β and *Pst* δ subclones, B. Forget for the plasmids JW151 and JW102, R. A. Flavell, J. Edwards and D. Roberts for helpful discussion, O. Smithies and B. Forget for sending us their results before publication, S. Goodbourn for preparing the *Pst* β and *Pst* δ subclones, and H. Ayyub for technical assistance.

Eternity matters

Don N. Page & M. Randall McKee

Departments of Physics and Astronomy, The Pennsylvania State University, University Park, Pennsylvania 16802, USA

The matter content of an ever-expanding Friedmann universe will never become negligible compared with the radiation, assuming electrons and positrons ($e^\pm$s) are absolutely stable, even if all other massive particles are unstable. The possible annihilation of $e^\pm$s in a $k = 0$ model occurs so slowly that the radiation density can never greatly exceed the matter density. For a very homogeneous distribution of $e^\pm$s which cool at just the expansion rate, the asymptotic ratio of matter to radiation density in a $k = 0$ universe is calculated here to be $(\sqrt{105}-3)/12 = 0.6039$. Heating by collisional recombination would probably keep the matter density far higher. A certain amount of clumping might make the annihilation occur faster, but larger inhomogeneities are likely to lead to black holes which could be even more effective in keeping the universe from becoming radiation dominated.

Several hypotheses[1–4] have been proposed to describe the future of an ever-expanding universe. To make some definite predictions, we assume here an open universe that is approximately homogeneous and isotropic (described by a Friedmann model) and which obeys Einstein's equations with no cosmological constant. (Without some such assumptions we could not rule out any conceivable influence coming in from beyond our present particle horizon.) We also assume that charge is absolutely conserved (so $e^\pm$s, as the lightest charged particles, are stable) and that no phase transitions bring in fundamentally new physics at arbitrarily low temperatures. Within such a model, the older picture of stray elementary particles, atoms, stars and black holes spreading out in space has been greatly altered by predictions of the decay of baryons[5–8] and black holes[9]. Thus it seems that the only stable particles may be electrons, positrons, neutrinos, photons and gravitons. In a $k = -1$ Friedmann model these particles would spread further and further apart and have a negligible chance of ever meeting after a sufficiently late time, so such a universe would always remain matters dominated. It has been argued[3] that a $k = 0$ universe would become radiation dominated after the thermal kinetic energy of the electrons and positrons ($e^\pm$s) drops below the Coulomb potential energy between pairs so that they become electrically bound and eventually annihilate. However, during this slow annihilation the energy in radiation is being redshifted, so a more careful analysis is needed to compare the decreasing mass density of matter with that of radiation.

Assume a $k = 0$ Friedmann universe expands according to $R \propto t^\alpha$ where $1/2 \leq \alpha \leq 2/3$, each extreme representing complete domination by either radiation or matter respectively. The direct collisional annihilation of free $e^\pm$s has a low-velocity cross-section[10] $\sigma \propto v^{-2} \propto t^{2\alpha}$ and hence a probability of occurring which becomes negligible at late times if $\alpha > 1/2$. It is more probable for $e^\pm$s to bind into positronium first. However, two-body radiative 'recombination' has a total cross-section[11] only logarithmically greater than the direct collisional annihilation and is, therefore, also negligible. Collisions of neutral particles are even more rare, so any stable massive neutral particles would keep the universe matter dominated. To continue the argument against radiation domination, we set this case aside and assume $e^\pm$s are the only stable massive particles.

Three-body collisional recombination of positronium is the dominant mechanism leading to $e^\pm$ annihilation at late times. Let $N = xt^{-3\alpha}$ be the number density of all $e^\pm$s that have not

0028-0836/81/190044—02$01.00

annihilated and $N_e = yt^{-3\alpha}$ be that of free e$^\pm$s. Then if the temperature of free e$^\pm$s drops as $T \propto t^{-2\alpha}$,

$$\begin{aligned} t^{-3\alpha}\ dy/dt &= -N_e^3 \sum_n C_{i,n} \\ &\sim -y^3 t^{-9\alpha}(m_e^{-4} e^{-4} T^{-1} n_{\max}^7) \\ &\propto -y^{11/6} t^{-7\alpha/2} \end{aligned} \tag{1}$$

using the collisional ionization cross-section[12,13] and detailed balance to get the recombination rate coefficient $C_{i,n}$ into the nth level and then summing over all levels up to $n_{\max} \sim m_e^{1/2} e y^{-1/6} t^{\alpha/2}$ where the size of the positronium atom equals the separation between free e$^\pm$s. (There is no problem forming new positronium atoms surrounding smaller ones, because as neutral objects the smaller atoms will have a negligible effect on the larger ones.) Thus at late times the fraction of the original e$^\pm$s that are still free is proportional to $y \propto t^{-3(2-\alpha)/5} \propto n_{\max}^{-6\beta}(t)$, where

$$\beta = (2-\alpha)/(2+4\alpha) \tag{2}$$

After forming in levels around $n_{\max}(t)$, the positronium spirals into the ground state by radiative transitions, annihilating at a time $t_a \propto n_{\max}^6(t) \propto y^{-1/\beta}(t)$. Hence the fraction of e$^\pm$s that have not annihilated by time t_a is proportional to $x(t_a) \approx y(t) \propto t_a^{-\beta}$. This decreases more slowly than the redshifting black-body radiation energy, so the e$^\pm$ mass density ρ_e always dominates that radiation density. However, the e$^\pm$ annihilation gives a coupling to the total radiation density ρ_r by

$$d\rho_e/dt = (-3H - \beta/t)\rho_e, \qquad d\rho_r/dt = -4H\rho_r + (\beta/t)\rho_e \tag{3}$$

In a $k = 0$ universe dominated by these two densities so that $H^2 \equiv \dot{R}^2/R^2 = 8\pi(\rho_e + \rho_r)/3$, the asymptotic solution of equation (3) is

$$\begin{aligned} &\rho_e = (1-2\beta)(1-\tfrac{1}{2}\beta)/6\pi t^2, \\ &\rho_r = \tfrac{3}{2}\beta(1-\tfrac{1}{2}\beta)/6\pi t^2, \qquad R \propto t^{(2-\beta)/3} \end{aligned} \tag{4}$$

This gives the $R \propto t^\alpha$ expansion assumed above with equations (2) and (4) implying

$$\alpha = (3+\sqrt{105})/24 = 0.5520, \qquad \beta = (13-\sqrt{105})/8 = 0.3441 \tag{5}$$

Then $\rho_e/\rho_r = (2-4\beta)/3\beta = (\sqrt{105}-3)/12 = 0.6039$. Even though the e$^\pm$s are annihilating, their density is thus never completely dominated by the radiation density.

The annihilation of e$^\pm$s may be even slower than this, because the collisional recombination of positronium will probably keep the temperature of the free e$^\pm$s from dropping as fast as $t^{-2\alpha}$. In fact, if the temperature is kept comparable with the energy that is released when each e$^\pm$ pair becomes bound, $T \sim m\, e^4 n_{\max}^{-2}$, then equation (1) becomes $t^{-3\alpha}\ dy/dt \propto -y^{3/2} t^{-9\alpha/2}$. This gives $\beta = 1 - 3\alpha/2$ with the asymptotic solution (4) implying $\alpha = 2/3$, $\beta = 0$. In this case the number of e$^\pm$s decreases only logarithmically with time, and the universe stays completely matter dominated.

All this assumes a nearly perfect Friedmann model with negligible inhomogeneities. Clumping of the e$^\pm$s will make their annihilation occur faster but the annihilation itself will tend to destroy the inhomogeneities. The asymptotic behaviour will depend on the spectrum of the inhomogeneities at large scales and their growth compared with their destruction. Inhomogeneities with vorticity insufficient to prevent them from collapsing gravitationally may form black holes if they are large enough to collapse completely before their e$^\pm$s annihilate. (This requires a mass $M \gtrsim e^4 m_e^{-3} \sim 10^{25} M_\odot$.) If black holes (which are here classified as matter as their rest mass dominates their energy) form with a spectrum[14] $\propto M^{-\gamma}\, dM$ up to arbitrarily high mass M, their decay[9] with lifetime $\propto M^3$ will produce a coupling to radiation with $\beta_H = (\gamma - 2)/3$. (We still assume an approximate $k = 0$ Friedmann model on sufficiently large scales.) If $\beta_H > \beta$, the black hole density ρ_H will decrease faster than ρ_e and equation (4) will apply. If not, ρ_H will equal or dominate ρ_e and equation (4) will have ρ_e replaced by ρ_H and β replaced by β_H. However, the black holes will probably coalesce into ever bigger and bigger holes. Indeed, even the radiative 'recombination' cross-section $\sigma \sim M^2 v^{-18/7}$ for two black holes to become bound and eventually spiral together will cause each black hole to undergo an infinite number of coalescences (if it gets big enough not to evaporate between collisions) for $\alpha \leqslant 0.7$, unlike the case for e$^\pm$ radiative recombinations which require $\alpha \leqslant 0.5$ to be effective. Multibody interactions are likely to be even more effective, as gravity is always attractive. Thus black holes may keep a $k = 0$ universe always entirely matter dominated.

If, on the other hand, there is a maximum mass to the black holes that form, then they will all evaporate, producing mostly massless radiation. This could make the universe radiation dominated temporarily, but eventually the stray matter or the roughly 10^{44} e$^\pm$s emitted during the final stages of each black hole decay[15] will become comparable with the radiation density. Thus in any case radiation will never completely dominate the density of an ever-expanding approximately Friedmann universe; matter will always be important.

More details of the e$^\pm$ annihilation in a $k = 0$ universe, including the spectrum of the enormous number of photons produced, will be given elsewhere[16].

Ultra-heavy cosmic ray studies with Ariel VI

P. H. Fowler, R. N. F. Walker, M. R. W. Masheder, R. T. Moses & A. Worley

H. H. Wills Physics Laboratory, University of Bristol,
Tyndall Avenue, Bristol BS8 1TL, UK

The satellite Ariel VI was launched on 3 June 1979 into a near-circular 625 km 55° inclination orbit. The Bristol experiment on board is of a novel design using a spherical gas scintillation chamber with an integral plastic Cerenkov element[1]. The data presented here were collected during an exposure of ~360 m^2 sr days with essentially 100% recording efficiency for events with $Z \geqslant 38$. The abundance spectrum, particularly for $Z \geqslant 50$, suggests that the cosmic ray source is significantly enriched in r-process material relative to the Solar System.

Charge estimates for ultraheavy nuclei ($Z \geqslant 30$) are made on the assumption that both components of the signal increase as Z^2 and use a daily calibration at $_{26}$Fe based on about 15,000 events. Both components of the signal have remained essentially

Table 1 Comparison of the spectrum $N(Z_{est})$ from the present experiment with those of previous experiments on balloons and Skylab

Charge	Present experiment		Balloon data (top of atmosphere)		Skylab

The balloon data have been corrected to yield the fluxes at the top of the atmosphere for a better comparison with the space data. The nominal exposures involved for the present experiment and the balloon data are each ~400 m^2 sr days, and for Skylab ~700 m^2 sr days. The balloon data is all obtained at high geomagnetic latitude and under ~4 g cm^{-2} of overlying air. Numbers using wider charge bins are also given for high Z because of the correlated errors in our data.

* The value is subject to significant and rapidly charge-dependent corrections due to threshold effects for the tracks in plastic.

constant since launch. The linearity has been confirmed for the lower charges with the observation of peaks for all the even charges $8 \leq Z \leq 26$ and the charge resolution at iron is $\sigma \sim 0.4$ charge. Data collected in the neighbourhood of the South Atlantic Anomaly and during occasional periods of interference from high particle rates in the auroral belts have been rejected.

Figure 1 shows the charge spectrum of apparent charge Z_{app} near $_{26}$Fe for events collected in regions where the geomagnetic cutoff is between 3 and 5 GV. The tail above $Z = 26$, caused by the relativistic rise in the scintillation signal, reduces the $_{28}$Ni peak to a shoulder and smothers the contribution from $_{30}$Zn. This process results in an uncertainty in charge ΔZ which is proportional to Z and is the dominant term at high Z. Nuclear fragmentation within the thin (~1 g cm^{-2}) detector will produce a tail to low Z_{app} which is masked by the form of the charge spectrum. Additionally, both electron showers generated in the spacecraft body and stopping iron nuclei have the ability to mimic high charge events, but these spurious events can be eliminated by suitable selection of the data. A plastic scintillator guard counter intercepts all electron shower events from the spacecraft and, unavoidably, ~30% of genuine events; all these events must be rejected to remove the showers. Electron shower contamination was found to be sufficiently low for $Z \geq 62$ that all events were accepted regardless of the guard counter signal. Spurious apparently high charge events due to stopping iron group nuclei can be produced by the very small fraction of such nuclei whose entry ranges are both ≳7 g cm^{-2} and exceed by only ~0.1 g cm^{-2} the total path in the detector, such that an excessively large energy deposition occurs during their passage through the final 0.01 g cm^{-2} of gas. The extent of the excess energy loss does, however, have a well-defined upper limit, and only events with $Z_{app} \leq 50$ may be produced in this way by $_{26}$Fe or $_{28}$Ni. For this reason the charge spectrum has been divided at $Z_{app} = 50$ and high latitude events excluded from the lower charge accumulation.

The spectrum of apparent charge that results from the experiment contains the effects of the relativistic rise. These effects can be removed statistically to give a spectrum of estimated charge Z_{est}. It is assumed that the spectra of energy per nucleon for ultraheavy cosmic rays and for $_{26}$Fe nuclei are indistinguishable[2]. Further evidence for the similarity of the energy spectra is obtained in this experiment from comparison of the flux values as a function of the geomagnetic cutoff. Table 1 compares our spectrum of Z_{est} with results from the Skylab experiment[3] and balloon work[2]. The comparison is valid only for $Z \geq 50$ due to the threshold effects of track registration in the Lexan plastic detectors. There are features common to the three spectra, the most significant being the overall flux values, the prominent peak at $Z \sim 78$ and a comparable abundance of nuclei with $58 \leq Z \leq 66$. The Skylab estimate for $Z \sim 66$ was considered by its authors to be uncertain due to the proximity of the threshold referred to above. The general agreement between the sets of results supports the charge scale used in the Lexan track analysis in both the Skylab and balloon experiments.

Table 2 presents the data from this experiment for the whole available charge range. The spectra of Z_{app} and Z_{est} are given together with the original number of events on which each entry was based. Also shown is our estimate of the charge spectrum of secondaries produced by interactions in the interstellar medium that are included among the nuclei detected. The difference between the two figures is the estimated number of residual primaries. This is extrapolated back to the source region to give our estimated source spectrum which again is normalized to Fe = 10^6 and which can be directly compared with the Solar System abundances compiled by Cameron[4]. We used the simplest form of 'leaky box' model for cosmic ray propagation which ignores ionization energy loss and assumes all cross-sections for interaction with interstellar hydrogen to be independent of energy. Cross-sections for nuclear interactions were based on those given for 2.3 GeV per nucleon by R. Silberberg (personal communication). The escape mean free path was taken as 5.0 g cm^{-2} of hydrogen. Clearly, except for the highest charges with $Z \geq 78$, a substantial fraction of the observed ultraheavy nuclei are secondaries arising from interactions in interstellar space. This will be the case whenever the amount of matter traversed by the detected particles is comparable with their interaction mean free paths.

Several authors have concluded that the ultraheavy cosmic ray spectrum seems to be enriched in material which has undergone nucleosynthesis by the rapid neutron capture process. More recently it has been suggested[5] that at least for the elements $Z \leq 28$ the cosmic ray source spectrum could be simply explained as a sample of normal interstellar material, modified only by the effects of differing ionization potentials for the various elements. The cosmic ray source spectrum in the ultraheavy domain would on this assumption have much in common

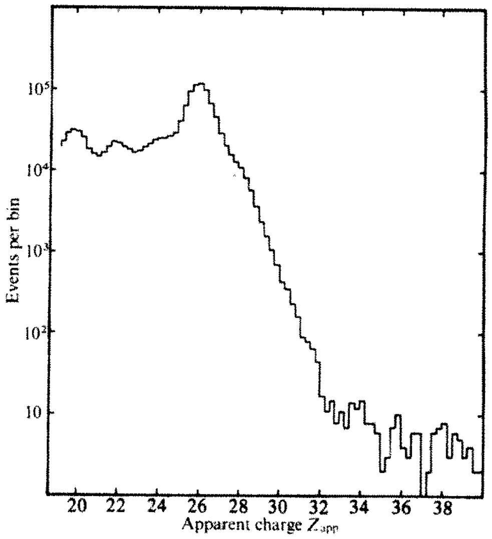

Fig. 1 Histogram of apparent charge of events collected during 110 days of operation for cutoffs between 3GV and 5GV. The sample contains $\sim 7 \times 10^5$ iron nuclei.

Table 2 Estimates of the spectra at several stages between detection and the computed source composition together with the Solar System composition of Cameron

For the highest charges all the detected events were used. For $Z \leqslant 60$, where selections were necessary, the values in brackets refer to the number of events utilized. The errors shown are due to Poisson statistics alone and are quite strongly negatively correlated in adjacent charge bins. Wider bins are therefore used at higher charges to display the features of the charge spectrum.

with the Solar System composition at all charges and, indeed, the overall abundance in our source spectrum is very similar to the Solar System value, a point which has been apparent from previous experiments for several years. In addition, the main features of the Solar System composition, namely the peaks at $Z \sim 54$ and $Z \sim 80$, are both clearly present in our data. However, the abundance ratio between $52 \leqslant Z \leqslant 56$ and $74 \leqslant Z \leqslant 84$ is 0.86±0.30 compared with a Solar System value of 2.9, and the predominant species in the upper peak is $_{78}$Pt rather than $_{82}$Pb. A striking anomaly also occurs at $Z \sim 64$ where the cosmic rays seem to be ~4 times over-abundant. These discrepancies cannot be attributed to the effects of ionization potentials. If as an alternative we suppose that much shorter mean free paths were to apply in the leaky box, the estimated source spectrum would approach the detected spectrum thereby reducing the excess for $Z \geqslant 74$ in the cosmic ray source. At the same time, however, the rare earths as a whole ($58 \leqslant Z \leqslant 72$) would become severely overabundant and the overall similarity to the Solar System abundances would not be improved.

There is a small Solar System abundance anomaly at $Z \sim 64 (A \sim 164)$ which has been attributed to fission fragments. Steinberg and Wilkins[6] consider that the feature may be produced by the heavier fragment resulting from asymmetric fission of superheavy nuclei with $A \sim 300$. Such nuclei are produced in nucleosynthesis models involving a cyclic r-process, but will be accompanied by substantially greater quantities of $A \sim 280$ nuclei. Our results seem inconsistent with this interpretation as our source spectrum contains neither a feature at $A \sim 280$ nor the excessive abundance at $A \sim 134 (Z \sim 54)$ which would result from the symmetric fission of the $A \sim 280$ nuclei advocated by Steinberg and Wilkins. We propose as an alternative that the $A \sim 280$ feature itself is responsible, by asymmetric fission, for the anomaly at $Z \sim 64$ in both the cosmic ray and Solar System abundances, the original mass being distributed between two peaks at $A = 105$ and $A = 164$ and perhaps 10 neutrons. Our data have as yet insufficient statistical weight to determine whether the region of the lighter peak, at $Z \sim 44$, is appropriately enhanced.

In the charge region $Z \geqslant 90$ we would have expected, on the basis of the Skylab and Solar System abundances, to have recorded respectively ~4 and ~0.2 such events in the present sample. Of the two events observed, the event with $Z = 99$ could be a perfectly normal actinide. Its light was well distributed among the photomultipliers of the detector sphere and the absence of a plastic scintillator signal rules out a shower origin in the spacecraft body. Because the highest charge event, with $Z = 114$, did activate the guard counter its interpretation as an electron shower cannot be excluded. Our conclusion that the cosmic ray source seems to be significantly enriched in the heavier r-process nuclei therefore rests on our discussion of the charge region $52 \leqslant Z \leqslant 84$.

Albedo change by man: test of climatic effects

Gerald L. Potter, Hugh W. Ellsaesser, Michael C. MacCracken & James S. Ellis

Lawrence Livermore National Laboratory, University of California,
PO Box 808 Livermore, California 94550, USA

Sagan *et al.*[1] have suggested that the cumulative impact of anthropogenic albedo changes may have contributed to global climate changes in the past and that its effect may be continuing. Using a statistical dynamic climate model (SDM) with more realistic surface albedo changes than previously used[2], we have computed the combined impact of desertification of the Sahara and deforestation of the tropical rain forest. While the model computed a surface cooling of 0.6 K for the Northern Hemisphere, the global mean of ~0.2 K was substantially less than the 1 K suggested by Sagan *et al.*[1]. We infer that man's cumulative impact on planetary surface albedo over the past few thousand years has had a small and probably undetectable effect on global climate.

Earlier numerical model experiments[2–4], suggesting that the main effect of man's past activities should have been a general increase of surface albedo resulting in lower surface temperatures, were not designed to incorporate more than single impacts, such as tropical deforestation or desertification. The suggestion of Sagan *et al.*[1] that combined effects may have long term global ramifications seemed sufficiently serious to warrant investigation in a more sophisticated model. We have therefore used the Lawrence Livermore National Laboratory (LLNL) two-dimensional SDM to calculate the combined climatic effect of desertification in the Northern Hemisphere subtropics and deforestation of the tropical rain forest. Other surface modifications suggested by Sagan *et al.*[1] were not included as they involved relatively small surface areas and there is less agreement as to their potential impact on climate.

The LLNL two-dimensional SDM model[5] is similar in many ways to general circulation models using the basic conservation equations to calculate zonal mean fields of pressure, temperature, wind and humidity. The model has nine pressure layers and a 10°-latitude grid. The surface area of each latitude zone is divided into land (of differing types and elevations) and ocean (partially covered by ice). Sea ice (with the appropriate albedo) is formed when the ocean temperature drops below 271.4 K. New ice spreads at a minimum thickness of 20 cm until it

0028-0836/81/190047—03$01.00

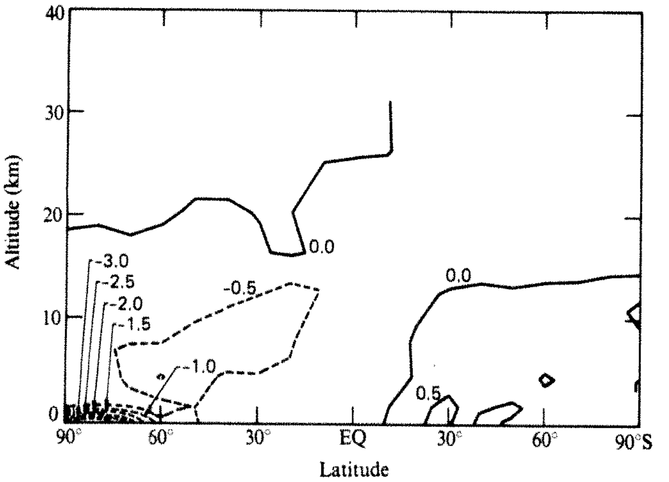

Fig. 1 Latitude–height temperature difference (perturbed minus control). Contour interval = 0.5 K.

Table 1 Model albedo changes from Sagan *et al.*[1]

Process	Land type change	Area [km^2] (% band)	Centred on latitude bands	Surface albedo change
Desertification	savanna to desert	9×10^6 (22%)	20° N	0.16→0.35
Tropical deforestation	forest to field savanna	7×10^6 (5% of 10° S, 10% of Equator)	10° S and Equator	0.07→0.16

occupies the maximum allowable fractional coverage (leaving some open ocean to simulate open leads). If the energy deficit continues the sea ice then increases in depth. Conversely, an energy excess would melt the ice before the water warms. The melt water (with the appropriate albedo) can refreeze on top of the older ice and thus increase the ice depth. Fractional grid zone assignments of various surface types with corresponding physical characteristics (for example, albedo, heat capacity, bulk transfer coefficients) enable the sensitivity of the model to modifications of these parameters to be tested.

Surface fluxes of sensible and latent heat are calculated using the vertical gradients of water vapour and temperature, the surface wind velocity and low-level convective activity. Clouds are randomly correlated vertically and are a prescribed latitude and height dependent function of relative humidity[6] (for further details see refs 4 and 7).

The sensitivity, or response to an imposed perturbation, of the model is conveniently measured by its response to an increase of its solar constant. The usual unit of comparison is the sensitivity parameter β (equal to 100 times the temperature change resulting from a 1% increase in solar flux), and experiments with our SDM give a global sensitivity factor $\beta = 70$ K. This is less than half the value quoted for simple energy balance models[8,9] and the Geophysical Fluid Dynamics Laboratory sector model[10]. At least some of this reduced sensitivity results from use of a global model and from the greatly reduced sensitivity of the Southern Hemisphere, which exhibits significantly less ice-albedo and land-surface albedo feedback.

The non-seasonal mode of the LLNL SDM simulates the annual average climate by using a fixed solar zenith angle for each latitude calculated to supply the appropriate annual average solar flux. By eliminating the diurnal and seasonal fluctuations, the model approaches a pseudo-equilibrium state after ~200 days of model integration time. This reflects the adjustment time implied by the heat capacities of the atmosphere, land, snow, ice and arbitrarily thin oceanic mixed layer. For this experiment, two model equilibrium states were achieved: a control case with standard surface conditions corresponding to a pristine environment; a perturbed case corresponding to the suggestion of Sagan *et al.*[1] in terms of tropical deforestation and desert denudation (see Table 1). The surface bulk transfer coefficients, the thermal and hydrologic characteristics were not altered; the only surface parameter modified for those areas perturbed was surface albedo which, after modification, was held constant. This reduced the degrees of freedom for the SDM.

The response to this change in albedo was generally consistent with previous surface albedo modification sensitivity studies[2,3]. Figure 1 shows the temperature difference (perturbed minus control) between the two cases. Generally, the Northern Hemisphere troposphere cooled, with a maximum change due to ice-albedo feedback near the surface at 70° N.

There seem to be two important factors in the chain of events leading from surface modification to cooling in the Northern Hemisphere. The first is the direct reduction in surface absorption in the zones of increased surface albedo (see Table 1). The change at 20° N was sufficiently strong to strengthen the temperature gradient between the Sahara[3] and the Equator which caused the northern Hadley cell to strengthen and shift southwards. This in turn weakened the hydrological activity at 20° N with less precipitable water associated convection and latent heat release, accompanied by maximum cooling in the upper troposphere, lowering of the tropopause and warming of the lower stratosphere. With less solar energy absorbed in the subtropics there was reduced poleward transport of sensible and latent heat and a general cooling of the higher northern latitudes. The second factor cooling the Northern Hemisphere was the ice-albedo feedback due to increased sea-ice coverage, primarily at 70° N.

Generally, the cloud cover increased in the Northern Hemisphere where the surface temperature had cooled 0.6 K. This agrees with reports[11–13] of global increases in cloud amount with decreased surface temperatures (Table 2). One exception was a general cloud decrease at 20° N due to increased Hadley subsidence. This latitude received the largest surface-albedo perturbation and hence the highest directly resultant surface temperature decrease[14].

In the Southern Hemisphere, only a small fraction of the latitude band at 10° S also had an albedo increase from deforestation. Figure 2 shows the zonal average conversion from potential to kinetic energy due to vertical motion. The heated air in the low level equatorial Hadley cell rises converting potential to kinetic energy. In the higher latitudes the sinking motion converts back to potential energy. This conversion term gives an

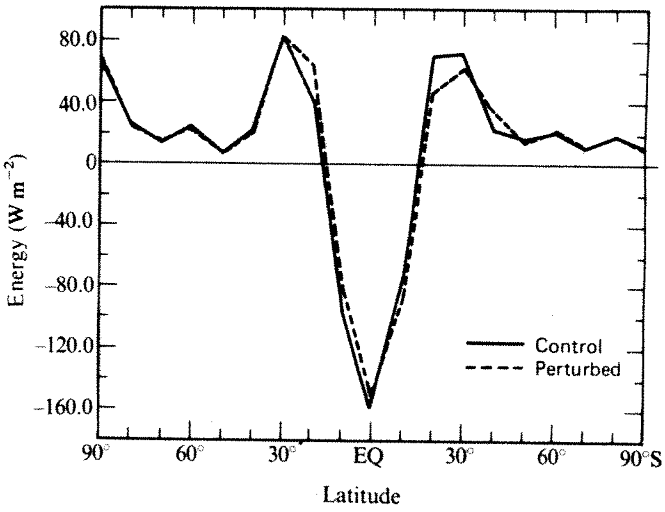

Fig. 2 Kinetic to potential energy conversion through vertical motion.

indication of the intensity of the Hadley cell. In the perturbed case, the Hadley cell shifted southwards with the ascending branch weakening slightly and the southern descending branch weakening more. The southward shift brought increased ascent to the southern subtropics. This with the weakened descending branch permitted increased convective activity, leading to clouds with more vertical structure and less horizontal extent. The total cloud coverage thus decreased at 30° S, allowing increased insolation. This increase, along with the albedo increase at the Equator and 10 °S, weakened the subtropical temperature gradient and presumably further weakened the Southern Hemisphere Hadley cell. However, other than the additional solar flux at 30° S, there seems little reason for the slight warming of the Southern Hemisphere.

To assess more fully the relative importance of the various model responses to the imposed increase in surface albedo, we can examine the contribution to the change in solar (S) and outgoing longwave (F) radiation at the top of the atmosphere as given by

$$\delta S = \delta S_r + \delta S_{A_c} + \delta S_{\alpha_s} + \delta S_f$$

$$\delta F = \delta F_T + \delta F_r + \delta F_{A_c} + \delta F_f$$

where r, T, A_c, α_s and f identify components due to precipitable water, temperature, cloud amount, surface albedo and fractional change in ice coverage, respectively. These individual contributions have been calculated by recomputing the planetary radiation balance keeping all of the input data fields fixed (control case) except for the perturbed data field of interest (for example, the temperature, water vapour, clouds or surface albedo from the modified albedo case).

Table 3 shows the change in solar, long-wave and net radiation due to the separated changes in various contributing factors; the two major components in changing the planetary energy balance are clouds and surface albedo. The mean global cloud fraction decreased 0.011, resulting in an increase in long-wave loss to space and an increase in solar radiation absorbed by the Earth–atmosphere system. The surface albedo increased as a result of both the imposed albedo modification and the ice-albedo feedback, decreasing the solar radiation absorbed by the previously clear portion of the Earth–atmosphere system. The mean surface temperature decrease reduced the long-wave loss to space because of the cooler radiating temperature.

Surprisingly, water vapour was the least important component in the long-wave response, although it did produce a reduction in long-wave loss to space. This small influence may be because water vapour experienced both vertical and horizontal redistributions in conjunction with the hemispheric asymmetries of the total model response. Thus the change in global mean precipitable water vapour was so small (−1.6%) that the radiative response was nearly insignificant.

As the model calculates sea ice, the ice cover fraction will differ from experiment to experiment. The effect of this change alone (all other effects held fixed) on the global energy balance is shown in Table 3*a*. Sea ice increased ~14% in the latitude band 65–75° N, which corresponds to an added sea-ice area of 2×10^6 km². The 0.26 W m^{-2} decrease in solar radiation represents the effect of sea ice alone, without cloud cover or surface albedo contributions. Long-wave radiation responded because of the larger area radiating at a colder sea-ice temperature (reducing the long-wave flux to space).

Sea ice (f)	$+2 \times 10^6$ km²	(+13.5% in 67–75° N band

The sensitivity of the LLNL SDM to the combined effect of deforestation in the tropics and desertification in the subtropics reveals several interesting responses. The Hadley cell shifted southwards and the northern descending branch intensified. Conversely, the southern descending branch decreased in intensity, thereby reducing subsidence. This reduction in stability in the Southern Hemisphere produced clouds with more vertical and less horizontal extent, allowing more solar radiation to reach the Earth's surface and to increase temperatures at 30° S. The Northern Hemisphere temperature decreased because of the reduced solar radiation reaching the surface coupled with additional cooling due to ice-albedo feedback.

While the LLNL SDM computed a Northern Hemisphere surface cooling of 0.6 K, the global cooling of 0.2 K was substantially less than the 1 K suggested by Sagan *et al.*[1] for the cumulative effect of anthropogenic surface modifications over the pass several thousand years. Our model results suggest, therefore, that the global temperature response is significantly less and the Northern Hemisphere temperature response slightly less than that of the simple energy balance model cited by Sagan *et al.*[1].

We thank Dr W. J. Quirk for suggestions and comments, Connee S. Mitchell for helping with the calculations, Floy Weichel and Joni Schuld for typing the manuscript. This work was performed under the auspices of the US Department of Energy by the Lawrence Livermore National Laboratory under contract no. W-7405-Eng-48. This paper is a continuation of work presented at the International Workshop on Energy–Climate Interactions, Munster, West Germany in March 1980.

The biological availability and the toxicological effects of As depend on its chemical state[1,2]. It is therefore important to know the speciation and transformations of As in terrestrial and aquatic environments. Arsenite, As(III), is much more toxic than arsenate As(V) (ref. 2). The suspended and bottom sediments can potentially detoxify As(III) that enters aquatic systems by converting it to As(V) through abiotic oxidation[3]. We hypothesized that the oxides of Mn(IV) and Fe(III) may be the primary electron acceptors in the oxidation of As(III) because Mn and Fe readily participate in many oxidation–reduction reactions in natural environments; however, their role in the oxidation of As(III) to As(V) is yet to be established. We report here that Mn(IV) oxide is a very effective oxidant with respect to As(III); on the other hand, despite the thermodynamic favourability[3], the evidence obtained from colorimetry and X-ray photoelectron spectroscopy shows that a redox reaction between Fe(III) oxide and As(III) does not occur within 72 h, indicating that the kinetics of the redox reaction between As(III) and Fe(III) is relatively slow.

Birnessite (δ-MnO_2) was prepared and used in this study because it is one of the most common Mn oxides in sediments and soils[4]. The appearance of As(V) in solution after adding solutions of various concentrations of As(III) to Mn(IV) oxide (Table 1) clearly shows that As(III) is converted to As(V) by Mn(IV); in a control experiment, no detectable As(III) was oxidized in the absence of Mn(IV) oxide. With increasing additions of As(III) above 300 μg ml^{-1}, the amount of As(V) produced increased very little (Table 1), indicating that the oxidation capacity of the 100 mg sample of Mn(IV) oxide for As(III) was being approached. Assuming that the Mn(IV) oxide (birnessite) contains 9.5% K and the oxygen : manganese ratio is close to 2 (ref. 4), the 216 μg As(V) ml^{-1} in solution after adding 1,000 μg As(III) ml^{-1} to 100 mg of Mn(IV) oxide (Table 1) indicates that at least ~19% of the Mn(IV) initially present is reduced to Mn(II).

Mn(II) is more soluble than Mn(IV) (ref. 5), therefore the high concentrations of Mn and K in solution in the As(III)–Mn(IV) oxide systems relative to the As(V)–Mn(IV) oxide system (Table 1) is further evidence that Mn(IV) is reduced to Mn(II) by As(III). The reduction of Mn(IV) and the subsequent partial dissolution of the Mn oxide on the addition of As(III) disrupts the crystal structure at the surface of the oxide and thus a portion of the K present within the structure is free to pass into solution. As the Mn oxide contains ~9.5% K (ref. 4), the 90.9 μg K ml^{-1} in solution for the 1,000 μg As(III) ml^{-1} treatment (Table 1) represents ~67% of the K initially present in the Mn oxide sample. The 50 μg K ml^{-1} in solution in the As(V)–Mn oxide system (Table 1) is attributed to exchangeable K present at or near the surface of the oxide. The K in solution in the As(III)–Mn oxide systems is thus attributed to exchangeable plus structural K.

The decrease in the Mn concentration in solution with the increase in the initial As(III) concentration from 300 to 1,000 μg ml^{-1} (Table 1) is attributed to an increase in the formation of a sparingly soluble manganese–arsenate complex, $Mn_3(AsO_4)_2$. This interpretation is substantiated by the fact that the solubility product of $Mn_3(AsO_4)_2$ (ref. 6) is very much lower than the ion product, $(Mn^{2+})^3(AsO_4^{3-})^2$, of the equilibrated solutions in the As(III)–Mn(IV) oxide systems.

Manganese oxide sorbs little As(V) (Table 1). The point of zero charge of birnessite is close to *p*H 2 (ref. 7), and therefore the oxide has a high negative charge density at *p*H values used in this study; As(V) (largely $H_2AsO_4^-$ and $HAsO_4^{2-}$) is also negatively charged at the *p*H of this system[8], consequently a high energy barrier must be overcome for As(V) to sorb onto Mn oxide.

When freshwater lake sediments from southern Saskatchewan, Canada were treated with hydroxylamine hydrochloride or sodium acetate (effective extractants for the selective removal of Mn from sediments and soils[9,10]), the oxidation of As(III) to As(V) by the treated sediments was greatly decreased relative to untreated samples of the sediments[11]. This is supporting evidence that Mn oxide is a primary sediment component responsible for the oxidation of As(III). In sediments and soils Mn oxides occur as discrete particles and/or as coatings on other sediment/soil components[12]; and Mn is present in both the colloidal and non-colloidal particle size fractions of stream and lake sediments[10].

No detectable As(V) was found in solution after the addition of As(III) to Fe(III) oxide (Table 1), showing that Fe(III) oxide does not oxidize As(III) at neutral *p*H values within 72 h (earlier studies[3] showed that 48 h was sufficient time for 0.7 mg As(III) to disappear when added to 1 g of sediment). The data in Table 1 also show that As(III) is more strongly sorbed by Fe(III) oxide than is As(V); this is attributed to structural and charge differences between the two As complexes: As(III) (H_3AsO_3, coordination geometry is pyramidal, at *p*H values <9.2 arsenious acid is predominantly a neutral complex[8]) and As(V) (H_3AsO_4, coordination geometry is tetrahedral, at *p*H values >2.3 arsenic acid is largely dissociated and negatively charged[8]).

Table 1 Oxidation of As(III) and sorption of As by Mn(IV) and Fe(III) oxides

Mn(IV) oxide						Fe(III) oxide			
As(III) or As(V) added (μg ml^{-1})	As(III)	As(V) (μg ml^{-1} in solution)	Mn (μg ml^{-1} in solution)	K	Final *p*H	As(III) or As(V) added (μg ml^{-1})	As(III) (μg ml^{-1} in solution)	As(V) (μg ml^{-1} in solution)	Final *p*H
100 As(III)	ND	83.5±1.4*	0.41±0.12	60.5±0.0	7.1	100 As(III)	3.67±0.24	ND	6.9
300 As(III)	63.2±7.0	186±5	8.08±0.36	90.0±1.5	7.1	100 As(IV)	ND	53.6±1.1	7.7
500 As(III)	213±4	205±1	6.06±0.60	90.5±0.6	7.3				
1000 As(III)	665±5	216±4	4.61±0.86	90.9±0.8	7.5				
300 As(V)	ND	298±1	0.06±0.02	50.0±0.9	7.5				

The Mn(IV) (birnessite) and Fe(III) oxides were prepared as outlined elsewhere[4,15]. 100 mg of Mn(IV) or Fe(III) oxide was suspended in 70 ml of a solution containing the various concentrations of As(III) and As(V) as $NaAsO_2$ and $Na_2HAsO_4 \cdot 7H_2O$, respectively. The *p*H of the suspensions was adjusted to 7.5, and the flasks containing the suspensions were placed in an oscillating shaker at 25±0.2°C for 72 h. After the reaction period, the concentration of As(III) and As(V) in solution was determined colorimetrically as described elsewhere[3].

* Mean ±s.d.; *n* = 3. ND, not detectable.

Table 2 Binding energies for As and Fe(III) reference oxides and As(ads)–Fe(III) oxide

Sample	$As_{3p_{3/2}}$	$As_{3p_{1/2}}$	Δ*	$Fe_{2p_{3/2}}$
$NaAsO_2$	143.4	148.2	4.8	–
$Na_2HAsO_4 \cdot 7H_2O$	144.1	148.9	4.8	–
Fe(III) oxide				711.7
As(III)†–Fe(III) oxide	143.7	148.4	4.7	711.3
As(V)†–Fe(III) oxide	144.4	149.2	4.8	711.5

The measurements were performed on a Vacuum Generators ESCA 3 Spectrometer equipped with a Tracor Northern NS 570 signal averager for signal-to-noise ratio enhancement. The samples were ground and dusted on double-sided adhesive tape. The sequence of spectra was such as to embrace the As_{3p} lines by the C_{1s} reference line at 285.0 eV. Each sample was run twice and the precision of the binding energies was ±0.1 eV. The signal-to-noise ratio was 50:1 for the C_{1s} and Fe_{2p} lines and at least 15:1 for the As_{3p} doublet.

* BE ($As_{3p_{1/2}} - As_{3p_{3/2}}$).

† Initial concentration of As(III) and As(V) was 100 μg ml^{-1} and the concentration of As(III) and As(V) remaining in solution after the 72-h reaction period is given in Table 1.

About 96% of the As(III) added to the Fe(III) oxide suspension is sorbed onto the surface of the oxide, and the colorimetric method yields no information on the oxidation state of the surface-sorbed As. X-ray photoelectron spectroscopy (XPS) is a powerful tool for investigating the oxidation state of surface-sorbed species. The results of an XPS study of the As–Fe(III) oxide system is presented in Table 2. The absolute use of binding energies alone for the assignment of the oxidation state is generally not reliable, especially in the case of an adsorbed species when the reference used is a bulk compound (in this case $NaAsO_2$ and $Na_2HAsO_4 \cdot 7H_2O$). However, the constancy of the 0.7-eV shift observed between the As(III) and As(V) samples ($As_{3p_{3/2}}$ and $As_{3p_{1/2}}$ lines) on one hand and between the As(III)–Fe(III) oxide and As(V)–Fe(III) oxide samples on the other (Table 2) is strong evidence that As(III) and As(V) are sorbed as such and no change in oxidation state occurs. The 0.3-eV increase when either As(III) or As(V) is absorbed onto iron oxide reflects extra atomic relaxation and/or Madelung potential effects. The inability of Fe(III) oxide to convert As(III) to As(V) within 72 h despite the thermodynamic favourability indicates that the kinetics of the redox reaction is relatively slow at pH values near neutrality.

The biological methylation of As, Hg and Se has attracted a great deal of attention in recent years. Because the methylation of inorganic arsenicals is essentially a reduction reaction[13], the abiotic oxidation of As(III) to As(V) by freshwater lake sediments would tend to counteract the methylation process. This is significant because some organic arsenicals such as the various methyl-substituted arsines are more toxic than the inorganic arsenic species in higher oxidation states[14].

Our data indicate that Fe(III) oxide does not convert As(III) to As(V) within 72 h. On the other hand, Mn(IV) oxide, which is common in freshwater sediments, is a very effective oxidant with respect to As(III). Our data thus indicate that Mn(IV) oxide may be very important in natural systems in decreasing the concentration of As(III), a highly toxic pollutant.

This study was supported by a grant from the Natural Sciences and Engineering Research Council of Canada.

Earthquake-induced ground acceleration

Michele Caputo

Istituto di Fisica, G. Marconi, University of Rome,
Piazzale Aldo Moro, 2, I-00185 Rome, Italy

Earthquakes may be characterized after the event by several physical parameters, including the linear dimension of the fault, l, and the stress drop, p. Although the direct measurement of these parameters is often difficult, there are data on the frequency distribution of l and p for certain series of earthquakes (refs 1–11; C. Archambeau, unpublished data; personal communications from T. Mikumo, T. Utsu and R. I. Archuleta). For p there is evidence[12–14] that the frequency distribution $N(p)$ is given by a relationship of the form

$$\log N(p) = c_1 - (1-\alpha)\log p \qquad (1)$$

where c_1 and α are constants (α lying between 0 and 1) and $N(p)\,dp$ is the number of stress drop in the range p to $p + dp$ and $p_1 < p < p_2 (p_1 > 0$, where p_2 is limited). We report here that a relationship of this type holds (with specific parameters c_1 and α) for 15 different sets of earthquake occurring in Japan, California, Mexico, Nevada, Italy and the Aleutian arc. We also show that the frequency distribution $N(p)$ provides some information about the frequency distribution of ground acceleration during earthquakes.

Figure 1 verifies that the density distribution of the stress drops is a decreasing function of p, and also that equation (1) is a satisfactorily representation of the frequency distribution of p. The stress drops computed by Archambeau (unpublished data) for the Alaskan–Aleutian region and the Japanese region have been obtained by fitting observed seismograms with synthetic ones obtained from source models of the events that have the observed source parameters. The stress drops of the data of Mikumo and Utsu (personal communications) have been computed by various methods including Brune's formula[15]. The value of $-1+\alpha$ obtained from the analysis of Archambeau's data for Japan is -1.2, that from the data of Mikumo and Utsu is -1.4: considering that there are relatively few data in both sets these two values agree well.

Few authors report the accuracy of their data. However, Peppin and Bufe[9] computed the seismic moment and the stress drop for 40 earthquakes; they did not find large differences between the stress drops measured from vertical P-wave and horizontal S-wave spectral corner frequencies. They also computed the moment and stress drop using records from several different instruments. The scatter of the data is acceptable, 65% of their corner frequencies have precision better than 10%.

The regression lines of Fig. 1 have been computed using the method of the maximum likelihood assuming $\sigma(\log N)/\sigma(\log p) = 1$. The values of $1-\alpha$ are affected by a mean standard deviation of at most 10%.

To obtain the density distribution of the r.m.s. acceleration of the ground we also need the density distribution $N(l)$ of the linear dimension of the faults l. This has the form $N(l) = c_2 l^{-\nu}$ (ref. 12) with $\nu = 2b + 1$, where b is given by the results from the Gutenber-Richter frequency (n) magnitude (M) relation $\log n = a - bM$, b is typical of each seismic region and generally varies from 0.5 to 1.

I. Archuleta, personal communication), $\bar{N}$ is the total number of events used in the analysis. SC, Scattered events; A, aftershocks; SW, swarm. *b*, The 1979 Coyote Lake (California) earthquake[6]; aftershocks of the 1978 Oroville (California) earthquake[4]; earthquakes of the 1974 sequence of Central California[2]; aftershocks of the 1978 Oaxaca (Mexico) earthquake[7]; scattered earthquakes in the Aleutian and Alaskan regions (C. Archambeau, unpublished data); scattered earthquakes in Japan (1) (C. Archambeau, unpublished data); scattered earthquakes in Japan (2) (personal communications from T. Mikumo, and T. Utsu); scattered earthquakes in Southern California[10].

If the density distributions of p and l are known the density distribution of the r.m.s. ground acceleration a, can be calculated using the relationship established by Mcguire and Hanks[17]

$$a = 0.317\frac{p}{\rho R}\left(\frac{f_{\max}}{f_0}\right)^{1/2} \tag{2}$$

where ρ is the density, R the hypocentral distance, f_0 the spectral corner frequency of the seismic signal and $f_{\max} = Q\beta/\pi R$ is determined by the distance from the point to the epicentre R, the velocity of the waves β and the specific dissipation Q. Substituting[15]

$$f_0 = 2.34\beta/2\pi l$$

in equation (2) we find

$$a = \frac{0.29}{\rho}(Q)^{1/2}\frac{p}{R}\left(\frac{l}{R}\right)^{1/2} = kpl^{1/2}, \quad k = \frac{0.52}{\rho R}\left(\frac{f_{\max}}{\beta}\right)^{1/2} \tag{3}$$

The cumulative distribution function $n(a)$ of a can be determined from the density distributions (1) of l and p as follows. If p_1, p_2, l_1, l_2 are the minimum and maximum values of p and l, of the seismic region[16] then by integrating[12] in the domain of the plane l, p defined by the minimum and maximum values of p and l, we find that the cumulative distribution of a for $a > kp_1\sqrt{l_2}$ (or $a > kp_2\sqrt{l_1}$ whichever is larger) is

$$n(a) = \frac{D}{1-\nu}\left\{\frac{p_2^{\alpha}l_2^{1-\nu}}{\alpha} - \frac{(2\nu-2)l_2^{1-\nu-\alpha/2}a^{\alpha}}{\alpha(2\nu+\alpha-2)k^{\alpha}} - \frac{p_2^{2\nu+\alpha-2}a^{2-2\nu}}{k^{2-2\nu}(2\nu+\alpha-2)}\right\} \tag{4}$$

In the crust it is reasonable to assume $\rho = 2.8$ and $Q = 300$ for the seismic waves of interest, this gives $k = 1.81R^{-3/2}$. Because $\alpha < 0$, $\nu > 2$ it is seen that $n(a)$ is an increasing function of p_2 and decreasing function of a and R.

For small values of a in the range $p_1k\sqrt{l_2}$ to $p_2k\sqrt{l_1}$ such as those considered here the second term of equation (4) is small relative to the third. Because $\nu \simeq 2.8$, $n(a)$ is nearly proportional to $(aR^{3/2})^{-\delta}$ $(\delta \simeq 3.5)$.

Note that, considering equation (3) and the density distributions of p and l given by equation (1), a given pair of values of a and R, correspond to an infinite number of values of M and that, of all the values of M associated with this pair, Fig. 2, the minimum values of M is that which has the highest probability of occurrence. This implies that the return periods of the accelerations of the ground caused by earthquakes are much longer than previously estimated through empirical relations between M and a.

If we take into account that the seismicity is not concentrated in a point at distance R but covers an area, which we assume here for simplicity to be a sector of a circular ring defined by the angles ϑ_1, ϑ_2 and by the radii R_1 and R_2, then $n(a)$ is

$$n(a) = \frac{Dp_2^{\alpha}l_2^{1-\nu}}{1-\nu}\left\{\frac{1}{\alpha} - \frac{4(\nu-1)(a/kp_2\sqrt{l_2})^{\alpha}(R_3^{\frac{3}{2}\alpha+2} - R_1^{\frac{3}{2}\alpha+2})}{(\frac{3}{2}\alpha+2)(2\nu+\alpha-2)(R_2^2-R_1^2)\alpha} - \frac{2(a/kp_2\sqrt{l_2})^{2-2\nu}(R_3^{5-3\nu}-R_1^{5-3\nu})}{(2\nu+\alpha-2)(5-3\nu)(R_2^2-R_1^2)}\right\}$$

where $R_3 = R_2$ or $(p_2\sqrt{l_2})^{2/3}$ whichever is smaller.

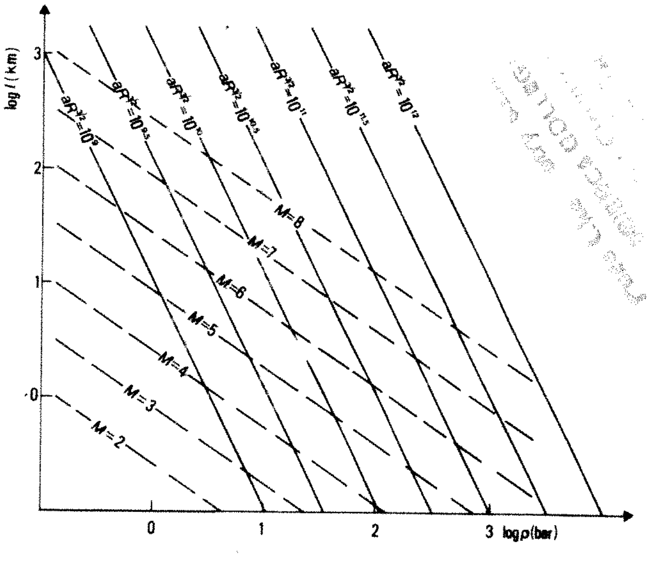

Fig. 2 Isolines of magnitudes and r.m.s. acceleration a in the plane of the linear dimensions of faults l and stress drops p. The lines $aR^{\frac{1}{2}}$ = constant have been computed from equation (3), the lines M = constant have been computed according to the formula $10^{11.1+1.46M} = \frac{16}{7}(l^3p^2/2\mu)$ of ref. 13.

In California $\nu = 2.78$, $\alpha = -1$, (ref. 13); a reasonable value of p_2 is 500 bar (refs 10, 13); we may tentatively consider a maximum linear dimension of a fault $l_2 = 5 \times 10^6$. Using equation (15) of ref. 12 with $p_2 = 5 \times 10^8$, $p_1 = 5 \times 10^5$ and the data of Epstein and Lomnitz[18] on Northern California Earthquakes one obtains $D = 10^{16.35}$ (ref. 12). For $a = 50$ Gal, $R_2 = 8R_1 = 8 \times 10^6$, equation (4) gives $n(50) = (17)^{-1}$ or a return period of 17 yr; this is much longer than the return period of $M = 5$ which, as shown by Fig. 2, could cause an acceleration of 50 Gal in the rare case when $l = 100$ m, and $p = 500$ bar.

Applying equation (2) to Southern California[17] and Friuli (E. Faccioli, personal communication) gave r.m.s. accelerations of the ground close to those observed; however, a test on a sequence of earthquakes recently observed in Northern California gave ambiguous results (T. C. Hanks, personal communication). If for some regions a formula for a must be used that is different from equation (2), such as that of Bernreuter[19] $a = (0.19p/\rho R)(l/R)^{0.7}$, the present method would still be valid, and a slightly different form for $n(a)$ would be obtained.

Kimberlites are characterized by a high concentration of incompatible elements, including light rare earths. However, Nd isotopic evidence indicates that their source regions do not have a long history of enrichment. If kimberlites can be generated from non-enriched mantle sources by simple partial melting processes, this implies that crystal–liquid partition coefficients for some trace elements are lower for kimberlitic liquids than for basalts or andesites. From a comparison of clinopyroxene megacrysts (regarded as equilibrated with kimberlite at depth) with existing kimberlite data we argue here that low crystal–liquid partition coefficients for the rare earths are plausible.

Experimental work on the melting relations of model peridotitic systems charged with CO_2 has shown that liquids of carbonatitic and kimberlitic composition may be produced by a small degree of partial melting of a carbonated peridotite[1,2]. This melting is likely to be caused by a change in the P–T conditions rather than an incursion of CO_2, because CO_2 cannot exist as a free fluid phase in a silicate mantle at pressures higher than ~32 kbar, but is bound by the formation of carbonate minerals[2]. The melting constitutes a single process and, therefore, trace-element enrichment in the liquid relative to its source is limited by solid–liquid partition coefficients.

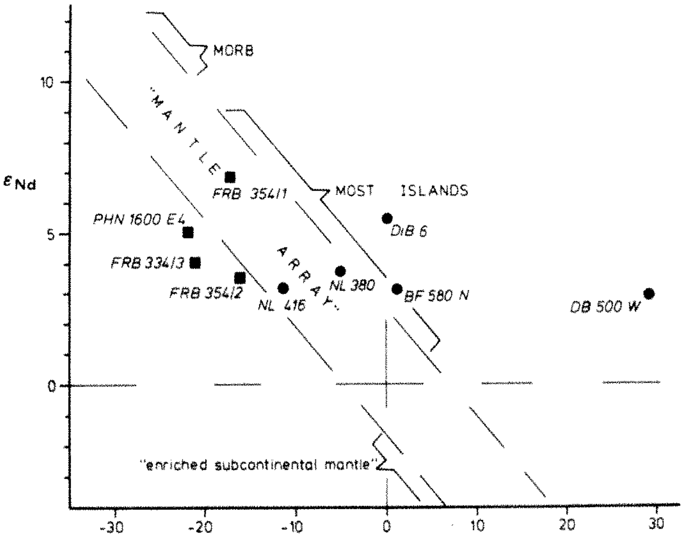

Fig. 1 ε_{Nd} plotted against ε_{Sr} showing kimberlite (●) and diopside megacryst (■) samples. The age[37] used for correction is 90 Myr. The 'mantle array' contains data from mid-ocean ridge basalts (MORB) and most oceanic islands[5] as well as 'enriched subcontinental mantle' as exemplified by diopsides from peridotite nodules in kimberlite[9].

$$\varepsilon_{Nd} = \left[\frac{(^{143}Nd/^{144}Nd)_{init} \text{ of sample}}{(^{143}Nd/^{144}Nd)_t \text{ of CHUR}} - 1 \right] \times 10^4$$

where t denotes the age of the sample. Analogous for ε_{Sr}. $(^{147}Sm/^{144}Nd)_{CHUR} = 0.194$; $(^{143}Nd/^{144}Nd)_{CHUR}$(present day) = 0.51264; $(^{87}Rb/^{86}Sr)_{UR} = 0.0827$; $(^{87}Sr/^{86}Sr)_{UR}$(present day) = 0.7045.

An assessment of the time-integrated enrichment or depletion in incompatible elements, including light rare earths (LREs), in the sources of volcanic rocks can be made from Nd and Sr isotope data. $^{87}Sr/^{86}Sr$ ratios of fresh kimberlites are ~0.704 (ref. 3), indicating time integrated source Rb/Sr ratios lower than that of the 'uniform reservoir' (UR)[4] also known as 'bulk earth'[5]. Recent Sm–Nd work on kimberlites ranging in age between 1,300 and 90 Myr (ref. 6) seems to point to time-integrated source Sm/Nd ratios close to that of the 'chondritic uniform reservoir' (CHUR)[4] or 'bulk earth'[5]. In contrast, combined Sr and Nd work on American kimberlites[7] has suggested both time integrated large-ion lithophile (LIL) and LRE element enrichment and depletion for their sources. We have measured the $^{143}Nd/^{144}Nd$ and $^{87}Sr/^{86}Sr$ ratios of five Cretaceous Southern African kimberlites, using methods described elsewhere[8], and the results are listed in Table 1. In the $\varepsilon_{Nd}/\varepsilon_{Sr}$ plot[4] (Fig. 1) the two dyke kimberlites from Letseng la Terai (NL 380 and 416) and the Bultfontein sample (BF 580 N) plot close to the 'mantle array' which is defined by both oceanic and continental volcanics[5] as well as some mantle derived xenoliths[9]. They indicate a slight time-integrated LIL and LRE element depletion of their sources. Kimberlite samples DiB 6 and DB 500 W plot well to the right of the mantle array, which is thought to be the result of Sr exchange with circulating groundwater[3]. Any effect on the $^{143}Nd/^{144}Nd$ ratios is likely to have been a lowering one[4]; thus these two kimberlites were probably also derived from sources with a time integrated LREE depletion. From published Sr and Nd isotopic data on kimberlites[3,6,7] and our results, the source regions of kimberlites seem to be similar in their LIL and LRE element characteristics to the sources of ocean island volcanics. These are characterized

Errors quoted on Sr and Nd isotope ratios are 2 standard deviations of the mean (except for standards). Errors on Rb/Sr and Sm/Nd ratios estimated at 2%. $^{143}Nd/^{144}Nd$ ratios normalized to $^{146}Nd/^{144}Nd = 0.7219$.

by trace element and isotopic heterogeneity, varying from no differentiation (relative to CHUR) to moderate LIL and LRE element depletion[5]. They also exhibit the same heterogeneous, mostly radiogenic lead isotopic signature as kimberlites[10].

Geochemical work on kimberlites[11-13] has highlighted their strong enrichment in incompatible elements, including LREE. One explanation invoked for this is that their mantle sources were pre-enriched[13,14], but long-term enrichment of kimberlite sources can be discounted on the grounds of the isotopic evidence discussed above, with the possible exception of highly micaceous kimberlites, which can have genuinely high initial $^{87}Sr/^{86}Sr$ ratios[3]. From isotopic[9,10,15] and trace element[16-18] studies on mantle derived xenoliths it has been shown that provinces exist in the upper mantle underneath Southern Africa which are anomalously enriched in LIL and LRE elements and have been so for a long period of geological time[9]. However, these were found to occur at shallower levels than the source regions of kimberlites[19,20] and their high $^{87}Sr/^{86}Sr$ ratios preclude a genetic link with most kimberlites.

The idea that kimberlites, with their strong enrichment in incompatible elements, could be derived from an 'ordinary mantle' which was slightly depleted in these elements, is an apparent paradox. Mechanisms which could resolve this paradox include:

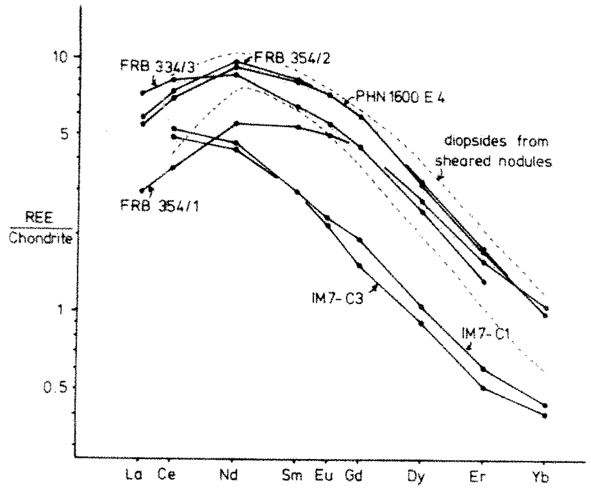

Fig. 2 Chondrite normalized rare earth abundances in diopside megacrysts. Stippled area, field for diopsides from Northern Lesothan sheared lherzolite nodules analysed by Shimizu[17].

(1) Transport of some incompatible elements as complexes in a CO_2 or H_2O vapour phase[11]. This mechanism may account for the great heterogeneities found in diatremes at near-surface level, but is unlikely to operate at the depth of origin of kimberlites[1,2].

(2) Metasomatic enrichment of the kimberlite source region shortly before melting, as proposed for some alkali basalts[21]. There is no evidence excluding this process, but for kimberlites the metasomatizing agent would have to be a melt[1,2] and the mechanism therefore involves 'two-stage' melting.

(3) Simple melting with trace-element partitioning governed by lower solid–liquid partition coefficients than are found in basaltic systems. This alternative is examined below, using K, Rb, Sr and REE data on subcalcic clinopyroxene megacrysts.

Among the otherwise variable inclusion population in kimberlite pipes, megacrysts (monomineralic inclusions over ~5 mm in size) of subcalcic clinopyroxene, garnet, olivine, orthopyroxene, phlogopite and ilmenite stand out by being almost ubiquitous. Subcalcic clinopyroxene megacrysts typically indicate equilibration temperatures[19,22,23] around 1,300–1,400 °C. Chemically they do not closely resemble clinopyroxenes in xenoliths (although some similarities exist with Northern Lesothan 'sheared lherzolites'[17,19]), and unlike other types of inclusions in kimberlites they consistently have low $^{87}Sr/^{86}Sr$ ratios[15]. They have been regarded as phenocrysts crystallized from the kimberlite magma at depth[22,24], which is particularly plausible for the low-Cr (0.3–0.6% Cr_2O_3) variety[22]. Because their composition usually indicates a whole range of temperatures of equilibration[19,22], this interpretation implies a diapiric origin for kimberlite[25], with fractional crystallization of phenocrysts occurring over a considerable depth range[22].

To test the isotopic consistency of the phenocryst hypothesis, we have measured $^{143}Nd/^{144}Nd$, $^{87}Sr/^{86}Sr$ and $^{18}O/^{16}O$ ratios of four subcalcic low-Cr diopside megacrysts from Southern Africa and the $^{87}Sr/^{86}Sr$ ratio of a similar diopside megacryst from the Colorado–Wyoming Front Range kimberlite province. Descriptions and major element analyses of the samples have been published elsewhere[19,22,23,26]. The isotopic results are listed in Table 1. The ε_{Nd} and ε_{Sr} values (Fig. 1) plot close to the mantle array in a 'moderately depleted' region. We have argued above that the kimberlite points in Fig. 1 were probably moved to the right (and possibly slightly downward) by interaction with groundwater, and might originally have plotted close to the mantle array in a similarly depleted region. The $\delta^{18}O$ values of the megacrysts (Table 1) are uniform around +6.5, a value higher than that obtained for most ultramafic xenoliths, but similar to phlogopite megacrysts in kimberlite[27]. Lead isotope ratios of the four Southern African clinopyroxene megacrysts (J.D.K., unpublished data) plot within the field defined by Southern African Cretaceous kimberlites[10].

Although the isotopic data discussed above do not prove that subcalcic clinopyroxene megacrysts crystallized from the kimberlite magma at depth, they do not conflict with this hypothesis, which has also stood up to petrological scrutiny[22]. Below, assuming equilibrium as a working hypothesis, we derive clinopyroxene–kimberlitic liquid partition coefficients for K, Rb, Sr and the REE and compare them with literature values for basaltic systems. Rb, K, Sr and REE concentrations measured by isotope dilution are listed in Table 2, including results on the kimberlite and megacryst samples listed in Table 1 and one additional diopside megacryst from the Front Range kimberlites. The chondrite normalized REE patterns of the clinopyroxenes (Fig. 2) are similar to patterns found by Shimizu[17] for clinopyroxenes from Northern Lesothan 'sheared' lherzolite nodules, for which an approximately chondritic whole rock REE pattern was reconstructed from the mineral data[17]. The subcalcic clinopyroxene megacrysts could thus be in equilibrium with a non-enriched mantle, either directly or through a liquid.

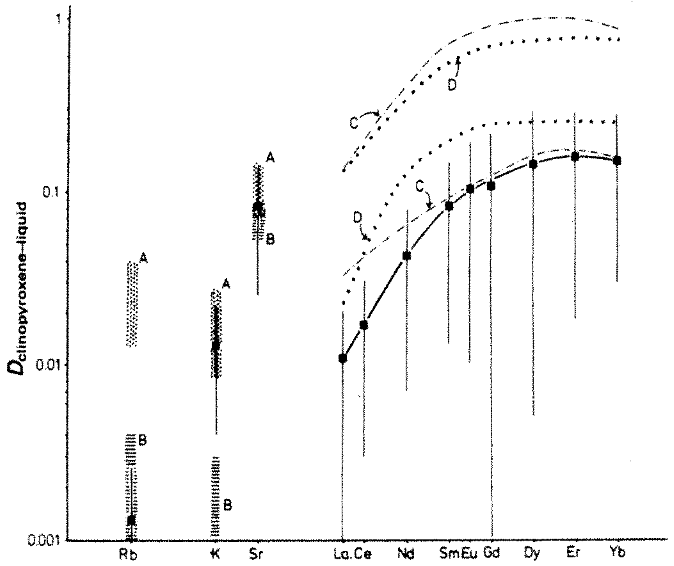

Fig. 3 Apparent clinopyroxene–kimberlitic liquid partition coefficients found in the present investigation (■, with one standard deviation error bars) compared with ranges of literature values for basaltic liquids. A, Philpotts and Schnetzler[33]; B, Shimizu[29]; C, boundaries of field for data of Onuma *et al.*[32] and Schnetzler and Philpotts[34], D, boundaries of field for data of Nicholls and Harris[31] and work reviewed by Irving[30].

The great heterogeneity of kimberlite occurrences and the variation between them means that the approach to the derivation of partition coefficients can only be semiquantitative, and we use an 'average kimberlite'. Its REE pattern is derived from the mean values of 23 kimberlite analyses, including the five listed in Table 2 and results from the literature[11–13,28], and its K, Rb and Sr concentrations are taken from values in Table 2 together with 11 analyses from the literature[10,15], avoiding upper diatreme facies kimberlites which can be heavily depleted in alkalies. The values for this 'average kimberlite' are also listed in Table 2, along with standard deviations. The apparent clinopyroxene–kimberlitic liquid partition coefficients listed in Table 2 have been derived from the average of the clinopyroxene analyses and the 'average kimberlite'. In Fig. 3 these apparent partition coefficients are compared with results obtained from experimental[29–31] and natural[32–34] systems. The value for Sr agrees well with the data from clinopyroxene–basaltic liquid studies[29,33]. For K and Rb there is a considerable discrepancy between Shimizu's[29] experimental results and Philpott's and Schnetzler's[33] data (Fig. 3). Our apparent partition coefficient for K agrees with the latter, whereas our value for Rb conforms to Shimizu's results. The apparent REE clinopyroxene–kimberlitic liquid partition coefficients follow a pattern which is strikingly similar in shape to those derived from both natural

Errors listed with averages are standard deviations of populations. Errors quoted for partition coefficients were calculated from these standard deviations.

basaltic systems[32,34] and experimental work[30,31] (Fig. 3), but the values are up to an order of magnitude lower. A general observation in studies on both synthetic and natural systems[30,31,34] has been that crystal–liquid partition coefficients decrease with decreasing SiO_2 and increasing MgO content (that is, decreasing polymerization) of the liquid, and kimberlites are much poorer in SiO_2 (30–40%) and richer in MgO (generally 20–30%) than any siliceous volcanic rocks used in partition coefficient studies. A decrease in polymerization of the melt and thus in partition coefficient values could also result from dissolved H_2O (ref. 31). Although dissolved CO_2 may not have a depolymerizing effect, it might lower REE partition coefficients by complexing with REE, as is in evidence in vapour-phase CO_2 (ref. 35). Finally, crystal–liquid partition coefficients generally decrease with increasing temperature[30,31]. Without attempting a quantitative assessment of these effects, it can be predicted from the physicochemical differences between a kimberlitic and a basaltic liquid in their respective source regions that REE crystal–liquid partition coefficients would be considerably lower for the former. The low partition coefficients found for the REE in this work would thus not be unreasonable. Partition coefficients for Sr seem to be less affected by the basicity of the melt than those for the REE[33], and the present results are consistent with this observation.

Because the low apparent values found for clinopyroxene–kimberlitic liquid REE partition coefficients, compared with basaltic systems, would be largely understandable as resulting from properties of the liquid rather than the solid, the REE partition coefficients for other minerals in equilibrium with a kimberlitic liquid could be expected to be correspondingly lowered. A kimberlite with a typical strongly LREE-enriched pattern could thus be in REE equilibrium with ordinary mantle material such as forms the source of ocean island basalts. However, equilibrium with the original parent material is only a boundary condition of any melting model and implies either an almost infinitely small percentage of partial melt, or complete equilibration of a relatively small amount of melt with a very large volume of rock similar to the source rock. This ultimately happens in zone refining[36], but could also be achieved if the melt existed as intergranular films in a source rock undergoing penetrative deformation, for instance, if melting occurred in a rising diapir[25].

Although the above argument is in some ways speculative, the hypothesis of kimberlite generation from an ordinary mantle by a single melting process merits consideration from a trace element point of view.

We thank J. C. Roddick for analytical assistance and W. Wilkinson for mineral purification. Isotope research at Leeds is supported by the NERC which is thanked by J.D.K. for a grant. P. J. Betton, R. A. Cliff, M. J. Norry and M. F. Thirlwall provided constructive criticism.

Late Phanerozoic extent of dry land

J. Graham Cogley

Department of Geography, Trent University, Peterborough, Ontario, Canada K9J 7B8

The extent of dry land during post-Carboniferous time seems to have fluctuated about a constant mean—no secular decrease in marine inundation of the continents can be identified. Such a decrease was first proposed by Egyed[1], who tried to show, with palaeogeographical measurements, that the seas have withdrawn steadily during the Phanerozoic; he deduced on this basis that the Earth is expanding. The idea of an expanding Earth has had little support[2], but the steady marine recession seems to be more widely accepted. Hallam[3], for example, confirmed Egyed's finding, and explained it as arising from orogenesis. My new estimate of the extent of the dry land, however, casts doubt on these earlier results, largely by taking into account continental drift and the progressive extension of shelf seas around the young Atlantic and Indian Oceans.

Wise[4] has argued that the secular withdrawal arises from the limitations inherent in palaeogeographical maps. An inevitable loss of resolution at more remote epochs imposes a temporal bias of uncertain direction, and a spatial bias towards shorter, simpler shorelines. These biases can be eliminated by sampling uniformly long intervals and by simplifying more recent shorelines; the resulting estimates are uniformly very inaccurate. Furthermore, the spectrum of sea-level change has a marked peak corresponding to periods of ~1–2 Myr (ref. 5). Such periods cannot be resolved easily (and perhaps not at all) by palaeogeographical methods, and they are much shorter than the present limits of palaeomagnetic resolution. Thus any palaeogeographical map will probably include information from more than one transgressive cycle, and in particular from the possibly asynchronous transgressive maxima of different regions. An overestimate of the extent of the seas will appear in any map which samples a period longer than ~1–2 Myr, and if the sample period grows shorter with time the extent of the seas will apparently decrease with time.

Notwithstanding these observations, Hallam's[3] data suggest secular withdrawal of the seas from the USSR and North America, and he concludes that the trend is real, and due most probably to orogenic thickening of the continents combined with variation in the length of oceanic ridges. It is not clear whether there ought to be a trend in ridge length (although large fluctuations are possible), but there may be a secular decrease in ridge volume, with a sea-level equivalent as great as −80 m (ref. 6) since −500 Myr if ridge volume is proportional to a 20% decrease in internal heat production; this latter estimate seems quite possible[7,8], although an 8–10% decrease may be more realistic. There are compelling arguments for a secular increase in the mass of the continents, but they are consistent with

0028-0836/81/190056—03$01.00

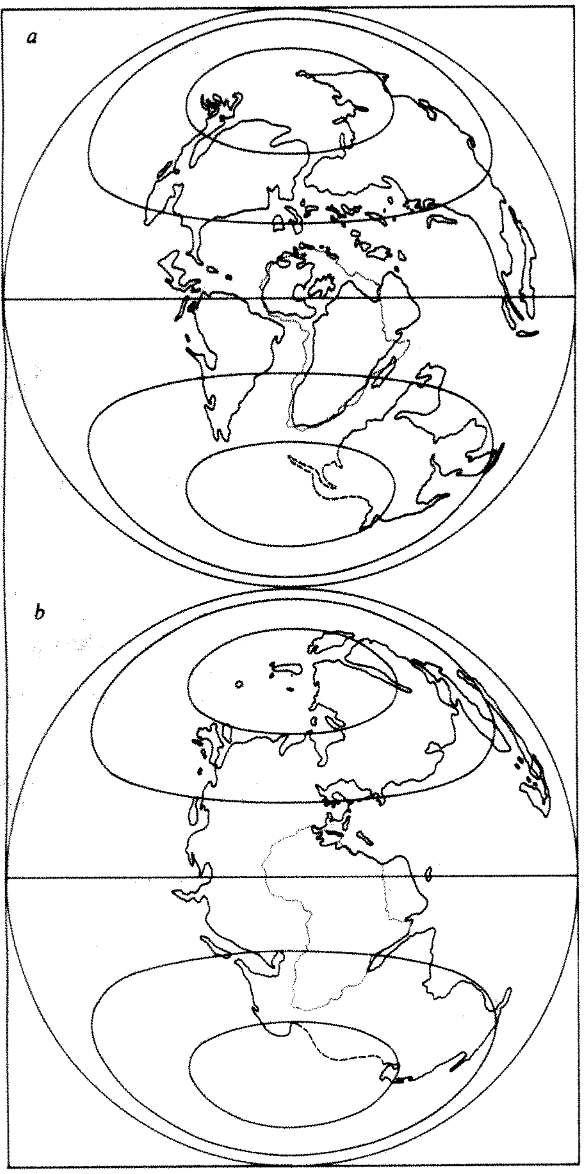

Fig. 1 Palaeographical reconstructions for *a*, −100 Myr and *b*, −200 Myr. Lambert equal-area projection of the whole sphere; parallels every 30°.

constant thickness (accommodating the added mass by an increase in area), and most of the increase may have been complete long before the Phanerozoic[9]. The continents may have thickened by net horizontal shrinkage without an increment of mass, as perhaps in the Appalachians[10], where wide, thick wedges of sediment and basement were thrust horizontally and stacked on top of each other in the Palaeozoic. Orogenic thickening, however, may be counterbalanced by the thinning recently described [11,12] as a precursor to the growth of sedimentary basins.

Fluctuations of sea level, as opposed to trends, may appear in history due to several causes[13–15]. Southam and Hay have shown that changes since −120 Myr can be explained by glaciation, episodic fast spreading at the ridges and a decrease in total ocean basin volume. Harrison *et al.* consider ocean sedimentation in more detail, and estimate the influence on apparent sea level of changes in the area–altitude distribution of the continents. Bond has also examined the latter influence, from a different perspective. Whatever the mechanisms that alter the sea level, I show here that the palaeogeographical evidence which prompted some of the earlier proposals is doubtful.

Table 1 Estimates of marine withdrawal from the continents

Sample	Withdrawal rate (10^3 km^2 Myr^{-1}) $-270 \leq T \leq 0$	$-582 \leq T \leq 0$
Cog	-6 ± 32	—
Bar	1 ± 43	—
Ter	67 ± 27	48 ± 9
TerH	67 ± 27	63 ± 9
Str	188 ± 106	101 ± 23
Hal1	55 ± 39	134 ± 18
Hal2	131 ± 100	119 ± 26
Wis	21 ± 29	15 ± 9

Sources: Cog, this work; Bar, ref. 30; Ter, ref. 1(*GPA*), Table 2; TerH, Ter with 12×10^6 km^2 subtracted from five earliest points[33]; Str, ref. 1 (*GPA*), Table 1; Hal1, ref. 3 (1977), Fig. 1 (USSR); Hal2, ref. 3 (1977), Fig. 2 (North America revised); Wis, ref. 4, Fig. 3 (North America: this work was an attempt to show that the rates of Str and TerH could be made to approach zero by sampling the record more densely).

There is no reason to suppose *a priori* that the continental shelves, which are below sea level today, have histories of inundation which differ significantly from those of areas which are above sea level today. It is not known whether at any instant the periphery of a continent is more likely to be inundated than its interior. Historically, however, a pattern of old fissures and sutures criss-crossing the continental interiors reveals that regions now far from oceans were once peripheral to old continents; conversely, all the modern Atlantic and Indian shelves were in continental interiors ~200 Myr ago. Earlier palaeogeographical analyses have ignored modern shelves for lack of offshore data, but consequently large areas of dry land have probably been left out. Indeed, if only present land areas are considered, then, unless the ancient and modern shorelines coincide everywhere, estimates of the extent of ancient seas must exceed the extent of modern seas. This property of the estimates is an artefact, and is neither logically nor geologically necessary.

Even without data from boreholes or seismic exploration, reasonable judgment can yield histories for modern shelves which are much simpler than those which would have to be contrived, often in conflict with palaeobiogeography, to ensure that they have always remained below sea level. Note that at −200 Myr in Fig. 1 the shelf off eastern North America is above sea level and well away from the shores of Pangaea; the alternative is a narrow seaway connecting Mexico with Scotland.

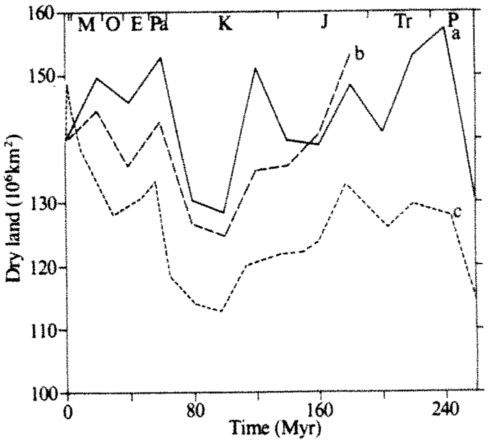

Fig. 2 Extent of dry land estimated from palaeogeographical maps: *a*, this work; *b*, ref. 30; *c*, ref. 1 after ref. 25 (Ter of Table 1). The points at −240 and −260 Myr in *a* have the same base map[34], dated at 250 ± 25 Myr; they are more uncertain, principally as to timing, than the others.

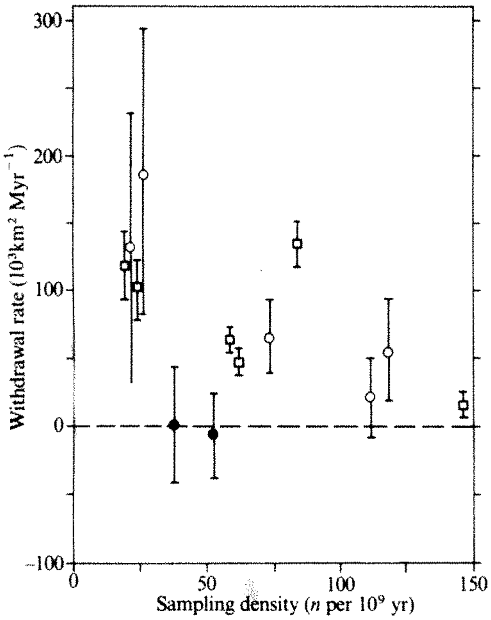

Fig. 3 Estimates of marine withdrawal from the continents. Symbols represent estimates of b (bounded by standard errors) from linear regressions $E = a + bT$, where T is time (adjusted from the Geological Society of London time scale and sources given in ref. 5) and E the extent of dry land (adjusted where necessary to global values). Modern E is set to 140.0×10^6 km^2 to simulate return of polar ice to the oceans[35]. (Rates are greater, though not significantly, if modern E is set to the observed 148.9×10^6 km^2.) ●, This work and ref. 30; ○, Table 1, column 1; □, Table 1, column 2 (note that the circles and squares are not from independent samples).

Without data from the shelf itself, the reconstruction as adopted is surely the more plausible. In fact, field data[16,17] show that the late Triassic is either absent, or represented by non-marine sediments penecontemporaneous with graben which suggest East Africa-style rifting. The narrow seaway can be ruled out. Field evidence also serves, with greater or lesser completeness, to rule out seaways between the various once-contiguous fragments of Gondwanaland[18–23].

Note too that the reconstructions of Fig. 1 allow for all known marine sediments within the present shoreline, and that they are conservative where data are lacking and no reasonable judgement can be made. There is, for example, no warrant for a landmass on the shelf south of the Falkland Islands at −100 Myr.

Figure 1 shows only specimens from a series constructed from 'palaeocontinental' maps[24] with shoreline information[25,26] superimposed. Offshore details were compiled from studies such as those in refs 16–23. These maps were planimetered to yield estimates of the extent of dry land at ~20-Myr intervals from 0 Myr to −260 Myr (Fig. 2a). The estimates are deficient in several ways. The continental reassemblies[24] are not unanimously accepted and are subject to errors of about 5–10° in positioning (95% confidence limits about inferred palaeopoles) and a few millions of years in time. The shoreline data were compiled 30 yr ago[25], and are from maps offset by up to 10 Myr from the palaeocontinental maps, but they do have the advantages of internal consistency and global completeness; more recent studies[27–29] tend to suggest revisions of detail, rather than of broad outline, to the work done by the Termiers. Offshore geology will always be less accessible than onshore, but its uncertainty, in the light of current knowledge, is no longer great enough to justify ignoring it. Percentage errors in offshore estimates can be appreciably worse than onshore errors and still contribute less to total error, because the offshore regions which might once have been land—up to $\sim 50 \times 10^6$ km^2—are less extensive than the onshore regions. About 10×10^6 km^2 of subglacial Antarctica, of which very little is known[26], are assumed here to have been above water since −260 Myr. It is difficult to place limits on errors from such diverse sources, but an estimate which is, at least partly, independent can be taken from recent work by Barron *et al.*[30] (Fig. 2b).

The trends (Table 1, Fig. 3) of Fig. 2a, b are statistically indistinguishable from each other and from zero. They should be compared with the trend seen in the curve of Egyed[1] (Fig. 2c), which was derived from ref. 25 but with data only from modern areas of dry land. The Egyed withdrawal rate and those below it in Table 1 all lack data from modern shelves. The rates in column 2 of Table 1 come from the longer span of the entire Phanerozoic, but only one of them significantly exceeds its counterpart in column 1. That is, most of the withdrawal rates are about as well defined in the past 270 Myr as in the past 580 Myr, indicating that it is reasonable to compare the rates which appear in column 1. Figure 2a lacks points in the Palaeozoic mainly because offshore palaeogeography becomes too speculative[31,32] for detailed mapping. Estimates of flooding within the present shoreline do not suffer this objection. However, as the arrangement of the continents in remoter times becomes less and less like the present one, the extrapolation from onshore results to putative global results becomes increasingly more doubtful. It may, in fact, be not only reasonable but prudent to concentrate on column 1. In any case, the trends of Fig. 2a, b are well below all the others of Table 1, and their zero secular trend appears also in graphs of relative change of Phanerozoic sea level[5]. (It is not certain, however, whether relative sea-level change and area of dry land are simply related[13].)

Thus, I conclude that the palaeogeographical evidence is not consistent with a secular withdrawal of the seas from the continents in the second half of the Phanerozoic. It is intriguing to speculate on the biases discussed by Wise[4], to which Fig. 2a is subject just as are other inundation curves. Does the zero trend of Fig. 2a imply that an 'ideal' version, that is, one with a uniform sampling interval ≤2 Myr, would show a secular encroachment of the seas?

I thank NSERC (Canada) for support.

Podzol chronosequences on coastal dunes of eastern Australia

SCIENCE COLLEGE
Upper Circular Road

C. H. Thompson

CSIRO Division of Soils, Chancellor's Place, St Lucia,
Queensland 4067, Australia

Chronosequences of freely drained podzols, formed in extensive dune systems of quartz sands along the east coast of Australia, offer unique opportunities for comparing temporal changes in different climatic zones during the late Quarternary. The largest areas and greatest number of dune systems occur along the subtropical coast near Brisbane. Here parts of six dune systems have not been covered by younger deposits and have been exposed to weathering since deposition. These areas constitute a relative age sequence on which podzols have formed with solum depths varying with age from <1 m to >20 m. Absolute ages for each system have not been determined but differences in erosion and weathering depths and comparisons with dated dunes elsewhere along the coast indicate an age sequence extending back at least to the last interglacial. Similarities in geomorphology and soils enable correlation with dune systems in other areas to the north and south and so provide a greater potential for examining temporal changes in soils and biological systems than that of previous soil chronosequences[1–5].

Because Australia largely escaped glaciation and has been relatively stable, tectonically, during the Quarternary, vast quantities of sand have accumulated along its coast[6]. Along the east coast siliceous sands dominate and have apparently been derived from the ocean floor during periods of marine transgression[6,7], the large accumulations representing intervals of marine and/or aeolian deposition when sea-level returned to similar positions in successive interglacial periods[8]. Two general types of deposits occur: low sandridges and swales parallel to the coast and widely distributed along its length, and multiple systems of transgressive parabolic dunes at 11 localities between 12 and 40° S latitude (Fig. 1). The parabolic dunes are generally oriented to the south-east onshore winds but their shapes reveal both the control of underlying topography, as in the case of nested dunes, and at exposed sites the influence of onshore winds from other quarters, which lead to multiple-lobe dunes.

Podzols and humus podzols have formed on both types of deposits[1,9–11] but the high transgressive dunes are more conducive to long-term soil formation because they lack watertables to considerable depth. On these porous, freely drained sands, podzol profile development reaches great depths and on the oldest dunes can exceed 20 m.

The largest area and greatest number of the large dune systems occur between 25 and 28° S. Here large areas of several sand-dune systems form North Stradbroke, Moreton and Fraser Islands and the mainland sandmasses at Cooloola and Peregian[10,12] (Fig. 1).

Studies of sand-dune systems and associated soils at Cooloola reveal eight periods of dune building. Sizeable areas of six of these dune systems have not been covered by successively younger deposits and have thus been subjected to sub-aerial weathering since deposition. The younger systems (1–4, Fig. 2) consist of parabolic dunes; the dunes of each system are clearly defined by their shape and distribution inland from the coast, the younger dunes being progressively smaller and deposited closer to the coast. The older systems (5 and 6, Fig. 2) extend further inland, have been much modified by erosion and have lost any recognizable dune orientation. They may have been more extensive in the past and parts of 6 may have been reexposed by erosion; however, the strong topographical difference between 5 and 6 makes this unlikely.

The sands are mostly quartz grains with usually <2% of heavy minerals (ilmenite, rutile, zircon and monazite) and some feldspar, but rarely any shell fragments. In all dune systems, the sands are well sorted and have modal grain sizes between 180 and 210 μm. However, the grains in the oldest system are more strongly weathered than those in the youngest (M. P. Green, personal communication), similar to those on nearby Fraser Island[13].

The unweathered sands are pale yellow-brown due to thin sesquioxidic coatings on the quartz grains. As weathering proceeds, the coatings on grains in the upper part of the profile are mobilized and together with humic compounds deposited lower in the profile to form the friable to firm, iron-humus B horizon (Bhir) of freely drained podzols. With increasing age the top of the Bhir is progressively remobilized and deposited deeper in the profile, the A and B horizons become thicker and more intensely developed, and there is a marked increase in thickness of A2 relative to A1 and B horizons[11]. In this way solum depth increases with age and is only limited by the thickness of freely drained dune sand and erosion rates since deposition. In the investigated sequences, depth of solum varies from <1 m on the youngest dunes to >20 m on the oldest (Fig. 2). All the sands except those of the youngest dune system are >30 m thick which ensures the pedological unity of the weathering column. This has been established by augering through the soil profiles to unweathered sand (systems 1–4) or into the B horizon (systems 5 and 6). If the trailing arms of parabolic dunes are intact, erosion losses are minimal on dune floors near the apex, low on the crests of trailing arms, and high on other slopes; depth of soil development varies accordingly.

Because both A1 and A2 horizons consist of clean quartz sand from which the sesquioxide coatings have been lost[14], the thickness of these horizons (depth to Bhir) may be used as a measure of relative weathering between analogous sites in different systems. Depth to Bhir is <1.2 m in systems 1–3 (Fig. 2), ~5 m in system 4 and commonly ~11 m in in system 5 and 15 m in system 6. However, both systems 5 and 6 have been

severely eroded and depth to B horizon varies accordingly, for example, in system 6 it ranges from 12 to >20 m.

Differences in soil morphology between the dune systems are reflected in the distribution of carbon, potassium and phosphorus down the profile (Table 1). The organic carbon profile indicates the development of A and B horizons. The potassium and phosphorus profiles reflect the weathering of feldspar and the removal of sesquioxide coatings from the quartz grains in the upper part of the profile. The unweathered sands contain virtually no apatite and phosphorus is held on the sesquioxide coatings.

Clay formation is limited by the very low content of weatherable minerals in the parent sands; the clay-size fraction in B horizons examined in systems 1–3 is <3%, in system 4 <7%, in system 5 <10% and up to 15% in system 6. Chlorite–vermiculite and kaolin dominate the clay fraction in the younger soils and kaolin and quartz in the older. The silt-size fraction is negligible (<1%) in the young systems 1–4, but may reach 7% in the top of the B horizon in systems 5 and 6, with negligible amounts above and below this position.

Stratigraphical and geomorphical relationships, and the differences in degrees of erosion, weathering and soil development show that the age sequence of the dunes at Cooloola extends over a long period. However, the absolute ages of these dune systems are unknown and no datable material has been recovered in the present study. A previous radiocarbon dating[12] of two pieces of wood embedded in the Cooloola sandmass near sea level indicated ages >40,000 and >45,000 yr BP from materials probably contaminated by modern carbon in groundwaters which issue at both sites. Additional dating of charcoal embedded in dune sands and a soil organic B horizon in overlying sands, both about 75 m above sea level, yielded ages of 39,000±3,000 and 30,300±800 yr BP[12]. Although the latter site cannot be located in relation to the dune systems now recognized it does show that the underlying sands are of Pleistocene age.

Dune systems 1–3 transgress, and in places fill, parts of deeply eroded valleys in the older dune systems. The preservation of dune outlines without erosion breaks and the limited depth of weathering in systems 1–3 (Table 1) also indicate young deposits. The diminishing size of these systems and of the individual dunes towards the coast suggests successive deposition from a diminishing sand supply during a high stillstand of the sea[7] as has occurred along the Australian coast during the Holocene[15]. Also, the degree of soil development on dunes in system 3 is similar to that observed in the dune at Triangle Cliff, Fraser Island, where a recent radiocarbon dating of charcoal at the base of the dune shows that it is <3,880 yr BP[16]. Therefore, systems 1, 2 and 3 are most likely of Holocene age.

In dune system 4, erosion has breached the trailing arms and reduced most of the dune floors and, together with the increased depth of soil weathering (Fig. 2; Table 1), indicates a sizeable time break between it and system 3. Even longer intervals are indicated by the increases in erosion and weathering between systems 4 and 5 and between 5 and 6. The increasing degree of modification indicates that these systems are older than Holocene and the early radiocarbon dates[12] show that their ages extend beyond 40,000 yr BP.

In New South Wales, two distinct barrier systems of low sand ridges have been recognized[9]—an Outer Barrier dated as a Holocene feature deposited over the past 6,000 yr (ref. 15) and an Inner Barrier which has been related, by uranium series dating of corals it overlies, to high sea levels of the last Pleistocene interglacial, ~120,000–135,000 yr BP[17]. While Inner and Outer Barrier equivalence has not been clearly established for the high dune systems along the Queensland coast, the younger

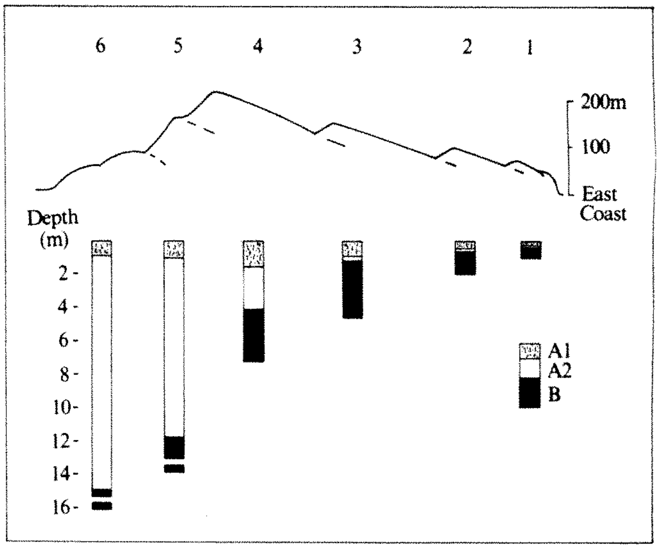

Fig. 2 Schematic cross-section of overlapping dune systems at Cooloola and podzol profiles associated with them. Numerals indicate dune systems, 1 being the youngest and 6 the oldest. The profiles represent soils at sites of least erosion for each system (dune floor in systems 1–4 and ridge crests in systems 5, 6). Thickness of B horizons in systems 5 and 6 is unknown.

systems (1–3) are probably equivalent to the Holocene transgressive parabolic dunes developed on parts of the Outer Barrier[9], judging from the limited amount of erosion and weathering evident at both localities.

Equivalence between the older dune systems at Cooloola and the Inner Barrier Deposits is less certain because of the greater areas of old deposits at Cooloola and the evidence of more events than can be reasonably represented by a single unit. For example, while no coastal sand deposition older than the Inner Barrier has been recognized in New South Wales[17], the coloured Teewah Sands are prominent in southern Queensland[12] and probably predate the Inner Barrier deposits. At Cooloola, the Teewah Sands underlie or form part of dune system 5 and at its northern end are underlain by older dune sands (system 6) which overlie a fossil beach. If system 6 deposits here equate with the Inner Barrier as suggested[18], there seem to be more depositional events at Cooloola between the last interglacial and Holocene than is suggested by records elsewhere. Alternatively, system 5 at Cooloola can be regarded as the most likely equivalent of the Inner Barrier and system 6 as an older deposit as has been suggested for the fossil beach[19].

In the Cooloola area, there is no firm indication of a change to markedly drier conditions during the last glaciation. The parabolic shape of the dunes in systems 1–4 and the lack of dune shapes characteristic of extensive bare sands suggest that this area has carried ground cover continuously since before the beginning of deposition of dune system 4. However, the evidence of extensive fluviatile erosion in systems 4–6 suggests that they have experienced wetter conditions at some time in the past than those that now prevail or are believed to have occurred since the onset of the last glaciation[20].

The soil landscapes here and those on Fraser, North Stradbroke and Moreton Islands have been correlated[10] and more recent field examinations indicate that sequences of podzols similar to that at Cooloola also occurs on these islands. Another such sequence is evident in the high dune systems further north at Shoalwater Bay (22.5° S) where at least four of the systems can be equated with those at Cooloola. To the south, soils on the parabolic dunes of the Outer Barrier[9] in the Myall Lakes area (33° S) are also similar to those of at least two of the systems at Cooloola. The soils of the parabolic dune systems further to the north and south have not yet been correlated; however, airphoto patterns of the dunes at Cape Flattery (15° S) and Shelburne Bay (12° S) show similar dune forms and descriptions from King Island[21] (40° S) suggest that one or more of the dune systems recognized at Cooloola are represented in these areas.

It is evident that the podzol sequence at Cooloola has developed over a considerable period including at least the last interglacial, last glaciation and postglacial periods, and podzol sequences on similar dune systems to the north and south can be correlated with it.

These podzol chronosequences provide unique opportunities for scientific study, both of changes that have occurred with time at one locality and of parallel changes that have occurred in temperate, subtropical and tropical areas. The sanddune systems at Cooloola are being intensively studied by the CSIRO Division of Soils, Brisbane, with collaboration from other institutions. Recognition of the dune systems and the podzol chronosequence has provided the framework for studies of erosion, nutrient movement, atmospheric accession, dune hydrology, and ecology of vegetation, fungi and soil fauna—these investigations need extending to the north and south.

Climatically controlled variation of Sr and Mg in Quaternary planktonic foraminifera

Hans G. Cronblad & Björn A. Malmgren

Department of Geology, Stockholm University, Box 6801,
S-113 86 Stockholm, Sweden

Despite studies on the distribution of Sr and Mg in shells of marine calcareous invertebrates, the question of possible seawater temperature control on the concentrations of these elements in carbonate material remains controversial. Some workers have shown that individuals of a species living in warmer waters are richer in Sr and Mg than those living in cooler waters[1–7]. Others have found no such relationship[8–12]. We report here in tests of two planktonic foraminiferal species that the Sr concentrations are strongly related to late Quaternary climatic oscillations. Mg concentrations also show correlations with palaeoclimate, but not consistently. Concentrations of these trace elements, especially of Sr, in planktonic foraminifera may, therefore, be valuable for analysing palaeoclimatic history.

We have examined two species, *Globigerina bulloides* and *Globorotalia inflata*, in two deep-sea sediment cores from the southern Indian Ocean: E49–19 from the central subAntarctic and E48–22 from the Subtropical Convergence (Table 1). *G. bulloides* is most abundant in subpolar waters, whereas *G. inflata* predominates in the transitional zone between subpolar and subtropical waters[13]. *G. bulloides* lives in 'intermediate waters' (upper 100 m of the water column) and *G. inflata* inhabits 'deep waters' (generally below 100 m)[13].

Table 1 Data for Eltanin cores used in the study

Core	Lat. (S)	Long. (E)	Water depth (m)	Core length (cm)	Age of sequence (kyr)
E48–22	39°53.7′	85°24.6′	3,380	400	220
E49–19	43°53.2′	90°06.0′	3,036	550	300

Size-fractionation of samples may affect the oxygen isotope composition of planktonic foraminifera[14,15]. Tests of small specimens tend to be isotopically lighter than tests of the larger size of the same species. A pilot study has shown that there are no major differences between Sr and Mg concentrations in the various size fractions in *G. bulloides* and *G. inflata* (Table 2). Therefore, we concentrated on the >250-μm fraction of these relatively large species. More than 150 specimens of each species were picked per sample.

Specimens were ultrasonically cleaned to remove sediment and clay contaminants, and analysed using standard atomic absorption spectrophotometric methods. Only those tests that were apparently free of extraneous material were included. The analytical precision (95% confidence) is ±14 p.p.m. for Sr and ±11 p.p.m. for Mg. These estimates were based on analyses of four replicate subsamples (two per species) from each of four samples. Sr and Mg variations were compared with palaeoclimatic indices established from 'total fauna' analyses and

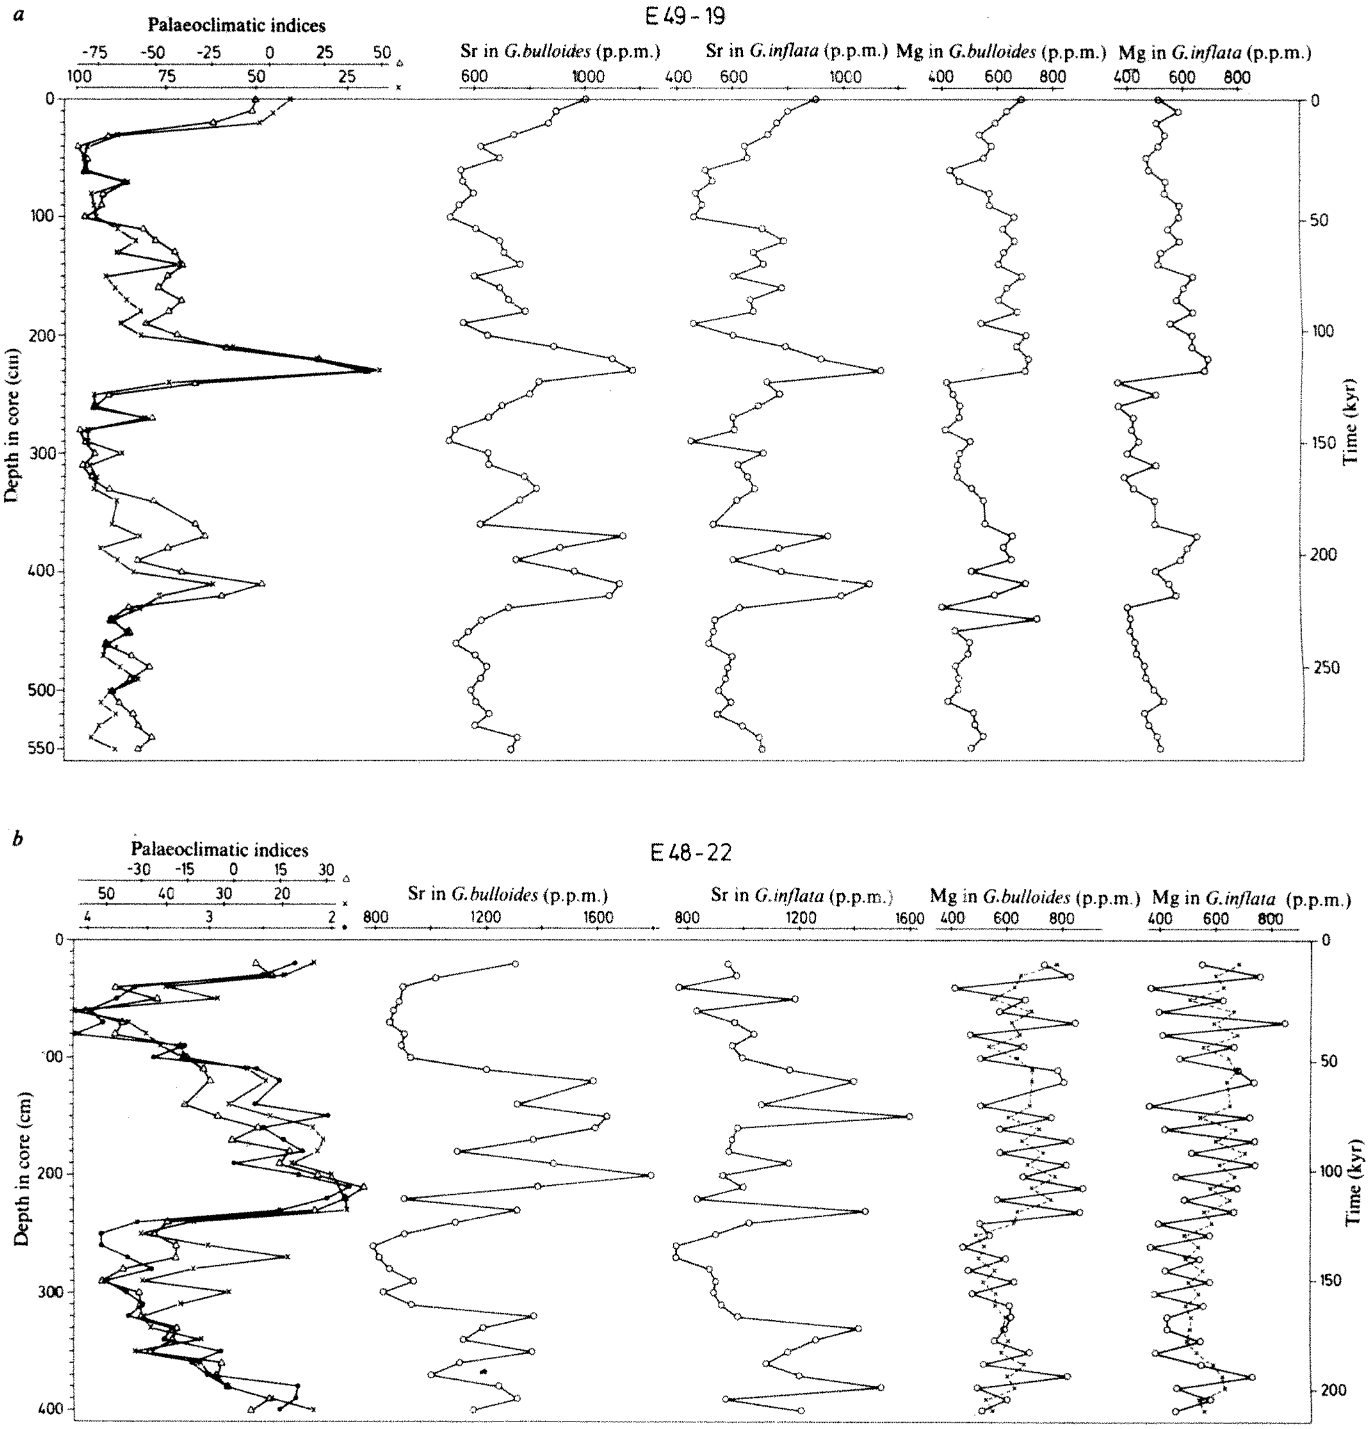

Fig. 1 *a*, Variation in Mg and Sr concentrations in *G. bulloides* in relation to two palaeoclimatic indices in core Eltanin 49–19 from the southern Indian Ocean. 'Warm' is to the right and 'cool' to the left. Chronology plotted on right is from Malmgren and Kennett[17]. *b*, Variation in Mg and Sr concentrations in *G. bulloides* and *G. inflata* in relation to three palaeoclimatic indices in core Eltanin 48–22 from the southern Indian Ocean. Dashed line curves for Mg show three-point moving averages. Chronology is from Williams[16]. △, 'Total fauna'; ×, % sinistral *N. pachyderma*; ●, $^{18}O/^{16}O$ ratios.

frequency in coiling proportions of *Neogloboquadrina pachyderma*, and also in E48-22 with a curve based on $^{18}O/^{16}O$ ratios in a planktonic foraminiferal species[16,17]. A 'total fauna' index is defined as the difference between relative abundances of a transitional and a subAntarctic assemblage of planktonic foraminifera[16].

In core E49–19, variations of the Sr concentrations in both species are remarkably similar in period and amplitude to the palaeoclimatic curves (Fig. 1). Mg concentrations are less variable and show less pronounced peaks, but the curves are clearly in phase with the palaeoclimatic oscillations. Cross-correlation analyses indicate that all curves have a very significant correlation (Table 3). Both elements are more enriched during warm climates (interglacial episodes) than during cool climates (glacial episodes).

Core E48-22 also shows good agreements between the Sr patterns in both species and the palaeoclimate (Fig. 2). Cross-correlation analyses between Sr and palaeoclimatic changes indicate that correlations in *G. bulloides* are highly significant (Table 3). Sr in *G. inflata* is correlated with $^{18}O/^{16}O$ ratios, but not with the other curves. The Mg concentrations in *G. bulloides* are also correlated with palaeoclimatic indices, whereas those in

Table 2 Sr and Mg compositions in *G. bulloides* and *G. inflata* from different size fractions

Size fraction (μm)	52 cm *G. bulloides* Sr (p.p.m.)	52 cm *G. bulloides* Mg (p.p.m.)	52 cm *G. inflata* Sr (p.p.m.)	52 cm *G. inflata* Mg (p.p.m.)	122 cm *G. bulloides* Sr (p.p.m.)	122 cm *G. bulloides* Mg (p.p.m.)	122 cm *G. inflata* Sr (p.p.m.)	122 cm *G. inflata* Mg (p.p.m.)
175–250	900	630	1,150	650	1,450	810	1,070	760

>351	890	660	1,200	640	—	—	—	—

Size fraction (μm)	222 cm *G. bulloides* Sr (p.p.m.)	222 cm *G. bulloides* Mg (p.p.m.)	222 cm *G. inflata* Sr (p.p.m.)	222 cm *G. inflata* Mg (p.p.m.)	362 cm *G. bulloides* Sr (p.p.m.)	362 cm *G. bulloides* Mg (p.p.m.)	362 cm *G. inflata* Sr (p.p.m.)	362 cm *G. inflata* Mg (p.p.m.)
125–175	850	580	840	510	—	—	—	—
175–250	880	570	—	—	1,090	520	1,050	560
250–351	850	570	870	510	1,070	540	1,110	590
>351	890	560	850	500	1,090	530	1,070	550

Specimens were randomly picked from two cooler-water samples (52 cm and 362 cm) and two warmer-water samples (122 cm and 222 cm) from E48–22.

G. inflata are not. Small-scale fluctuations in this element are greater than in E49–19, but plots of three-point moving averages (Fig. 2) bring out these palaeoclimatic signals in *G. bulloides* more clearly. The peculiar 'sawtooth' pattern is probably only an analytical artefact.

Various hypotheses have been suggested for the calcification mechanism in marine calcareous organisms[18–21]. The observed trends indicate that the biomineralization in planktonic forminifera is, at least partly, controlled by seawater temperature. It has been shown empirically[22] that substitution of exchangeable elements in the molecular lattice is greater at higher temperatures. Other environmental parameters may also play a part in the calcification process. The uptake of trace elements is also partly controlled by genetical differences among organisms. Differences in trace element concentrations among various planktonic foraminiferal species have been noted[9,10], and are apparent in our material (Fig. 1).

Sr and Mg concentrations in *G. bulloides* and *G. inflata* are lower on average in cores from cooler waters (E49–19), and still lower in samples from cool subAntarctic waters (compare tops of cores in Fig. 1 and core-top data in Fig. 2). This suggests that temperature-related gradients exist in Sr and Mg concentrations. If they did, the down-core variations may reflect climatically induced periodic expansions and contractions of the cooler water masses to the south of the core sites. Despite the possible existence of similar latitudinal gradients in both elements, palaeoclimatic correlations are weaker in Mg. This may be because the Sr ions are more tightly bound to the calcite lattice[23], but could also be explained by the stronger influence of clay contamination on the Mg composition[24,25].

Within individual species of planktonic foraminifera, the degree of dissolution on the sea floor has been shown[10] to affect the Mg concentration; a less dissolved sample is more enriched in Mg compared with a sample of the same species subjected to stronger dissolution. Differential susceptibility to dissolution between glacial and interglacial episodes could, therefore, also explain the trends in Mg. To determine dissolution effects on *G. bulloides* and *G. inflata*, we analysed recent subAntarctic core-top samples from the Maurice Ewing Bank (eastern Falkland Plateau), South Atlantic Ocean. No biogeographic

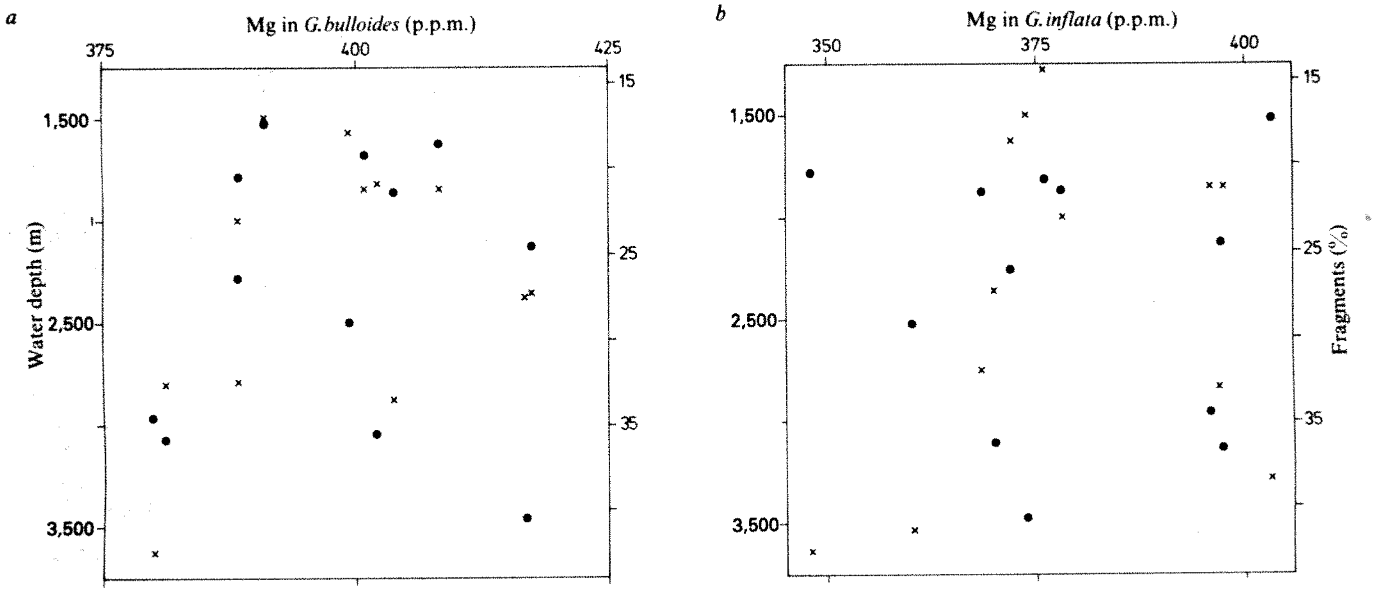

Fig. 2 Mg concentrations in *G. bulloides* (*a*) and *G. inflata* (*b*) in relation to water depth and degree of fragmentation of planktonic foraminiferal tests in cool subAntarctic core-top samples (Eltanin and Islas Orcadas) from the Maurice Ewing Bank, South Atlantic Ocean. Mg is not related to these parameters, which indicates that it is not affected by calcium carbonate dissolution as suggested previously[10]. ●, water depth; ×, % fragments.

Table 3 Cross-correlation coefficients among trace element compositions in *G. bulloides* and *G. inflata*, and palaeoclimatic indices in cores E49–19 and E48–22

E49–19

	Total fauna	% Sinistral *N. pachyderma*
Sr in *G. bulloides*	0.80*	−0.70*
Sr in *G. inflata*	0.77*	−0.69*
Mg in *G. bulloides*	0.64*	−0.51*
Mg in *G. inflata*	0.57*	−0.43*

E48–22

	Total fauna	% Sinistral *N. pachyderma*	$^{18}O/^{16}O$
Sr in *G. bulloides*	0.54*	−0.50*	−0.69*
Sr in *G. inflata*	0.19	−0.13	−0.38†
Mg in *G. bulloides*	0.43†	−0.36†	−0.44‡
Mg in *G. inflata*	0.30	−0.27	−0.29

These coefficients were determined for lags of zero, where correlations are normally at a maximum.
* $P \leq 0.001$; †$P \leq 0.05$; ‡$P \leq 0.01$.

differences exist over this narrow latitudinal belt (50–51°S), and differences in Mg should be due to dissolution. The Mg content does not change with water depth, and is also not related to the degree of fragmentation of the planktonic foraminiferal tests (Fig. 3). The degree of fragmentation has been shown[26,27] to represent a dissolution index in marine sediments. Therefore, it is less likely that the Mg signals in the cores are affected by dissolution. Likewise, no dissolution effects were found on Sr, which is in agreement with previous observations[28].

The results indicate that Sr concentrations in *G. bulloides* and *G. inflata* closely follow the late Quaternary climatic variations. The material available allowed only single analyses per sample; the precision of individual sample estimates could be improved by replicate analyses. Also, with further refinements of laboratory techniques, much of the 'noise' in the Sr curves might be reduced, which could aid in clarifying the palaeoclimatic signals. If so, Sr concentrations in these and other planktonic foraminiferal species, are a new independent means for palaeoclimatic analysis of Quaternary and, possibly, older sediments.

This research was supported by grant G4076-101 from the Swedish Natural Science Research Council. We thank Drs M. L. Bender, J. P. Kennett, F. T. Manheim and L. Sjöberg for helpful comments, and D. S. Cassidy for providing the material from the South Atlantic. Chemical analyses were made by Adnan Fahmy, Stockholm University.

Intra-sex and inter-sex sibling interactions as sex ratio determinants

P. D. Taylor

Department of Mathematics and Statistics, Queen's University,
Kingston, Ontario, Canada K7L 3N6

Fisher[1] produced the first general argument that a random-mating sexually-reproducing population should devote equal reproductive resources to the production of male and female offspring, while Hamilton[2] considered several unusual situations in which the expenditure of reproductive resources should be biased towards one sex or the other. His 'host' model has been widely cited[3–6] and at least three factors proposed as the cause of the sex ratio bias: local mate competition, sib-mating and inbreeding. The problem of which of these factors is the real cause of the biased sex ratio seems important in view of the large number of apparently different but often closely related sex ratio models which are now being proposed. It would be useful to have ways of classifying them according to the presence of different factors which affect the equilibrium sex ratio. Here, I present a general equation (equation (2)) for differential change in fitness which exhibits the equilibrium sex ratio as achieving a balance between the factor contained in Fisher's standard grandchild argument[1] and a second factor resulting from intra-sex sibling interactions over reproductive resources. In particular, I analyse Hamilton's host model[2] for the presence of these different factors.

I will present the model for the special case of discrete non-overlapping generations. Although many of the phenomena I wish to study lie outside this special case, the formulation of the model is complicated by the mixing of generations, and it seems best to start with a simple situation. We divide the life cycle of the organism into two phases. Phase 1 encompasses the time from birth to the point at which some significant sex-specific behaviour begins, and phase 2 continues from there to the birth of the next generation. The purpose of the model is to relate the effects of sex-specific sib interactions in phase 2 to the equilibrium sex ratio.

Suppose in the population a typical mated female produces a total of x^* daughters and y^* sons at the end of phase 1. Consider a rare female who manages to produce x daughters and y sons. Her fitness in the $*$-population will be

$$w(x, y) = D(x, y)x + S(x, y)y \qquad (1)$$

where D is her expected ultimate genetic contribution through daughters per daughter and S is her expected contribution through sons per son. If at the end of phase 1, the offspring disperse at random into the general population, with no further non random sib interaction, then $D(x, y)$ and $S(x, y)$ are constants equal to their values D^* and S^* at (x^*, y^*); but otherwise they may not be constant.

Constraints operating during phase 1 will restrict the possible values of x and y in the population to a one-parameter family parameterized by the proportion r of reproductive resources allocated by the mother to the production of sons. In the simple case of a linear interchange between sons and daughters, with both sexes equally expensive, we have $x = K(1-r)$ and $y = Kr$, where K is the litter size. With this parameterization, w, D and S become functions of r and the value of $\mathrm{d}w/\mathrm{d}r$ at $r = r^*$ (the value giving x^* and y^*) is a measure of the evolutionary pressure for an increase in r^*. If $\mathrm{d}w/\mathrm{d}r > 0$ we expect the population to evolve towards an increase in the proportion of resources allocated to the production of sons; if $\mathrm{d}w/\mathrm{d}r < 0$, this proportion should decrease. Now, differentiating equation (1),

0028-0836/81/190064—03$01.00

$$\frac{dw}{dr} = \left[D^*\frac{dx}{dr} + S^*\frac{dy}{dr}\right] + \left[\frac{\partial D}{\partial x}\frac{dx}{dr} + \frac{\partial D}{\partial y}\frac{dy}{dr} + \frac{\partial S}{\partial x}\frac{dx}{dr} + \frac{\partial S}{\partial y}\frac{dy}{dr}\right] \qquad (2)$$

where everything is evaluated at r^*. The second term on the right measures the effect of sibling interactions in phase 2 on the mother's reproductive success, and it vanishes in the absence of these. Let us interpret the four summands of this term.

The partial derivative $\partial D/\partial x$ measures the change in the quantity 'fitness through daughters per daughter' per extra daughter, with number of sons, y, held constant. Thus, it measures the influence of extra daughters on the reproductive success of each daughter. For example, competition among daughters for reproductive resources during phase 2 would tend to make $\partial D/\partial x < 0$. Similarly, the analogous term $\partial S/\partial y$ measures absence of competition among brothers for reproductive resources. The cross term $\partial D/\partial y$ measures the influence of extra sons on the reproductive success of each daughter and similarly $\partial S/\partial x$ measures the influence of extra daughters on the reproductive success of each son.

Let us consider some examples. Clark[7] has studied African galagos in which young males disperse, but females remain within their home ranges and compete with their mother and sisters for reproductive resources (space, food). The resulting competition between sisters may contribute negatively to $\partial D/\partial x$. In MacDonald's foxes[8], females form cooperative breeding groups in which non-breeding vixens seem to confer benefits on the mother. There is strong evidence that members of a group are closely related, contributing positively to $\partial D/\partial x$.

Where males enhance the reproductive success of their sisters, we may get a positive contribution to $\partial D/\partial y$. Woolfenden[9] has shown that male helpers at the Florida scrub jay nest can have a significant effect on reproductive output. In all three of the above examples much of the interaction is between generations and may have important effects on the equilibrium sex ratio. However, the simple assumption of our model of non-overlapping generations restricts our attention to interaction within the same generation.

If competition between males for mates is more intense between brothers than between unrelated males, this contributes negatively to $\partial S/\partial y$. Partial sib-mating often has this effect, because brothers are competing for their sisters. Positive contributions to $\partial S/\partial y$ may result from cooperative behaviour among brothers. This is apparently the case, for example, for the lions studied by Bertram[10], who often hunt together and protect one another.

Partial sib mating also contributes positively to $\partial S/\partial x$, since extra daughters will increase the reproductive success of the sons. It is not so easy to find other examples in which daughters affect the reproductive success of their brothers. Pickering[11] describes a parasitoid wasp in which larval sibs growing on the host pupa compete for food. There is evidence that female larvae behave less altruistically towards their brothers than their sisters. An extra sister will affect both male and female reproductive success, but the effect on males may be greater.

To make specific calculations, we must find expressions for D and S in terms of x, y, x^* and y^*. In the above example of Pickering, the organisms are haplodiploid, and the resulting genetic asymmetry between males and females makes it difficult to find comparable measures for D and S. In this case special arguments are required[6,12]. The calculation of equilibrium sex ratio is further complicated by a conflict between mother and daughter over sex ratio[3,13]. In our calculations I will assume a diploid population. In this case, D and S can be calculated using the common measure of mated females; each mated daughter counts 1 and each female mated exclusively by a son counts 1 (with shared matings discounted by the appropriate factor). From this method of counting it follows that $D^*x^* = S^*y^*$.

The equilibrium value of r^* is obtained by setting dw/dr, given by equation (2), equal to zero. An examination of the various terms of equation (2) at equilibrium will display the different forces (on the value of r^*) which are held in balance at equilibrium.

As a normative example, consider Fisher's standard situation[1] in which offspring disperse after phase 1 and mate at random. Then $D(x, y) = D^*$, $S(x, y) = S^* = D^*x^*/y^*$, $x = K(1-r)$ and $y = Kr$. Therefore, all partial derivatives of D and S vanish, and equation (2) becomes

$$-D^*K + D^*K(1-r^*)/r^*$$

which, when set equal to zero, gives the equilibrium value $r^* = \frac{1}{2}$. We will refer to the first bracket in equation (2) as the Fisher term, as this is the term which must vanish at equilibrium in his standard model.

In Hamilton's model[2], mated females collect on hosts in random groups of size N to produce and raise K offspring each. At the start of phase 2, the KN offspring mate at random among themselves, and the mated females go out into the general population to form new host groups and start the cycle again. Because a mutant female is rare we can assume the other females in her host group are normal. Hence, $D(x, y) = D^*$ and $S(x, y) = D^*(x + (N-1)x^*)/(y + (N-1)y^*)$. With these expressions both partial derivatives of D vanish, $\partial S/\partial x$ is positive because of the sib-mating and $\partial S/\partial y$ is negative because of male reproductive competition resulting from the sib-mating. Then equation (2) has the form

$$D^*\left[\frac{dx}{dr} + \frac{x^*}{y^*}\frac{dy}{dr}\right] + \left[\frac{\partial S}{\partial x}\frac{dx}{dr} + \frac{\partial S}{\partial y}\frac{dy}{dr}\right]$$

Since $dx/dr < 0$ and $dy/dr > 0$ both terms in the second bracket are negative, and both act in the same way on r^*. At equilibrium the Fisher term must be positive, requiring a female-biased sex-ratio. With $x = K(1-r)$ and $y = Kr$, the equilibrium ratio turns out to be $r^* = (N-1)/2N$. Thus, the female bias, which is often loosely thought to result from sib-mating, actually results from two different forces: the effect of extra daughters on male mating success, and the effect of fewer sons on male reproductive competition.

Finally, the general model applies equally well to the model of Charnov[14] for barnacles and Fischer[15] for coral reef fish, of sex allocation in hermaphrodites. (Replace mated female by individual, daughter and son by egg and sperm, and the process of mating by that of fertilization.) Each individual delivers its sperm to fertilize the eggs of N other individuals, and has its own eggs fertilized by, on average, N other individuals. As before a linear tradeoff is assumed between production of eggs x and sperm y. Thus $D(x, y) = D^*$ and $S(x, y) = D^*Nx^*/(y + (N-1)y^*)$. This is formally the same as Hamiltonian's model, except that we have removed the possibility of sib-mating, and $\partial S/\partial x$ is now zero. However, $\partial S/\partial y$ is the same as before, again forcing the Fisher term to be positive, creating a female-biased equilibrium ratio, this time, only through the effect of fewer sons on male reproductive competition.

The significance of equation (2) is that it resolves the evolutionary pressure on r^* into a sum of two factors which are held in balance at equilibrium: the standard Fisher factor and a second factor containing the effect of intra- and inter-sex sibling interactions. This second factor again resolves into four terms. Different sex ratio models can be compared according to the presence of these factors. Sib-mating (or selfing in hermaphrodites) or more generally mating between relatives, often contributes to these factors, but the inbreeding which results, in itself, has no role in determining sex ratio.

This research was supported by a grant from the Natural Sciences and Engineering Research Council of Canada. I thank Michael Bulmer for many discussions which sharpened my understanding of the causes of sex ratio bias and George Williams for valuable comments on the first draft.

Retinal projection in a non-visual area after bilateral tectal ablation in goldfish

S. C. Sharma

Department of Ophthalmology, New York Medical College,
Valhalla, New York 10595, USA

If, in the adult goldfish, one optic tectum is ablated, the regenerating optic axons from the contralateral retina innervate the remaining tectum, where they form a retinotopically ordered map[1–3]. The pathway for this induced ipsilateral projection[1] coincides with many of the pathways which normally connect the two tecta, but early in regeneration the optic fibres also enter non-visual centres to which there are degenerating tectal efferent pathways to follow[4]. We have therefore now investigated the fate of regenerating optic axons in goldfish from which both optic tecta have been removed; they are found to innervate non-visual centres, where again they generate a retinotopic map.

Fifteen adult goldfish (10–12 cm long and 2.5 yr old at the time of surgery) were anaesthetized with 0.5% MS222. The tectum was ablated bilaterally and extreme care taken not to damage the diencephalon, which joins the tectum at its rostral pole. Animals were allowed to survive between 380 and 620 days after tectal removal before electrophysiological mappings of the retinal projections were made. In five animals, the right eye was injected with 10 μl of [3,4-^{3}H]proline (specific activity 50 Ci mmol^{-1}) 1 day before mapping; the brains of these animals were processed for autoradiography. In five other animals, after visuotopic mapping, the right optic nerve was cut and 50% horseradish peroxidase (HRP) solution (Sigma type VI) applied to the cut end. The retinal projection of the remaining five animals was studied anatomically, using HRP orthograde transportation after injection of 5–7 μl of 30% HRP intraocularly. In the HRP studies, animals were killed 1–3 days later and processed for HRP reaction[5].

Autoradiographic analysis showed that, in addition to a high concentration of termination sites in the primary diencephalic visual centres, the optic fibres terminated in most tectal efferent areas[6,7]. In normal fish these areas do not receive direct retinal fibre terminations[8,9] and include the tori semicircularis, nucleus isthmi, nucleus of the rostral mesencephalic tegmentum, dorsolateral tegmental nucleus and nucleus reticularis superior of the hindbrain. In addition, radioactive grains were seen in the rostral valvula cerebelli.

Orthograde transport of HRP studied in 10 animals basically confirmed the autoradiographic identification of target centres of regenerating optic axons (Fig. 1). Most optic fibre fascicles in the regenerated optic nerve appear linearly arranged. The optic fibre fascicles separate from the ventral part of the optic tract at the diencephalic level and travel caudally before arborizing. The first bundle of optic fibres detached itself from the nerve at its rostral ventral position then the next dorsal bundle did the same. The uppermost portion of the nerve travelled farthest and apparently terminated in the valvula cerebelli (Fig. 1*b*, *c*). This pattern of axonal trajectories from the optic nerve is similar to that observed in normal goldfish (S.C.S., unpublished observation).

The visuotopic projection of either the right or left eye was determined in 10 animals by electrophysiologically mapping the area directly beneath the ablated tectum. This area includes the valvula cerebelli medially and the torus semicircularis laterally and ventrally. The visuotopic projection represented in Fig. 2 was essentially similar to that seen in eight other animals and was confined to the rostro-medial portion of the contralateral valvula cerebelli. The projection map in the remaining animal was incomplete. The representation of the superior contralateral visual field was similar in its extent to a normal visuotopic projection onto the contralateral tectum. The receptive field sizes of the multi-units were in the 10–15° range, which is similar to the size of normal retinotectal units.

In three animals, in addition to the projection to the valvula cerebelli, large receptive fields (60–80°) were recorded from the torus semicircularis and were mostly from the inferior visual field. It was not possible to record any meaningful visuotopic maps from the torus. Large receptive field units were also recorded from the the deeper tegmental areas.

These results imply that, in the absence of both optic tecta, the optic axons can regenerate to non-visual centres and generate a retinotopic projection which approximates to the normal map. As the retinotopic map represents presynaptic optic fibre terminations, it is not certain whether fibres formed synaptic connections with cells in anomalous areas. Anomalous connections to non-visual targets following one tectal removal have been reported in various vertebrates[10–13].

The valvula cerebelli extend rostrally into the optic ventricle and lie apposed to the ventral surface of the dorsal tectum

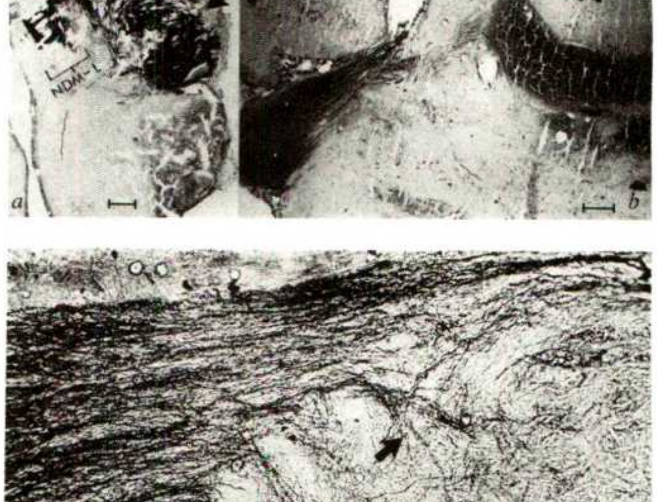

Fig. 1 *a*, Coronal section through the diencephalon showing contralateral retinal projection in a fish 380 days after tectal ablation where the eye was injected with HRP. The medial diencephalic retinal target areas (nucleus dorsalis medialis and lateralis, NDM, NDL are heavily labelled. The arrow points to a neuroma (a misleading entity as neuroma does not appear in sagittally sectioned brains). Scale bar, 100 μm. *b*, Sagittal section through the brain of a fish 390 days after tectal ablation. The arrow points to the fibre entering the valvula cerebelli (VC). Scale bar, 100 μm. *c*, High power photomicrograph of the optic nerve from *b*. The arrows point to optic fascicles separating from the nerve. Scale bar, 100 μm.

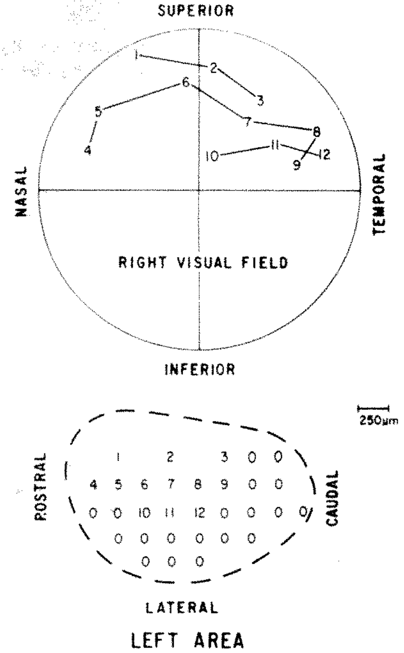

Fig. 2 The visual projection map from the right eye to the left portion of the valvula cerebelli, marked in the diagram as left area. Each number in the visual field shows the position of the stimulus that evoked maximum potential, recorded by an electrode at the position indicated by the same number on the left area. Empty circles represent electrode positions from which visually evoked potentials could not be recorded.

at the level of the diencephalic tegmental junction. Similarly, the rostral extent of the torus semicircularis begins at the level of the posterior commissure and is apposed to the ventral surface of the ventrolateral tectum. Removal of optic tecta is followed by injury and deafferentation to these structures, with the regenerating optic fibres entering them at their rostral poles. It is suggested here that innervation of the regenerating optic axons is facilitated by degenerating debris.

These results contradict the recent findings in frogs of Bohn and Stelzner[14], who, after unilateral tectal ablation and lesion in the isthmal region, showed that regenerating optic axons did not innervate the non-visual areas deafferented by isthmal transection. Note that in Bohn and Stelzner's study, one optic tectum was always left intact[14]; when a tectal tissue is left intact, optic fibres preferentially innervate it[15].

In normal goldfish, most optic axons terminate in the contralateral tectum. However, in the absence of both tecta, regenerating optic axons innervate non-visual areas and apparently form a topographically ordered map. Hence, it could be concluded that the tectum is not necessary for the formation of an ordered projection by the optic axons. The present results support the possibility that topography is intrinsic to the optic axons and that the formation of an ordered map may be guided by the presence of general axial cues (that is, rostro-caudal, medio-lateral) within the brain tissue.

Birds can overcome the cardenolide defence of monarch butterflies in Mexico

Linda S. Fink* & Lincoln P. Brower†

* Webster Center for the Biological Sciences, Amherst College, Amherst, Massachusetts 01002, USA
† Department of Zoology, University of Florida, Gainesville, Florida 32611, USA

Flocks of black-backed orioles (*Icterus abeillei* Lesson) and black-headed grosbeaks (*Pheucticus melanocephalus* Swainson) eat several hundred thousand monarch butterflies (*Danaus plexippus* L.) in the dense overwintering colonies in central Mexico, and in 1979 were responsible for over 60% of the butterfly mortality at several sites[1]. Such predation is unusual because, during larval development the aposematically coloured monarch butterfly sequesters cardenolides from its milkweed foodplants (Asclepiadaceae)[2,3]. These bitter-tasting heart poisons cause vomiting in 12 species of birds in 9 families (refs 4–9, and L. P. Brower, unpublished observation), although the domestic chicken, Japanese quail, hedgehog, mouse and sheep[8,10,11] have been shown to be insensitive to their emetic effects. Extensive predation of monarch butterflies by birds has never been observed except in Mexico. We report here that the Mexican butterflies are weakly emetic, and that taste discrimination by orioles and cardenolide insensitivity of grosbeaks allow these birds to feed freely on monarch butterflies.

To verify that a substantial proportion of the Mexican butterflies contain cardenolides, we collected 198 of these in January 1980 from Site Alpha[1] and stored them on dry ice before spectrophotometric assay[12,13]. In common with wild populations from Massachusetts and California[14], they varied widely in total cardenolide content (Fig. 1).

Our first hypothesis was that the birds taste each butterfly captured, release the emetic (bitter) ones, and kill and eat only the individuals containing little or no cardenolide[15]. Observing the birds through binoculars, we saw orioles attack 98 butterflies and release 75 without apparent harm; grosbeaks similarly released 65 of 92. Because orioles and grosbeaks never eat the butterfly wings we were able to measure the cardenolide content of butterflies killed and partly eaten by the birds. We collected damaged butterflies from the forest floor during feeding bouts from 7 to 19 January 1980, and spectroassayed one fore and one hind wing of each. The cardenolide concentrations of the wings of 177 butterflies damaged by grosbeaks, 142 damaged by orioles and 150 undamaged (control) butterflies are shown in Fig. 2. The frequency distributions of the three samples are very similar which provides strong evidence that the birds kill monarch butterflies randomly with respect to cardenolide content.

Our second hypothesis, based on our observations that the birds eat only parts and drop large portions of the butterflies, was that the birds ate less of the more emetic individuals. Table 1 relates the cardenolide content of the 142 butterflies damaged by orioles to the degree to which they were eaten by the birds. Clearly orioles eat fewer of the butterflies with more cardenolide content ($P < 0.005$). Damage to thoraces showed the same relationship: mean cardenolide concentration of wings of butterflies with heavily damaged, slightly damaged and undamaged thoraces was 32, 44 and 55 μg per 0.1 g, respectively (one way analysis of variance, $F_{2,138} = 4.8$, $P < 0.01$). Thus, although individual butterflies were not initially protected from predation by containing more cardenolide, once killed, the amount of butterfly eaten by an oriole was inversely proportional to cardenolide content. The oriole further reduces its cardenolide intake by stripping out the thoracic muscle and abdominal contents without eating the cuticle in which these compounds are more highly concentrated[16]. Table 2 shows a similar analysis of the 177 butterflies damaged by grosbeaks which indicates no overall relationship between the extent of damage and cardenolide content ($P = 0.32$). In contrast to the orioles, grosbeaks consume cuticle as well as internal tissues. Thus, the orioles are selective once they have killed the butterflies, whereas the grosbeaks kill and continue to eat the butterflies randomly with respect to cardenolide content.

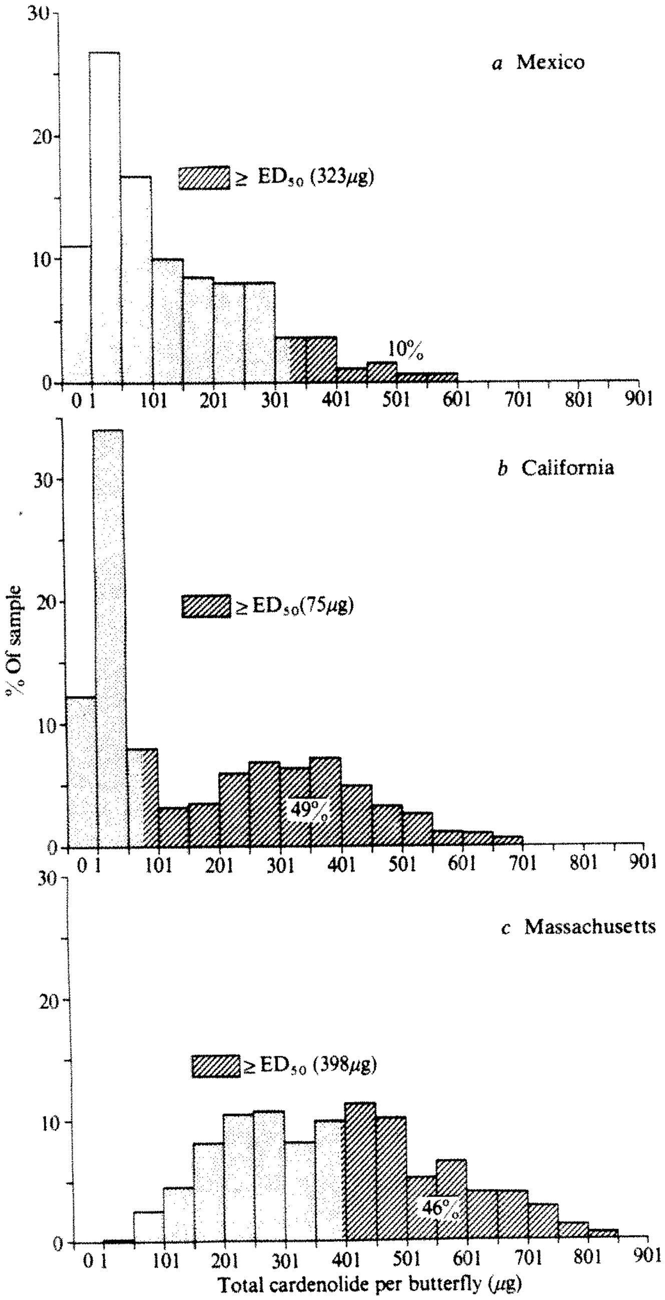

Fig. 1 *a–c* Compare total cardenolide per butterfly in overwintering monarch butterflies from Mexico (*a*) and California (*b*), and in autumn migrants from western Massachusetts (*c*). The hatched portions of the histograms are butterflies which contain sufficient cardenolide to cause a blue jay to vomit (that is, contain ≥1 blue jay ED$_{50}$ unit per butterfly). Because the Mexico population combines weakly emetic cardenolides with a high proportion of low cardenolide butterflies, only 10% carry more than one emetic dose, in contrast to 49 and 46% of the California and Massachusetts butterflies. The potential protection of the Mexico population against sensitive bird predators is therefore much reduced. The data for the Massachusetts and California butterflies are calculated according to the method of Brower *et al.*[13] from previously published absorbance values[14]. *a*, Site Alpha, 1980: $n = 198$, $\bar{x} = 128$, s.d. = 126, range 0–551. *b*, Muir Beach, 1971: $n = 351$, $\bar{x} = 165$, s.d. = 179, range 0–684. *c*, Hockanum, 1971: $n = 355$, $\bar{x} = 384$, s.d. = 172, range 34–850.

Table 1 Cardenolide concentrations (μg per 0.1 g dry weight of the wings) of monarch butterflies eaten to various degrees by black-backed orioles at the Site Alpha Mexican overwintering colony, January 1980

Damage category	% Of abdominal contents eaten	Sample size	Cardenolide concentration (μg per 0.1 g dry weight)		
			$\bar{x}$	s.d.	Range
a	91–100	29	20	30	0–106
b	51–90	43	31	41	0–156
c	11–50	32	49	50	0–204
d	1–10	25	57	58	0–234
*e**	0	13	65	72	0–208
Entire sample		142	41	50	0–234

The butterflies are grouped into five categories of decreasing abdominal damage. The data indicate a highly significant (one way ANOVA $F_{4,141} = 3.91$, $P < 0.005$) inverse relationship between the cardenolide content of the butterflies and the extent to which orioles eat them. Duncan's multiple range test indicates that categories *a* and *b* differ from categories *c–e* ($P < 0.05$).

* Abdomen unharmed, thorax partly eaten.

We next tested the sensitivity of the orioles and grosbeaks to the presumed emetic effect of the butterflies. For comparison with previous data, we first used our standard blue jay emetic dose 50 (ED$_{50}$) assay in which predetermined doses of dry powdered butterflies are force-fed in gelatin capsules to jays[3]. (The ED$_{50}$ is that dose at which there is a 50% probability that a bird will vomit.) In the first test we combined 24 butterfly abdomens from Site Alpha (January 1980 collection), and fed four jays increasing doses up to 590 mg of powder containing 236 μg of cardenolide—no bird vomited. This high dose, equivalent in weight to more than six abdomens, reached the upper physical limit of the test. To make a more potent force-feeding powder we screened butterflies for cardenolide content and selected those with substantial amounts. Two wings from each of 453 Site Alpha butterflies were tested qualitatively with the spectroassay reagents, and only the abdomens of those showing a positive reaction were used ($n = 158$). This screening increased the concentration of cardenolides in the force-feeding powder from 40 to 105 μg per 0.1 g. We assumed, as determined in the Massachusetts and California populations[14,17], that we did not differentially select for particular cardenolides. For 25 jays the ED$_{50}$ was 323 μg of cardenolide per 85 g (95% confidence limits = 247–425 μg).

We next tested the rosebreasted grosbeak (*Pheucticus ludovicianus* L.) which is closely related to the black-headed grosbeak[18]. Six birds were force-fed the powder previously given to the jays in doses from 132 to 331 μg of cardenolide (that is, from 0.41 to 1.0 blue jay emetic units). None of these birds vomited. Two additional grosbeaks were force-fed abdomens of butterflies reared on *Asclepias curassavica* L., previously shown[19] to contain cardenolides 7.5 times as emetic as those of the Mexican monarch butterflies (Jay ED$_{50}$ 43 μg per 85 g). One bird was fed an intact abdomen, estimated by spectroassay of a sibling to contain 270 μg of cardenolide. The second was fed a capsule of powdered abdomens containing 700 μg (16 blue jay emetic units) of cardenolide. Neither bird vomited, although both showed other signs of poisoning[5,20].

In January 1981 at Site Alpha, 10 black-headed grosbeaks and 11 black-backed orioles were force-fed powder made from monarch butterflies collected in Santa Cruz, California, the jay ED$_{50}$ of which was previously estimated to be ~75 μg (ref. 14).

All birds were fed 130–140 mg of powder containing 146–157 μg of cardenolide, except one oriole that was fed half this dose. As controls, four additional orioles were force-fed 130–140 mg of ground Mexican butterfly abdomens, which contained low cardenolide content (35–38 μg). All 11 experimental orioles vomited, but none of the grosbeaks or control orioles became ill. These data show that the oriole is sensitive to the emetic effects of the cardenolide, but that the grosbeak is not.

The ED_{50} of the Mexican butterflies, combined with the data shown in Fig. 1a, shows that most of the Site Alpha monarch butterflies contain less than one emetic unit of cardenolide. The Mexico and California populations have a high proportion of butterflies with little or no cardenolide and contrast with the Massachusetts population in which no butterfly completely lacks poison. However, the cardenolides in both the Mexico and Massachusetts populations are much less emetic than those in the California butterflies. Consequently, the probability of any bird ingesting an emetic dose in Mexico is lower than in either of the other two populations (Fig 1b, c).

We offer three possible explanations for the high percentage of relatively non-emetic butterflies at Site Alpha. Total cardenolide decreases with time in overwintering monarch butterflies[21,22], and may result in increasing predation as the winter progresses. Second, Urquhart[23] has suggested that butterflies from different regions of the eastern breeding range may migrate to geographically distinct overwintering sites in Mexico. If this is correct, then other Mexican sites may contain more emetic butterflies reflecting regional differences in the local milkweed floras[24]. However, heavy bird predation has been observed at all known sites[1]. A third more general explanation results from preliminary TLC separations of the cardenolides in the Site Alpha butterflies. These suggest that a large proportion of the butterflies fed as larvae on *Asclepias syriaca* L. and/or *Asclepias speciosa* Torr., both of which contain low-potency cardenolides[9,25]. Agricultural and land use changes have increased the abundances of both plants in North America[24,26].

Our finding that individual monarch butterflies containing high concentrations of cardenolides are not protected against two major bird predators raises questions about the part played by these compounds in the butterflies' defence. It is possible that some of the overwintering butterflies which were rejected by the birds without being killed may be protected by other distasteful or toxic substances, such as pyrrolizidine alkaloids[27,28]. Alternatively, the chemical defence of the monarch butterfly may be ineffective in these overwintering sites and the only advantage to individuals within the colonies may derive solely from a reduced probability of being killed, comparable with the advantages of herding[1,29]. It is possible that the extensive predation is a recent phenomenon attributable to changes in the relative abundances of the milkweed species in eastern North America.

Table 2 Cardenolide concentrations (μg per 0.1 g dry weight of the wings) of monarch butterflies eaten to various degrees by black-headed grosbeaks at Site Alpha, January 1980

	Damage category and description	Sample size	Cardenolide concentration (μg per 0.1 g dry weight)		
			$\bar{x}$	s.d.	Range
a	Lacking abdomen and 2–3 wings	41	40	41	0–128
b	Lacking abdomen and 1 wing	19	42	42	0–129
c	Lacking abdomen only	30	42	47	0–207
d	Abdominal contents squeezed out, exoskeleton not eaten	9	20	26	0–77
e	Abdomen slightly squeezed	7	84	106	0–290
f	Thorax damage only	18	46	50	0–199
g	Lacking head only	10	78	65	0–186
h	Lacking 1–3 wings only	12	35	56	0–177
i	Moribund (unable to fly but with no visible damage)	31	33	51	0–169
	Entire sample	177	42	51	0–290

The butterflies are grouped into nine damage categories, the mean cardenolide concentrations of which do not differ significantly (one way ANOVA $F_{8,176} = 1.17$, $P = 0.32$). The absence of an obvious relationship between degree or kind of damage and cardenolide concentration indicates that once they have attacked monarchs, grosbeaks, unlike orioles, feed indiscriminately on them.

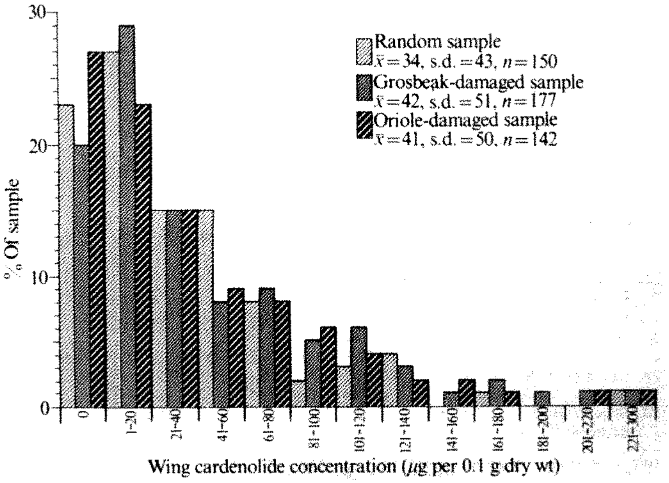

Fig. 2 Frequency distributions of cardenolide concentrations in three samples of overwintering monarch butterflies from Site Alpha in Mexico, January 1980. The oriole and grosbeak samples are partly eaten butterflies dropped to the ground by the birds and collected by us during their feeding bouts in the butterfly colony. The random sample consists of undamaged live butterflies collected within the colony. Two wings per butterfly were analysed. To verify that wing concentration reflects that of the body, we separately analysed the wings and intact bodies of 50 male and 50 female monarch butterflies and found a high correlation between μg of cardenolide per 0.1 g of wing and the total μg per wingless body; $n = 100$, $r = 0.88$, $F = 320$, $P < 0.0001$. The figure shows that the concentrations of the cardenolides in the butterflies damaged by both bird species are distributed similarly to those of the random collection. Because the three distributions are skewed, we subjected all data to $\log_{10}$ transformations and compared the three means by one-way analysis of variance ($F_{2,466} = 0.91$, $P = 0.40$). These data provide strong evidence that cardenolides give individual butterflies at Site Alpha no obvious protection from either orioles or grosbeaks.

This research was supported by NSF grant DEB78-10658 with L.P.B. as principal investigator, and by the Leslie T. Webster Fund of Amherst College. We thank E. Romero, J. and E. de Jesus, R. Eclosion hormone may control all ecdyses in insects

James W. Truman*, Paul H. Taghert,
Philip F. Copenhaver, Nathan J. Tublitz
& Lawrence M. Schwartz

Department of Zoology, University of Washington, Seattle,
Washington 98195, USA

The moulting process in insects is initiated and directed by the hormone 20-hydroxyecdysone[1], which causes the secretion of a new cuticle and the internal changes that are necessary for the new stage. When the new cuticle is complete, the old one is then shed or *ecdysed*. In Lepidoptera a neurosecretory peptide, eclosion hormone (EH)[2–4], triggers adult ecdysis by acting on the central nervous system to elicit the ecdysial motor programmes[5] and also causes other physiological changes associated with ecdysis[6]. Although it was originally thought that EH was used only for the rather specialized adult ecdysis[3], we report here that the hormone is used for all postembryonic ecdyses in the life history of moths, but its source varies with developmental stage. Moreover, EH may be common to a wide variety of insects. For the ecdyses of the adult[4], pupa[7] and the 5th instar larva of the tobacco hornworm, *Manduca sexta* (P.F.C., unpublished results), EH appeared in the blood before the start of the behaviour. Also, injections of partially purified EH caused precocious ecdysis of the three stages with 50% responses occurring at 0.3, 0.02 and 0.01 EH units, respectively.

Although EH seems to be associated with the ecdyses of the adult, pupa and 5th instar larva, the source of the blood-borne hormone varies. EH is distributed in the CNS between the brain and its neurohaemal organ, the corpora cardiaca (CC), and the ventral chain of segmental ganglia[8]. The roles of these two regions in the control of ecdysis were examined by determining their EH titres throughout the life history of *Manduca*.

As seen in Fig. 1, ~10^{-3} units of EH activity were extracted from heads or ventral ganglia at the time of hatching. Through the five larval instars, both tissues showed accumulation of hormone during the feeding period of each stage, followed by a plateau during the time of formation of the new cuticle for the next stage. In the case of the 5th instar, this plateau extended from the start of the wandering stage through the period of pupal cuticle production. At each ecdysis, a sharp drop was then seen in the hormone stores of the ventral ganglia. A drop was also observed in the hormone content of the head during ecdysis of the 2nd instar but no further depletions were detected in either whole heads or brains at subsequent larval ecdyses or at pupal ecdysis. Examination of the CC before pupal ecdysis revealed no detectable EH activity.

Adult development was marked by a gradual increase in the titre of hormone in the ventral ganglia. No depletion was seen at adult ecdysis and accumulation continued into adult life. Titre changes in the brain and CC during this time were more complex. Hormone levels increased in the brain through the first half of development but gradually declined during the second half. These changes were accompanied by a >100-fold increase in activity in the CC. This accumulation of hormone in the CC was apparently due to hormone transferred from the brain because when brains were removed from animals early in adult development and their CC later assayed for the presence of EH, the latter lacked any activity ($n = 5$). At adult eclosion the CC showed a 70% loss of activity. EH activity persisted in both structures through at least the first 4 days of adult life.

A major feature of the titre curves in Fig. 1 is the prominent depletion in stored hormone which occurs at each ecdysis. At the ecdyses of the adult, pupa and 5th instar larva, each drop coincides with the appearance of EH activity in the blood. Moreover, the magnitude of the depletions (0.7, 0.06 and 0.05 EH units, respectively) compares favourably with the dosages required to provoke ecdysis in the same stages. On the basis of these data we have concluded that the sudden drops observed at each of the six ecdyses represent a release of EH into the blood and therefore that all ecdyses in *Manduca* are triggered by EH.

A role for EH during embryonic development was determined using the relatively large embryos of the moth *Hyalophora cecropia*. Preliminary experiments indicated that EH was present in embryos, mainly in the head region. As seen in Fig. 2, significant quantities of EH activity appeared in the head on day 5 of development. The titre remained high for the next 2 days but then dropped sharply between days 7 and 8 and remained low until the time of hatching on day 10. This drop in stored hormone coincided with the ecdysis of an embryonic cuticle by the developing 1st instar larva within the egg. Thus, it seems that EH is involved in embryonic as well as postembryonic ecdyses.

Our data suggest that EH storage and release occurred in either of two regions of the nervous system—the brain–CC complex or the ventral ganglia. Partial chemical characterization of the ecdysis stimulating activity from both regions revealed a single peptide with properties extremely similar or identical to EH[8]. The two regions seem to function independently. Indeed, experiments on adult ecdysis of the giant silkmoths show that the brain controls EH release at this stage[2], whereas at an earlier stage (pupal ecdysis) in *Manduca*, the previous removal of the brain from wandering stage larvae did not interfere with the subsequent release of EH from the ventral ganglia[8]. These experiments, albeit on different moth species, together with the data in Fig. 1, suggest two anatomically distinct systems for the synthesis and release of EH. However, the final proof requires the identification of the EH neurones in both regions.

Release occurs from the ventral ganglia during all postembryonic ecdyses, except for that of the adult which is controlled by the brain–CC axis. In these ecdyses, the choice of release site is correlated with the nature of the control over EH release. The time of adult ecdysis is controlled by a circadian clock which, at least in the case of the silkmoths[2], is in the brain. This clock regulates adult ecdysis through the brain–CC system[3]. By contrast, there is no direct circadian control over the larval and pupal ecdyses, but they occur at a developmentally fixed time after the start of the moult[9]. These developmentally triggered ecdyses are controlled by the ventral ganglia neuroendocrine system. A circadian involvement in the embryonic ecdysis has not been determined. Thus it is not known whether the above correlation also holds in the embryo. The use of the brain system by the embryo may also be due to its being the earliest part of the CNS to mature[10]. The transition from brain regulation in the embryo to regulation by the ventral ganglia in larvae seems to occur gradually as ecdysis to the 2nd-stage larva uses both systems.

The search for EH in insects other than Lepidoptera has been suggestive but not conclusive[11,12]. However, in these studies

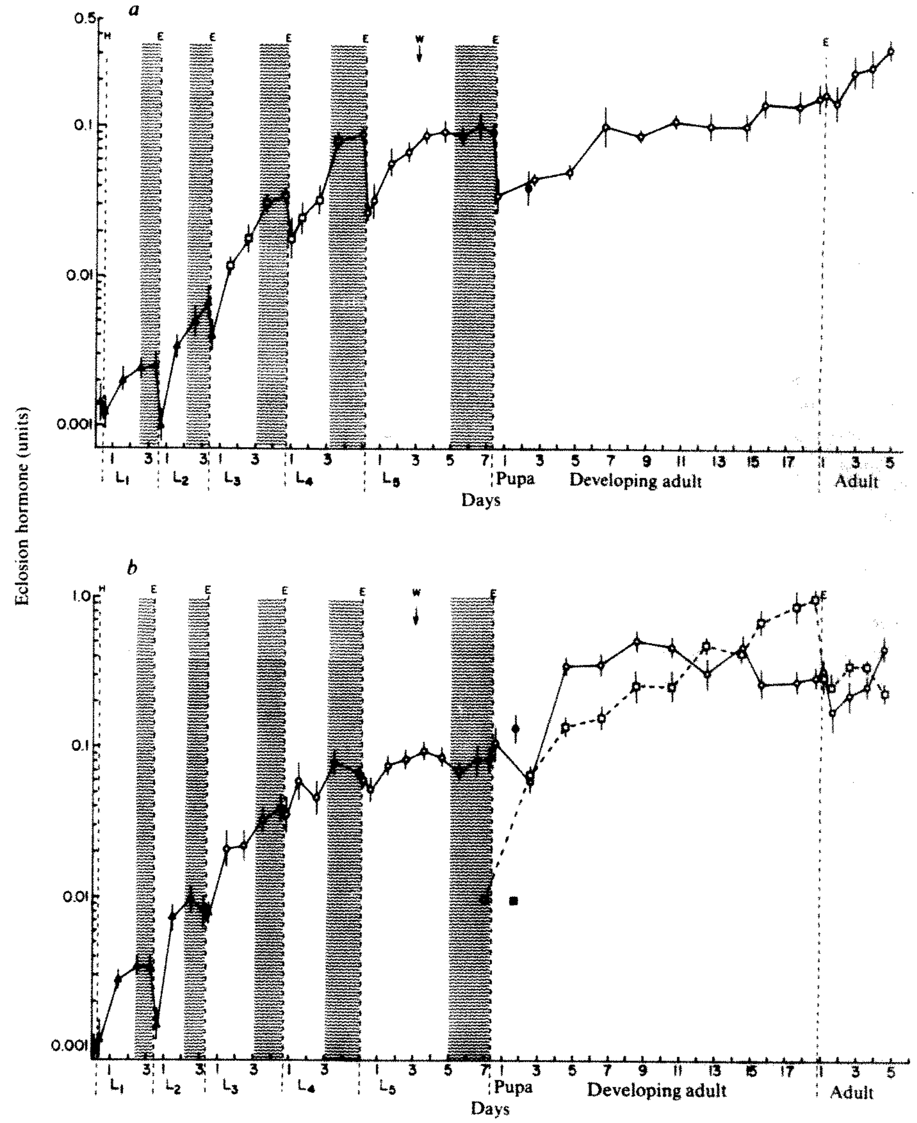

Fig. 1 Eclosion hormone activity extracted from the nervous system of *M. sexta* during its larval, pupal and adult stages. Depending on the stage, tissues from 5 to 300 animals were pooled, homogenized in saline with phenylthiourea, heat treated at 80 °C, centrifuged and the supernatant assayed for EH activity by injection into staged *Manduca* prepupae. The EH activity is expressed in units per animal (one unit being defined as the activity present in a CC pair from a *Manduca* on the last day of adult development). *a*, EH activity stored in the ventral ganglia. Symbols represent the hormone present in: △, mid-ventral strip of integument that included the segmental ganglia; □, abdominal and last two thoracic ganglia; ○, abdominal ganglia. *b*, EH activity present in cephalic structures. Symbols represent activity from extracts of: △, head and prothorax (the latter taken to insure inclusion of the CC); ○, brain and □, CC pair (the first two values represent the maximum amount of activity that could have been present but not detected in the conditions of the assays). At the times of hatching (H) and ecdyses (E), animals were selected ~4 h before (as judged by developmental markers) and 1 h after the event. W, start of wandering stage. The shaded areas represent the approximate time that new cuticle is being made in preparation for ecdysis (not indicated for adult development). The time marks along the abscissa correspond to lights-off for each day. Each determination is the mean (±s.e.) of at least nine assays. Solid symbols are from diapausing pupae.

only the brain was examined as a possible hormone source. The finding that the ventral ganglia controlled most of the ecdyses in *Manduca* prompted us to examine the ventral ganglia as well as the brain in a number of species. A preliminary survey revealed EH activity (as evidenced by the stimulation of precocious pupal ecdysis in *Manduca*[7]) in heat-treated extracts of nervous systems of juvenile forms from the hemimetabolous orders, Orthoptera (*Schistocerca*, *Melanopus*, *Periplaneta*) and Hemiptera (*Pyrrhocoris*), and the holometabolous orders, Coleoptera (*Dytiscus*), Trichoptera (*Dicosmoecus*) and Diptera (*Tipula*, *Calliphora*). These preliminary results should be regarded with caution because we have not yet shown that these activities from other orders are chemically similar to the moth EH, and that they are used to stimulate ecdysis in the insects in which they are found. Nevertheless, these results suggest that EH is present in a wide variety of insects and that it provides a general mechanism by which ecdyses are triggered in insects.

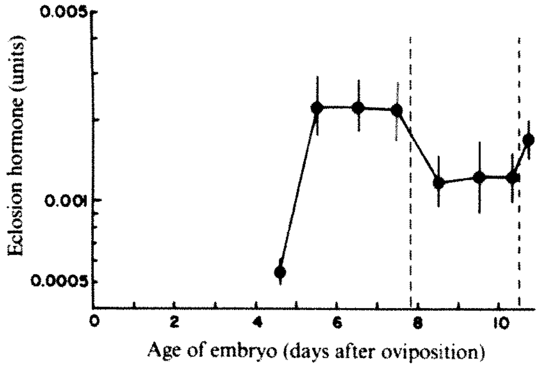

Fig. 2 Eclosion hormone activity extracted from the head and prothoracic segment of *Hyalophora cecropia* embryos during embryonic development. Activity is expressed as units per animal. Symbols represent the mean (±s.e.) of eight determinations. The time marks correspond to lights-off. The dashed vertical lines indicate the times of ecdysis of the embryonic cuticle and of hatching, respectively.

We thank Dr Shirley Reiss for technical assistance during part of this study and Professor Lynn M. Riddiford for helpful comments on the manuscript. Positional signal transmission in the developing chick limb

Lawrence S. Honig*

Department of Biology as Applied to Medicine, Middlesex Hospital Medical School, London W1P 7PN, UK, and Division of Developmental Biology, National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

* Present address: Laboratory of Developmental Biology, University of Southern California, GER-319, PO Box 77912, Los Angeles, California 90007, USA.

It has been suggested that the pattern along the antero-posterior axis of the embryonic developing chick limb arises from a gradient of diffusible morphogen[1,2] produced by a special region of cells on the posterior margin of the limb bud, called the polarizing region[3]. Grafts of posterior polarizing-region tissue to an anterior site in an embryonic chick wing bud result in mirror-image duplication of the limb bud; typically three extra wing digits are produced (Fig. 1*f*, *g*). Direct evidence for a long-range signal has, however, been lacking, and recently it has been suggested[4] that chick wing development might better be understood as resulting only from local, neighbour–neighbour-like interactions of the sort postulated to occur during regeneration of insect and amphibian limbs and insect imaginal disks[5]. As we report here, operations were performed in which chick wing buds were made host to grafts of leg bud responding tissue adjacent (posteriorly) to a grafted polarizing region (Fig. 2). The results showed that the pattern signal from the polarizing region can be transmitted through the leg tissue over distances of tens of cell diameters.

Double grafts in which leg tissue provides a living 'barrier' between grafted wing polarizing region and distal host chick wing tissue, are shown diagrammatically in Fig. 2. Leg tissue maintains its character in wings and when placed at wing bud tips develops into toes[6] which are recognizable through the patterns of their distinctively shaped cartilage elements and associated tissue (Fig. 1*h* and legend). (Many grafts also used quail marked tissue and the details of these will be presented elsewhere.) Sixty-six grafts were performed as described in Fig. 2 using leg anterior pieces ranging in width from 100 to 350 μm. In nearly all (61) cases the leg tissue, as expected, developed into recognizable toes. The important question was whether the signal from a grafted polarizing region could influence the wing tissue on the posterior side of the leg tissue barrier. In 34 cases (average width 215 ± 70 μm s.d.), only host wing digits were found posteriorly to toes (Fig. 1*e*), but in another 27 cases (average width 189 ± 57 μm s.d.) mirror-image duplicated wing digits appeared posterior to the toes (Fig. 1*a–d*). In general, leg anterior grafts of narrower width tended to yield limbs of this latter category, in which the posterior host tissue was influenced, while anterior grafts of large width provided more examples of posterior host tissue being unaffected.

Interpretations of these experiments depend on several considerations. First, control grafts of anterior leg tissue, without the additional polarizing region grafts, commonly did not give rise to any extra digits (Fig. 1*g*) in the resultant chick wings: out of 32 such operations, only 5 wings presented extra cartilage elements of which 4 possessed toe digits I and 1 had only an unidentifiable cartilage nodule. Therefore, it was the long-distance influence of the grafted polarizing region, not the interaction between the graft of the leg anterior tissue and the

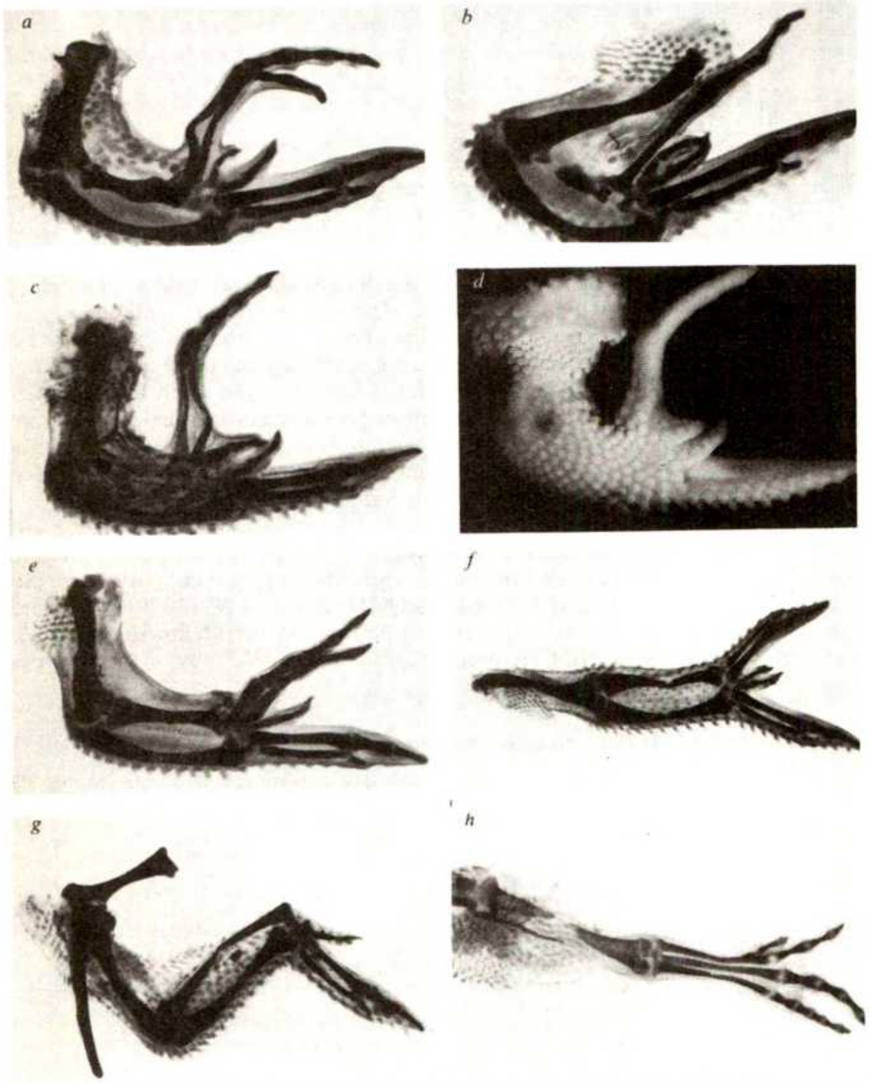

Fig. 1 Wholemount limbs from 10–12-day chick embryos (magnifications about ×6) following fixation, staining with alcian green 2GX, dehydration with ethanol and clearing with methyl salicylate[9]; limb *d* was not cleared. Wing digits are denoted by Arabic numerals; leg digits are represented by Roman numerals. Digit patterns are specified in anterior to posterior order. Toe digits (*h*) differ from wing digits (*g*) by the long thin metatarsals of II, III and IV and their more numerous phalanges. Toe I has some similarity to wing digit 2 but is distinguished by several features. Toe I normally arises not at the wrist but as an incomplete metatarsal of inverted triangular shape at distal metatarsal level. By contrast, metacarpal 2 arises at the wrist and is of thick rectangular shape with an anterior 'knob' at midlength. The first phalange of toe I is, in common with other proximal toe phalanges, of hour-glass shape: the basic cylindrical shape is constricted at the centre so as to resemble an 'X'; the first phalange of digit 2 is more like a narrow truncated cone whose proximal width is greater than that distally and is not constricted in the centre. The soft tissue of toe digits clings closely to the skeleton whereas it is more muscular and filled out for wing digits. At late stages, feather germs are present on avian wing digits but are not present on the toes which only develop distinctive scale primordia in these chicks and quail. *a–d*, Examples in which posterior host wing was influenced through a leg barrier: digit patterns are (*a*) III II 2 2 3 4, (*b*) II 2 2 3 4 and (*c*) 4 III 2 2 3 4. In *d*, specimen *c* is shown before it was cleared, showing the feather germs on the duplicate host digit (digit 2) and scales on the leg digit. *e*, Result of an operation in which posterior host wing was unaffected; the identifiable digit pattern is III II 2 3 4. *f*, Wing reduplication following graft of polarizing region only, with digit pattern 4 3 2 2 3 4. *g*, Wing with normal set of cartilage elements found after graft of leg anterior tissue alone, with digit pattern 2 3 4. *h*, Distal elements (tibia–fibula and foot) of normal control unoperated leg showing digit pattern I II III IV.

0028-0836/81/190072—02$01.00

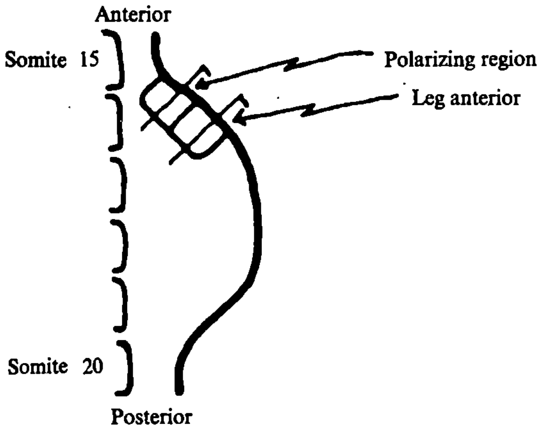

Fig. 2 Diagram of operation consisting of double graft, of wing polarizing region (donor stage 20–22) and leg anterior tissue (donor stage 19–23), each pinned with a platinum pin made from 25-μm diameter wire, replacing host wing bud tissue opposite somites 16/17. Hosts were chick embryos stage 19–21 and received several drops of Hank's balanced salts solution containing 20 mm HEPES and 1% antibiotic–antimycotic (Gibco) before being resealed with Sellotape and reincubated at 38 °C.

host, which caused the extra wing digits 2 obtained above, following the double grafts. Second, it is possible that polarizing region cells were physically migrating (in a posterior and distal direction) around the leg anterior tissue so as to contact directly the host tissue giving rise to the digits 2. This seems unlikely in the absence of any evidence for such migration in chick wing buds[7]. Nevertheless, control experiments were performed as in Fig. 2 but using anterior tissue from proximal parts of older (≥stage 22) limb buds. Such tissue has less competence to respond to or transmit the signal of the polarizing region and after such grafting operations 13 cases had no toes at all and 4 had a toe adjacent to host structures; in none of these operations were host structures duplicated. Third, although the host origin of duplicate wing digits 2 of the sort in Fig. 1*a–d* was indicated by their morphology and feather germs, it was confirmed by histological sections of limbs of this type resulting from operations using quail anterior tissue barriers. The duplicate digits 2 consisted almost entirely (>90%) of host chick cells.

The ability of polarizing region tissue to influence distal wing tissue a distance away from it is in direct distinction to expectations of local intercalation type models[4,5]. The experiments here show that the polarizing region can signal patterning information over a distance of about 200 μm, or about 20 cell diameters. But, there is no evidence for influencing positional information of cells at larger distances of over 300 μm. The results of several lines of investigation suggest that this distance is, at the stages operated on, roughly the antero-posterior extent of the presumptive limb field[8]: these include the absolute number of marked digits obtained using the double grafts described here (L.H., in preparation), fate maps[7], barrier experiments interpretable as fate maps[9], and grafts of two polarizing regions[10,11]. The long-range communication over ~20 cell diameters may be through a freely diffusible morphogen, but equally might occur through cell-to-cell transferred molecule(s), electric potentials, or even through a sequence of cell surface–surface interactions[12].

I thank Dr Lewis Wolpert for discussion and advice, and acknowledge the support of the Anna Fuller Fund (Fellowship No. 487) and the MRC.

Neurotensin blocks certain amphetamine-induced behaviours

Gregory N. Ervin, Larry S. Birkemo,
Charles B. Nemeroff & Arthur J. Prange Jr

Biological Sciences Research Center, Departments of Psychiatry,
Psychology and the Neurobiology Program,
University of North Carolina, School of Medicine, Chapel Hill,
North Carolina 27514, USA

Bilateral injections of either neurotensin (NT; 0.3, 1 or 5 μg in 1 μl artificial CSF) or haloperidol (HA; 2.5 or 5 μg in 1 μl 0.3% tartaric acid) into nucleus accumbens of rats markedly diminished the forward locomotion and rearing induced by d-amphetamine (AM; 2 mg per kg, IP). Neither NT nor HA affected the insomnia or sniffing component of AM arousal. Isovolumetric intra-accumbens injections of artificial CSF or the endogenous decapeptide, luteinizing hormone-releasing hormone (LHRH; 3 μg), did not affect AM behaviours. Since intra-accumbens injections of NT (1 μg) or HA (2.5 μg) neither altered forward locomotion or rearing observed in untreated rats placed in an open field nor a variety of reflex activities, the observed effects of NT and HA in AM-treated rats were probably not due to impaired motor function *per se*. In contrast, NT does not produce neuroleptic-like effects when injected into nucleus caudatus; HA (5 μg) blocked stereotyped sniffing, licking, biting and head bobbing observed after AM (5 mg per kg, IP), but NT (3 or 5μg) did not. Since NT and dopamine are present in substantial quantities in the nucleus accumbens, NT may act in the nucleus accumbens to modulate dopaminergic function.

Neurotensin (NT), a tridecapeptide (pGlu-Leu-Tyr-Glu-Asn-Lys-Pro-Arg-Arg-Pro-Tyr-Ile-Leu-OH), is an endogenous brain peptide which satisfies several neurotransmitter criteria[1,2] and may participate in both endocrine and behavioural functions[3,4]. Radioimmunoassay and immunohistofluorescence studies of rat brains indicate that certain diencephalic regions may have especially high concentrations of NT[5]. The nucleus accumbens is rich in both NT and dopamine (DA). Nucleus accumbens DA is contained in a rich plexus of nerve terminals that is an important part of the forebrain DA terminal system, which functions in arousal and exploration[6,7] and mediates increased forward locomotion and rearing stimulated by low doses of (+)amphetamine (AM)[8,9]. We describe here experiments which show that NT and the neuroleptic haloperidol (HA) have similar effects on AM-induced behaviour when injected into the nucleus accumbents of the rat, but that NT differs from HA in having no effect on AM behaviour when injected into the caudate. This suggests that NT may have a neuroleptic action without some of the side effects of drugs such as HA.

To test for possible interactions of NT and DA systems within the nucleus accumbens, we observed the effects of bilateral intra-accumbens microinjections of NT on the behavioural responses produced by a fixed dose of AM, and which are believed to be mainly dependent on DA release. Using a standardized technique of time sampling and behavioural scoring[9], we observed that NT attenuates AM-induced locomotion and rearing but not the associated insomnia or sniffing. Similar effects were also produced by bilateral intra-accumbens injections of HA, a DA receptor antagonist. We also studied the interactions of NT and the striatal DA system by comparing the effects of NT and HA on behavioural response to a high dose of

Medians and ranges of behavioural scores over 3 h after (+)amphetamine (2 mg per kg i.p.) are shown. Immediately before amphetamine administration, all rats received injections into nucleus accumbens through indwelling cannulae. Doses shown were delivered bilaterally in 1 μl injectate over 1 min. Animals were observed for 30 s every 10 min for 3 h, and scored by a 'blind' observer using a standard sampling technique. The maximum possible score for each item was 54. Peptide scores were compared with artificial CSF scores, and HA scores with tartaric acid scores, by the Mann–Whitney *U*-test.

AM acting on the striatum[8,10]. Although intracaudate injections of HA blocked AM-induced stereotyped behaviour, injections of NT did not.

Male Sprague–Dawley rats (350–450 g, Zivic Miller) were housed in individual cages at a temperature of ~23 °C with 12 h of light (0600–1800 h). Rats were cannulated under ketamine and phenobarbital anaesthesia when mounted in a stereotaxic instrument with the incisor bar 5 mm above the inter-aural line. Guide cannulae (22-gauge stainless steel), affixed to the cranium with dental acrylic, ended 3 mm dorsal to the sites of interest in the medial nucleus accumbens (9.6 mm anterior to inter-aural line, 1.25 mm right and left of sagittal sinus, and 6 mm ventral to dura) or caudate head (8.6 mm anterior to inter-aural line, 2.5 mm right and left, and 5 mm ventral to dura). These cannulae were implanted at least 2 weeks before behavioural testing. Stainless steel injection cannulae were 30 gauge. After testing, verification of accumbens cannulae placements was made in 70 out of 75 rats by frontally sectioning freshly frozen brains; 132 cannulae tracks terminated in the anteromedial nucleus accumbens, and eight were within 0.5 mm of this structure. Caudate cannulae placements were examined in 25 out of 30 rats; all cannulae tracks terminated within the nucleus caudatus.

On a test day, rats were placed individually in clear Plexiglass test cages (21 × 44 × 20 cm high) with wire mesh floors. Each test cage was mounted in a wooden box, with a smoked Plexiglass window (14 × 65 cm) which allowed viewing of a rat from ~20–40 cm. Test cages were lit with a 7.5 W lamp; the experimental room was dark. After an habituation period of 2 h, rats were removed from test cages and injection cannulae, connected by polyethylene tubing (PE 20) to a 10-μl Hamilton syringe and automatic dispenser, were inserted into nucleus accumbens or nucleus caudatus bilaterally; 1 μl of fluid was injected over 1 min into each site. Each injection contained 0.1, 0.3, 1.0 or 5.0 μg NT (in artificial cerebrospinal fluid (CSF), *p*H 7.4, Beckman); 3.0 μg luteinizing-hormone releasing hormone (LHRH, in CSF, Parke-Davis); 2.5 or 5.0 μg HA (in 0.3% tartaric acid, *p*H 3.0, MacNeil Laboratories); or CSF[11] or tartaric acid vehicles alone. Immediately after intra-accumbens injections, rats were injected intraperitoneally (i.p.) with 2 mg per kg AM (Smith, Kline and French), returned to test cages, and observed over the next 3 h by an observer ignorant of the treatments. Animals with cannulae in the nucleus caudatus were treated in the same way except that they received a higher dose of AM (5 mg per kg). Occurrence of the following six behavioural items was recorded in the rats with nucleus accumbens cannulae[6]: (1) forward locomotion—movements of the rat from one end of the cage to the other; (2) rearing; (3) sniffing—rapid and repetitive movement of the nostrils and/or snout; (4) sleeping—any resting posture with eyes closed throughout a whole 10-s interval; (5) rapid bobbing of the head; (6) grooming. In rats with nucleus caudatus cannulae receiving the higher dose of AM, the following behaviour types were considered to be stereotype indices: head bobbing (as described above), biting of the wire mesh floor, licking (of the floor or walls), and sniffing stereotype—continuous rapid and repetitive movement of nostrils and/or snout directed in patterns towards the floor or walls. Behaviour of each rat was observed for 30 s every 10 min for 3 h, and each 30-s observation was divided into three 10-s intervals. When a behaviour type was observed in a 10-s interval, that behaviour received a score of 1. Thus the total score for each behavioural item indicated the number of 10-s intervals in which that behaviour occurred, with a maximum possible score, after injection, of 54. It should be emphasized that these scores represent the incidence of behaviours; except for sniffing or sniffing stereotypes, we did not attempt to rate intensity of behaviours. Scoring of sniffing and sniffing stereotype was mutually exclusive. Using the Mann–Whitney *U*-test[12], we

Medians and ranges of behavioural scores of rats observed for 6 min in an open field are shown. On the basis of their performance in the open field on the previous day, cannulated rats were sorted to establish four comparable groups. Cannulated rats received injections into the nucleus accumbens 6 min before being put into the open field. Bilateral injections of NT (1 μg) and HA (2.5 μg) were given in 1 μl of artificial CSF and 0.3% tartaric acid, respectively. Statistical comparisons were made using the Mann–Whitney *U*-test. Rats injected with NT or HA did not differ from vehicle-injected or uncannulated rats.

compared scores from peptide-treated rats with scores from artificial CSF-treated rats, and HA scores with tartaric acid scores. (To determine if intra-accumbens vehicle injections alone affected AM-induced behaviours, we also observed nine cannulated rats which received AM but no intra-accumbens injections. Vehicle-treated animals were identical to non-injected animals except that tartaric acid significantly reduced amphetamine-induced rearing ($P < 0.05$).)

The four behavioural types affected by the low dose of AM in rats with nucleus accumbens cannulae are shown in Table 1. Nucleus accumbens injections of 0.3, 1.0 or 5.0 μg NT significantly attenuated the forward locomotion and rearing elicited by AM, but did not affect sniffing or insomnia. Injections of 2.5 or 5.0 μg HA also significantly decreased AM-induced locomotion, as described by others[13]. Injections of HA did not decrease insomnia, but the higher dose of HA (5.0 μg) significantly attenuated, but did not block, the sniffing component of AM arousal. The effects of NT on AM arousal were apparently not nonspecific attributes of neuropeptides because LHRH did not significantly alter AM-induced behaviours.

Table 2 shows the behavioural effects of the high dose of AM in rats with intracaudate cannulae. After AM administration, rats locomoted until stereotyped behaviours emerged and then prevailed. Caudate injections of HA (5.0 μg) blocked these stereotypes, and rats locomoted and sniffed as did rats given the lower dose of AM (Table 1). Such a shift in behavioural response to AM is also seen in rats with striatal DA denervations[8]. In contrast to the effects of intra-accumbens injections of NT, intracaudate injections of NT did not have the same effect as HA; intracaudate NT injections (3–5 μg) did not block stereotypes induced by a high dose of AM, but intrastriatal HA (5 μg) did, as described elsewhere[13].

We performed two evaluations which indicated that the effects of NT and HA on AM-induced locomotion and rearing were not due to generalized hypokinesia or motor impairment caused by intra-accumbens injections of NT or HA alone. Eight cannulated rats were examined for neurological functions daily for 4 days and showed stable behaviour. We observed hopping reaction in each limb, righting response on, or 30 cm above, a surface, vibrissae placing, chin placing, and the ability to right on an inverted metal grid[14]. Immediately after final baseline testing, rats were given intra-accumbens injections of 1 μg NT ($n = 3$), 2.5 μg HA ($n = 2$), or 1 μl CSF ($n = 3$). They were re-examined after 3.25 h by an observer ignorant of the treatments. None of the nucleus accumbens injections altered the performance of rats in these neurological tests (data not shown), suggesting no gross motor debilitation by NT or HA.

We observed open field (OF) performance of other intra-accumbens cannulated ($n = 26$) and uncannulated ($n = 5$) rats during 6-min sessions conducted on 2 consecutive days. A clear Plexiglass OF (80 × 80 × 60 cm high) was placed in a wooden box having a smoked Plexiglass top which allowed viewing of rats from ~90 cm. A grey piece of paper was placed under the OF; black lines drawn on the paper divided the floor into 64 squares 10 × 10 cm. The box was illuminated by two 7.5 W lamps; the experimental room was dark. Rats were placed in the OF facing the corner, and the following two behavioural items recorded: squares traversed—number of squares through which the rat moved all four limbs, and rears—vertical extension of forelimbs in any part of the OF. On the basis of OF performance on day 1, cannulated rats were divided into four equivalent subgroups which did not differ from uncannulated rats (data not shown). On day 2, cannulated rats received intra-accumbens injections containing 1 μg NT ($n = 8$), 2.5 μg HA ($n = 5$), 1 μl CSF ($n = 8$) or 1 μl tartaric acid ($n = 5$) 6 min before being placed in the OF. Scores of NT- or HA-treated rats did not differ significantly from scores of vehicle-treated or uncannulated rats (Table 3), which suggests that attenuation of AM-induced locomotion and rearing by intra-accumbens NT and HA was not due to an inability of rats to execute locomotor or rearing movements.

The neuroleptic-like effect of intra-accumbens NT on AM-induced behaviours is not the only evidence for possible NT–DA interactions in the brain. Like neuroleptics, NT delivered into the ventricular system elicits hypothermia[15,16], muscle relaxation[17], and potentiation of pentobarbital-induced narcosis[15]. Of particular interest is the recent report[18] that treatment of rats with HA produces marked increases in immunoreactive NT levels in the nucleus accumbens, with only a small increase in the striatum. Furthermore, intracerebrally administered NT has recently been shown to elicit an effect in two commonly used screens for neuroleptic agents, electrical self-stimulation and active avoidance responding[19]. Taken together these results suggest that NT may possess anti-dopaminergic (neuroleptic-like) properties[20]. However, because the precise central synaptic sites where NT and neuroleptics produce these various effects are unknown, the principle of central NT–DA interactions is still tentative. In view of the known anatomy of NT and DA systems, this work suggests that exogenous NT produces its effects at sites where endogenous NT is plentiful (for example, nucleus accumbens), and not where it is scarce (for example, nucleus caudatus) although DA may be concentrated at both sites. Further support for an NT–DA interaction in the nucleus accumbens has recently been provided by the finding that NT, applied iontophoretically, exerts a potent inhibitory effect on DA-sensitive neurones in the nucleus accumbens[21]. Because most clinically useful antipsychotic agents act at all DA receptor sites, they produce various neurological side effects presumably mediated by the nigrostriatal DA system. The finding that NT blocks AM-induced behaviours at a mesolimbic DA site but not at the extra-pyramidal DA sites, suggests the possibility of developing new pharmacological agents with antipsychotic efficacy, but without the unwanted side effects.

A preliminary account of certain of these data has appeared elsewhere[20]. This work was supported by grants from USPHS.

Studies, San Diego, California 92138, USA

The widely occurring[1–3] tetradecapeptide somatostatin (SRIF-14) has been variously implicated[4–8] as a neurotransmitter, a neurohormone, a cybernin (local regulatory factor) and a hormone. In the first isolation of SRIF-14 from hypothalamic extracts[9,10] and subsequent extracts of other tissues[11–15], peptides of higher molecular weight but with similar activity have been noted. Recently two such peptides have been characterized as the 28-amino acid SRIF-28 (from porcine gastrointestinal tract[16] and porcine and ovine hypothalamus[17,18]) and the 25-amino acid SRIF-25 (from ovine hypothalamus[17]), each of which consists of an N-terminal extension of SRIF-14. We now report that SRIF-28 and SRIF-25 are more potent than SRIF-14 in the inhibition of insulin release, but that SRIF-14 preferentially inhibits glucagon release. This suggests that SRIF-28 and SRIF-25 are not mere biosynthetic precursors of SRIF-14 and that their differential release may be physiologically important.

To compare the relative effects of SRIF-28, SRIF-25 and SRIF-14 on secretion of insulin and glucagon *in vitro*, each peptide was synthesized by solid phase methods[19]; their primary structure was recharacterized on a Beckman 8900 amino acid sequencer, and purity confirmed by HPLC. The peptides were dissolved in pancreas perfusate[20] and infused by side-arm syringe (0.1 ml min^{-1}) starting 10 min before and continuing for 5 min after a 15 min pancreatic stimulation by arginine (10 mM). Each pancreas was exposed to only a single concentration of a peptide.

Pancreases were isolated from overnight fasted Wistar rats (220-280 g) and perfused *in vitro* with a non-recirculating medium (3 ml min^{-1}) as described elsewhere[20]. Portal venous effluent was collected at 1-min intervals into chilled tubes containing 25 μM EDTA; after completion of experiments, the effluent was aliquoted and frozen until determination of insulin[21] and glucagon[22] contents by radioimmunoassay. Hormone secretion, presented as the total amount of hormone released during each 15-min stimulation period (see Table 1), was calculated by summation of the amount of the hormone released for each minute of the 15-min stimulation. Basal glucagon (~ 0.1 ng min^{-1}) and insulin (~ 1.5 ng min^{-1}) secretory rates during individual experiments were not significantly different.

SRIF-25 and SRIF-28 did not differ in their biological effects. At all concentrations studied, both peptides inhibited secretion of insulin more potently than did SRIF-14. Linear regression analysis indicated that 50% inhibition of insulin occurred at $\sim 1.4 \times 10^{-11}$ M for SRIF-28 and SRIF-25 and at $\sim 1.5 \times 10^{-10}$ M for SRIF-14. In contrast, SRIF-14 inhibited secretion of glucagon more potently than did SRIF-25 and SRIF-28; 50% inhibition of glucagon release occurred at $\sim 3.3 \times 10^{-12}$ M SRIF-14 and at $\sim 3.2 \times 10^{-11}$ M SRIF-25 and SRIF-28. Thus, both SRIF-25 and SRIF-28 seem to inhibit preferentially insulin release whereas SRIF-14 seems to inhibit preferentially glucagon secretion. As a non-recirculating perfusion system was used in these experiments, the different activities observed for these peptides cannot be explained by their differing rates of degradation.

It has been suggested that SRIF-28 may represent prosomatostatin, the biosynthetic precursor of SRIF-14[16,18,23]. However, prohormones have been found to be considerably less potent than their product[24]. Thus, the present demonstration that SRIF-25 and SRIF-28 are about 10-fold more potent than SRIF-14 in inhibiting insulin *in vitro* and previous reports[17,28] that synthetic replicates of these peptides are 10-fold more potent in inhibiting growth hormone secretion *in vitro* and *in vivo* suggest that SRIF-25 and SRIF-28 are not mere biosynthetic precursors for SRIF-14 in the classical sense of a prohormone but rather that they should be considered as alternate forms of biologically active somatostatins.

As even the secreted peptides may be further processed before interaction at receptors in target tissues[25], it will remain uncertain which peptide is the precursor and which the ultimate product until it is determined which peptide is actually bound at the SRIF receptor *in vivo*. Furthermore, it is possible that, as with proopiocortin which is processed differently in adenophyseal cells and cells of the pars intermedia[26], prosomatostatin may also be processed differently in various tissues. In some tissues, SRIF-14 may represent the predominant secretory product whereas in others it may be SRIF-28 or SRIF-25. Moreover, the same cell may release different amounts of the peptides in different physiological or pathological conditions.

There is evidence that both SRIF-14 and SRIF-28 are present in the pancreas, presumably in islet D-cells[27]. That SRIF-14 is a

more potent inhibitor of arginine-stimulated glucagon release than of insulin release has been previously noted[20]. The present finding that SRIF-28 is a more potent inhibitor of arginine-stimulated insulin release than of glucagon release raises the possibility that preferential secretion of SRIF-14 and SRIF-28 may provide a novel mechanism for selective regulation of insulin and glucagon release. This suggestion is consistent with the observation that SRIF-28 seems to comprise less than 5% of SRIF-like immunoreactivity within the pancreas[27] because SRIF-28 is a 10-fold more potent inhibitor of insulin release than is SRIF-14, the predominant molecular species in the pancreas. It remains to be determined, however, whether the present observations regarding arginine-stimulated insulin and glucagon release are applicable to other secretagogues of these hormones.

γ Interferon induced by *S. aureus* protein A augments natural killing and ADCC

William J. Catalona, Timothy L. Ratliff

St Louis and the Division of Urology, Washington University School
of Medicine, St Louis, Missouri 63110, U.S.A.

***Staphylococcus aureus* produces a protein identified as protein A (SpA) with a molecular weight of 41,000 (ref. 1) which binds to the Fc region of many types of mammalian IgG[2], activates complement[3], blocks opsonins[4] and is both chemotactic[5] and mitogenic[6,7]. SpA has been used for various immunological purposes including removal of immune complexes[8], arming effector cells with antibody[9], distinguishing between antibody-dependent cell-mediated cytotoxicity (ADCC) and natural killing (NK)[10], and exerting anti-tumour activity[11]. We have now demonstrated that SpA induces the production of γ interferon (IFN-γ) in nonadherent, T lymphocyte-depleted (E$^-$), Fc receptor-bearing (FcR$^+$) human peripheral blood lymphocytes. Our data also suggest that IFN-γ is a potent stimulator of both NK and ADCC activity.**

Table 1 Antigenic and physicochemical characterization of SpA-induced IFN

	Treatment of supernatant	Interferon (unit ml^{-1})
Physicochemical characterization	None (mock interferon)	≤5
	None (interferon)	250
	Trypsin	≤5
	*p*H 2	≤5
	56 °C	≤5
Antigenic characterization	None	2,000
	Anti-hu IFN-α	2,000
	Anti-hu IFN-γ	100

Human PBLs were treated with SpA (50 μg ml^{-1}) for 2 h, washed and incubated for an additional 24 h. Supernatants were collected as interferon preparations. Mock interferon was prepared in an identical fashion except that PBLs were treated with SpA diluent only. Supernatant treatments: trypsin: supernatants were treated with 100 μg ml^{-1} trypsin for 30 min at 37 °C; *p*H 2: supernatants were dialysed against glycine-HCl buffer (*p*H 2.0) for 24 h. The *p*H was returned to 7.2 by dialysis against minimal essential medium with Earl's salts; 56 °C: Supernatants were maintained at 56 °C for 1 h. Neutralization studies with antiserum against human (hu) IFN-α and hu IFN-γ were kindly performed by Dr John Stanton, University of Texas Medical Branch, Galveston, Texas.

Previous reports have shown that staphylococcal enterotoxin A (SEA), a T-cell mitogen, induces IFN-γ production[12]. However, the interferon-producing potential of SpA has not previously been reported, and has not hitherto been a consideration in the interpretation of the biological properties of SpA.

In the present study, human peripheral blood lymphocytes (PBLs) were isolated by centrifugation of heparinized whole blood on Ficoll–Hypaque gradients as described previously[13]. Interface cells were washed three times with phosphate-buffered saline (PBS) and resuspended to the desired concentration in RPMI 1640 medium supplemented with 10% fetal calf serum and 1% antibiotic–antimycotic solution (Gibco) (complete medium). Interferon was induced by incubating PBLs (5×10^6 ml^{-1}) with 50 μg ml^{-1} SpA (Pharmacia; no SEA contamination has been detected in SpA preparations from Pharmacia [James L. Richey (Pharmacia), personal communication]) for 2 h at 37 °C in a 5% CO_2 atmosphere. Following incubation with SpA, PBLs were washed three times with PBS, resuspended to 5×10^6 cells ml^{-1} in complete medium and incubated for 24 h at 37 °C. Supernatants were collected as interferon preparations and frozen at −70 °C until used. Mock interferon was prepared in an identical fashion except that SpA was not added to PBL cultures. Supernatants were assayed for interferon activity by measuring their capacity to inhibit the cytopathic effect of vesicular stomatitis virus on human foreskin fibroblast cultures (Biofluids). Titres are reported as International Reference units (NIH Human Leukocyte Reference Standard GO 23-902-527).

Interferon assays were performed on supernatants of SpA-treated PBLs from more than 20 donors. The interferon titres varied between donors, ranging from 100 to 300 U ml^{-1} (mean = 160 ± 20 U ml^{-1}) using unfractionated PBLs. A representative experiment is shown in Table 1. The results show that supernatants from SpA-treated PBLs exhibited antiviral activity whereas none was present in mock interferon preparations. Physicochemical and antibody neutralization studies (Table 1) suggest that SpA-induced interferon is immune interferon (IFN-γ). Cell fractionation studies (Table 2) showed that depletion of adherent cells on glass surfaces and removal of the majority of T lymphocytes by E-rosette depletion enhanced interferon production, whereas depletion of FcR$^+$ cells on antibody-sensitized sheep erythrocytes abrogated interferon production. These results suggest that with SpA, unlike other mitogen interferon inducers, macrophage depletion enhances

0028–0836/81/190077—03$01.00

Table 2 Determination of the mononuclear cell subpopulation responsible for SpA-induced interferon production

Experiment no.	Cell fraction	Interferon (units ml^{-1})	% Latex positive	Cell markers % FcR positive	% E-rosette positive
1	Unfractionated	250	18	ND	ND
	Macrophage enriched	125	64	ND	ND
	Macrophage depleted	1,580	2	ND	ND
2	Macrophage depleted	625	ND	5	ND
	FcR negative	25	ND	1	ND
3	Macrophage depleted	200	ND	ND	70
	T-lymphocyte depleted	1,250	ND	ND	16

The measurement of latex ingestion, Fc receptors and E-rosette formation was performed as previously described[13]. PBLs were incubated on glass Petri plates for 1 h at 37 °C. Macrophage-depleted cells were removed by vigorous washing. Macrophage-enriched cells were removed from the glass with a rubber policeman. For FcR-negative cells, FcR-positive lymphocytes were removed by IgG-coated sheep erythrocytes as previously described[13]. For T lymphocyte-depleted fraction, PBLs were incubated with sheep erythrocytes overnight at 4 °C. After incubation T lymphocytes were removed by Ficoll–Hypaque density centrifugation as previously described[13]. ND, no data.

rather than reduces interferon production[14] and further, that nonadherent, non-T, FcR^+ lymphocytes produce interferon after SpA stimulation.

Interferons have been classified as IFN-α, IFN-β and IFN-γ, based on antigenic and physicochemical properties. IFN-α, -β and -γ are antigenically distinct compounds[14]. Furthermore, IFN-α and IFN-β, unlike IFN-γ, are stable to pH 2 and to heating at 56 °C for 1 h (ref. 15). All interferon types are inactivated by trysin treatment. Our characterization studies revealed that SpA-induced interferon was inactivated by pH 2 treatment for 24 h or heating at 56 °C for 1 h. Moreover, treatment of SpA-induced interferon with antiserum to human IFN-α failed to neutralize its antiviral activity whereas antiserum to human IFN-γ succeeded, suggesting that SpA-induced interferon is IFN-γ.

Previous reports have shown that IFN-α and IFN-α inducers augment both ADCC and NK activity[16]. We therefore evaluated the effect of SpA-induced IFN-γ-containing supernatants on ADCC and NK activity (Fig. 1). Effector PBLs were treated with SpA-induced interferon-containing supernatants overnight at 37 °C (controls were treated with mock interferon) before the addition of ^{51}Cr-labelled target cells. The cytotoxic activity of both NK directed against K562 human myeloid leukaemia target cells and ADCC directed against Chang human liver cell targets was augmented by interferon-containing supernatants (Fig. 1). Significant augmentation was observed at effector/target cell ratios ranging from 6 : 1 to 50 : 1 (data not shown). Furthermore, trypsin digestion, heating at 56 °C and pH 2 treatment which inactivated the antiviral activity of SpA-induced interferon also significantly diminished that augmentation of cytotoxic activity (data not shown).

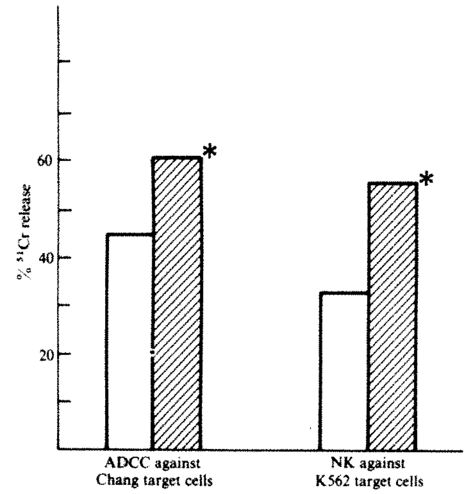

Fig. 1 Effect of SpA-induced interferon-containing supernatant on NK and ADCC activity of human PBLs. Both ADCC and NK assays were performed at 50 : 1 effector/target ratios as described previously[13]. Open bars represent untreated effector cells, hatched bars interferon-treated effector cells. *, $P < 0.005$ by Student's t-test.

SpA has often been used in short-term cytotoxicity assays to distinguish between ADCC activity, which is inhibited by SpA, and NK activity which is not[17]. Kinetic studies on the rate of interferon production after SpA treatment showed that interferon activity was not apparent until 8 h after SpA treatment and peaked by 24 h (data not shown). Thus, only long-term cytotoxicity assays would be expected to reflect the interferon-induced augmentation of NK and ADCC activity. Indeed, Pape *et al.*[18] recently reported that SpA-treated PBLs exhibited augmented NK activity against T 24 bladder cancer cells in an 18-h assay, but not against K562 cells in a 4-h assay. Other investigators have observed that SpA-treated effector cells exhibited augmented NK activity in 18-h, but not in short-term[10], assays[17].

Previous investigators have not considered the interferon-inducing potential of SpA in interpreting its diverse effects in biological systems. Cowan *et al.*[8] added SpA to ADCC assays containing immune complexes and attributed the enhanced cytotoxicity observed to removal of the immune complexes. Sulica *et al.*[9] found that effector cells treated with target cell-specific antibody complexes to SpA exhibited greater cytotoxic activity than effector cells treated with antibody alone. They attributed the enhanced cytotoxicity to increased antibody arming in the presence of SpA. Our results suggest that the enhancement of cytotoxicity observed by both Cowan *et al.*[8] and Sulica *et al.*[9] may be attributed, at least in part, to interferon induction.

Ray and co-workers[11] demonstrated that *S. aureus* (Cowan), a producer of SpA, has antitumour activity against a murine methylocholanthrene-induced fibrosarcoma. These investigators suggested that the antitumour activity was associated with augmentation of the humoral immune response to tumour antigens and removal of immune complexes. Again, our results suggest that SpA-induced interferon production may be implicated.

Thus, our results demonstrate that SpA induces IFN-γ production by nonadherent, T lymphocyte-depleted, FcR^+ human PBLs, and that IFN-γ augments both NK and ADCC activity. Our results suggest that the induction of IFN-γ by SpA exhibits several unique characteristics. Interferon induction by SpA seems to be less dependent on macrophages than induction of IFN-γ by other mitogens[14] and is apparently produced by non-T lymphocytes although more complete cell fractionation studies must be performed to confirm this preliminary observation. Maximum production of IFN-γ by SpA occurs within 24 h whereas other mitogens require 3–5 days for maximum IFN-γ production[14]. Finally, our data suggest that investigators using SpA as an immunological reagent for its Fc receptor-bearing properties must consider its interferon-producing potential in interpreting results.

Production of immune interferon by murine T-cell clones from long-term cultures

Fabrizio Marcucci*, Michael Waller†, Holger Kirchner* & Peter Krammer†

* Institute of Virus Research and † Institute of Immunology and Genetics, German Cancer Research Centre, Heidelberg, FRG

Production of leukocyte interferon (IFN-α) and fibroblast interferon (IFN-β) can be induced by a variety of agents[1] but immune interferon, IFN-γ, is only obtained when lymphoid cells are stimulated by specific antigens, allo-antigens or T-cell mitogens[2,3]. Moreover, in bulk cultures, only small quantities of IFN-γ are produced. The type of cell producing IFN-γ has not been unambiguously defined[4–6] and so we set out to determine whether a pure T-cell population could produce it, exploiting the knowledge[7,8] that T cells can be maintained indefinitely in tissue culture by the addition of T-cell growth factors. Although not all T cells can found long-term cultures of this kind[9], cultures of antigen-specific helper, suppressor and killer T cells have been obtained[10–15] in this way. We now describe the production of substantial amounts of INF-γ when some (but not all) murine T-cell clones derived from such cultures are stimulated by either concanavalin A (Con A) or phytohaemagglutinin (PHA).

We obtained such a source of homogeneous T cells from clones of a 4-day culture of cells from the draining axillary and inguinal lymph nodes of AKR/J mice sensitized on the abdominal skin by 2,4,6-trinitrophenyl chloride (picryl chloride, PC) 5 days earlier[14]. These clones had been passaged in tissue culture for several months with a doubling time of ~20 h and grew strictly dependent on the presence of T-cell growth factors in the supernatant from rat spleen cells stimulated by Con A for 48 h. Cells from these clones were stimulated with Con A or PHA and tested for interferon production in different culture conditions.

The first series of experiments showed that these two mitogens induced interferon only when the T-cell growth factor-containing medium was replaced by fresh culture medium during interferon induction (Table 1). No antiviral activity could be detected without addition of T-cell mitogens or in the presence of B-cell mitogens (data not shown). The optimal dose for interferon induction, subsequently used for all further experiments was 5 or 10 μg ml^{-1} Con A or PHA. Table 1 indicates that interferon was also generated by mitogen stimulation in serum-free medium and its production significantly increased by addition of 2-mercaptoethanol to the medium. The antiviral activity in the supernatant of the stimulated T-cell clones was characterized as IFN-γ by the following criteria (outlined in Table 2): (1) species-restricted activity, (2) induction of the antiviral state dependent on intact RNA synthesis in the target cell, (3) sensitivity to pH 2 and to trypsinization, (4) resistance to RNase treatment, (5) persistence of the antiviral activity after ultracentrifugation, (6) loss of activity after incubation with anti-IFN-γ antiserum and persistence of activity after incubation with anti-IFN-α and β antiserum.

Thus, production of IFN-γ could be induced by T-cell mitogens from continuously growing, nontransformed T cells maintained by passage in long-term culture in medium containing T-cell growth factors and in the absence of adherent cells. Table 3 shows that this was true for several randomly selected T-cell clones. Furthermore, while most clones responded equally well to stimulation with Con A or PHA, some produced more interferon on stimulation with one or the other. Few clones gave only marginal responses; most produced IFN-γ at titres considerably higher than those obtained in bulk cultures stimulated with the same mitogens (data not shown). The capacity to produce IFN-γ in response to mitogen stimulation seemed to be a stable property of the clones as approximately the same titres were obtained from two randomly selected clones tested after a 2-month interval (Table 3).

Our cultures had not been established by deliberate isolation and further growth of single cells but by seeding 1 cell per culture well. As 5.2% of the initial culture wells were positive for growth, most of the established long-term cultures from these wells could be considered clones according to Poisson statistics. The clones originated from a bulk culture of more than 95% T cells and grew strictly dependent on the presence of T-cell growth factor-containing medium. Furthermore, IFN-γ release could only be stimulated by T-cell mitogens.

To characterize the phenotype of one of the clones producing IFN-γ we treated the clone PC AKR 96, from the same series as the other clones, with the monoclonal anti-Thy 1.1, anti-Lyt 1.2 or anti-Lyt 2.1 antibodies and complement. As shown in Table 4, the cells were resistant to lysis, evaluated by Trypan blue exclusion, even after two consecutive treatments with any of the above antibodies. This insensitivity to complement treatment for T-cell clones in long-term culture has been described by others[15]. Antibody-treated and control cells were resuspended in T-cell growth factor-containing medium and after 4 days, growth (evaluated by ^{3}H-thymidine uptake) and mitogen-induced IFN-γ production were determined. At this time, cells treated with anti-Thy 1.1+complement incorporated only low levels of ^{3}H-thymidine and almost no IFN-γ production could be observed. The phenomenon was specific because ^{3}H-thymidine uptake and IFN-γ production were unaltered after treatment of the cells with the monoclonal anti-Thy 1.2 antibody,

Table 1 Conditions for IFN-γ production by T-cell clones stimulated with Con A or PHA

			IFN-γ titres in different culture conditions (International Units per ml)			
Clone	Mitogen added	μg ml^{-1}	NCM	TCGFCCM	SF-NCM	NCM + 2-ME
PC AKR 29	None		<3	30	<3	10
	PHA	5	240	45	300	550
	PHA	10	550	30	550	720
	Con A	5	240	30	240	550
	Con A	10	720	45	720	1,000
PC AKR 54	None		<3	30	<3	5
	PHA	5	350	30	500	720
	PHA	10	240	45	240	500
	Con A	5	550	45	550	720
	Con A	10	300	45	300	450

NCM, normal culture medium, RPMI-1640 (Gibco), supplemented with L-glutamine (2 mM), streptomycin (100 μg ml^{-1}) + 5% fetal calf serum (FCS). TCGFCCM, T-cell growth factor-containing conditioned medium, as NCM with 2-mercaptoethanol (2-ME, 3×10^{-5}M) and substituted with 10 mM HEPES, 10% FCS and 10% supernatant containing T-cell growth factors. This supernatant was obtained by stimulation of 5×10^6 Sprague–Dawley rat spleen cells (70 ml in Falcon bottles (flat), 3024 F) with 5 μg Con A for 24 h. The stimulation was done in medium with the same constituents as above except that Iscove's modified Dulbecco's medium without HEPES was used. SF-NCM, serum-free normal culture medium. T-cell clones were obtained in the following way. The draining axillary and inguinal lymph node cells of AKR/J mice sensitized 5 days previously on the abdominal skin by PC were put into culture as described in ref. 14. On day 5 of culture, cells cleared from dead cells and debris by centrifugation over Ficoll–Urovison[14] were cloned by seeding 1 cell per well in 200 μl TCGFCCM containing 3×10^4 3,300-rad-irradiated AKR/J peritoneal exudate filler cells in 96-well flat-bottom microtitre plates (Linbro no. 76-003-05, Flow Laboratories). The old TCGFCCM was replaced once a week. After about 4 weeks all growing clones were separately transferred into 24-well plates (Linbro no. 76-033-05, Flow Laboratories) and after an additional 2 weeks the surviving clones were passaged and usually subcultured once a week in Falcon bottles (3024 F, Falcon) in TCGFCCM. All cultures were kept at 37° C, in humidified atmosphere, 95%–5% air–CO_2 mixture. For interferon induction, cells grown in TCGFCCM were centrifuged, washed twice and resuspended in NCM or in SF-NCM, or in NCM + 2-ME at a concentration of 1×10^6 ml^{-1} and stimulated with PHA or Con A. Culture supernatants were collected 24 h later and interferon was titrated by means of a plaque reduction assay using L cells and vesicular stomatitis virus as challenge virus[18].

which recognizes the allelic specificity of the Thy-1 locus not expressed on T cells from AKR mice. Typing of the Lyt markers for which monoclonal reagents were available (Lyt 1.2 and Lyt 2.1) was negative in all the assays performed. Thus, cells from this clone either are Lyt 1^-2^- or possess these surface antigens at low density and are therefore not detectable in our experimental conditions. Clones negative for the expression of these markers have already been described[15,16]. Bearing in mind that cultivation of long-term T-cell clones in T-cell growth factor-containing medium is accompanied by change in quantity or loss of expression of cell-surface antigens, particularly of the Ly series[15], these observations suggest that the cells from the clone PC AKR 96 are derived from a single T cell and continue to express the θ antigen.

The clones had been passaged in tissue culture for more than 3 months without addition of adherent cells before they were tested for IFN-γ production. We therefore assume that they were virtually free of macrophages and that IFN-γ was being produced by T-cell clones without help from adherent cells. That some clones yielded titres of IFN-γ considerably higher than those normally obtained from cell mixtures in bulk cultures stimulated with the same mitogens indicates that, in these conditions either we obtained an expansion of the IFN-γ-producer cells or some regulatory mechanism acting in bulk cultures was bypassed.

When cultured in the absence of growth factor-containing medium, T-cell clones produced IFN-γ after mitogen stimulation (Table 1). Unstimulated cells from these cultures did not

Table 2 Characterization of antiviral activity in the supernatant of murine T-cell clone PC AKR 29 stimulated with Con A or PHA

Treatment of supernatant	Activity* on mouse cells
pH 2 for 24 h	–
Centrifugation at 100,000g for 1 h	+
Trypsin (100 μg ml^{-1}) for 1 h at 37 °C	–
RNase (1000 μg ml^{-1}) for 1 h at 37 °C	+
Incubation with anti-mouse IFN-α and -β antiserum for 1 h at 37 °C	+
Incubation with anti-mouse IFN-γ antiserum for 1 h at 37 °C	–

Anti-mouse IFN-α and -β antiserum was a rabbit anti-L cell interferon antiserum with a neutralization titre of 1:6,000 on IFN-α and -β. Anti-mouse IFN-γ antiserum was a rabbit antiserum raised against PHA-induced, mouse spleen cell interferon with a neutralization titre of 1:640, ref. 19. +, Activity undiminished; −, 4>90% loss of activity.

* Loss of antiviral activity was observed after pretreatment of L cells with 1 μg ml^{-1} actinomycin D for 1 h. The antiviral activity was species restricted as no reduction of virus plaques was observed on Rita (monkey kidney) cells.

Table 3 IFN-γ production by different T-cell clones stimulated with Con A or PHA

	IFN-γ titres (IU ml^{-1}) after stimulation with			
	PHA		Con A	
T-cell clones	5 μg ml^{-1}	10 μg ml^{-1}	5 μg ml^{-1}	10 μg ml^{-1}
PC AKR 28	500	300	60	80
PC AKR 37	15	10	15	30
PC AKR 41	300	240	240	240
PC AKR 74	150	100	500	800
PC AKR 75	50	15	240	100
PC AKR 81	90	30	150	100
PC AKR 83	720	600	800	720
PC AKR 89	30	15	15	30
PC AKR 96	250	400	60	100
PC AKR 45/1*	240	800	30	80
PC AKR 45/2*	300	720	20	60
PC AKR 59/1*	720	800	720	720
PC AKR 59/2*	500	600	600	720

Stimulation of T-cell clones was done in NCM (see Table 1 legend).

* 1 and 2 represent the results from clones PC AKR 45 and 59 at a time interval of 2 months.

Table 4 Analysis of cell-surface markers of the T-cell clone PC AKR 96

	Characterization of the cells after treatment			
	Day 0		Day 4	
Treatment	% Living cells	IFN-γ production (IU ml^{-1})	Growth (^{3}H-TdR incorporation, c.p.m.)	IFN-γ production (IU ml^{-1})
Control	90	1,000	148,520	600
Complement (C′) alone	80	800	139,343	600
Anti-Thy 1.1+C′	75	720	3,047	10
Anti-Thy 1.2+C′	70	720	122,250	720
Anti-Lyt 1.2+C′	80	1,000	121,342	800
Anti-Lyt 2.1+C′	70	800	156,528	600

The control was NCM alone. Antibodies were monoclonal antibodies anti-Thy 1.1, anti-Lyt 1.2, Lyt 2.1 (code NEJ-014, NEJ-017 and NEJ-004, respectively, NEN) and anti-Thy 1.2 (code FfB5, Olac), and were used at a final dilution of 1:100, 1:50, 1:50 and 1:100, respectively. Complement was 1:6 diluted, selected rabbit complement. Treatment with antibodies and complement was performed twice with 2×10^6 cells as previously described[20]. At the end of the treatment the cells were resuspended in 1 ml NCM. 0.2 ml of each cell suspension was induced for IFN-γ production with PHA (10 μg ml^{-1}). 0.2 ml of a 1:10 dilution of each cell suspension were separately transferred into 24-well plates (Linbro no. 76-033-05, Flow Labs), each well containing 1 ml fresh TCGFCCM. 4 days later 3×0.2 ml of each cell suspension were separately transferred into a 96-well plate, pulsed for 4 h with 1 μCi ml^{-1} of tritiated thymidine (^{3}H-TdR, Amersham) after which the cultures were aspirated on filter paper by use of a semi-automated collecting device (Skatron, Flow Labs) and radioactivity of the filters measured in a scintillation counter (Mark II, Searle-Nuclear, Chicago). Another 0.2-ml aliquot was centrifuged and resuspended in 0.2 ml NCM containing PHA (10 μg ml^{-1}). 24 h later the supernatants were tested for IFN-γ as described in Table 1 legend. Per cent living cells was determined by Trypan blue exclusion. Growth results are the mean value of triplicate samples.

release antiviral activity. Supernatants from unstimulated cells cultured with T-cell growth factor-containing medium were positive for IFN-γ because the medium itself contained IFN-γ. Addition of mitogens to cells from these cultures did not increase IFN-γ titres above the medium background (Table 1). This might have been due to blocking activity exerted by IFN-γ similar to the blocking observed for IFN-α and β production[17].

T-cell help, cytotoxic activity and suppression can be obtained from T-cell lines and clones without antigen or mitogen stimulation[10–12]. Our data indicate that other T-cell activities, like IFN-γ production, can be stimulated from T-cell lines and clones only with mitogens. It remains to be determined whether other stimuli, such as specific antigens, which resemble more closely the *in vivo* situation, are also able to induce IFN-γ production from T-cell clones.

Finally, the fact that large quantities of IFN-γ can be produced in serum-free conditions (Table 1) from homogeneous cells in continuous culture could be useful for its biochemical isolation.

We thank Professor K. Resch and Drs S. Landolfo and M. Simon for helpful discussions, Ms A. Michnay and M. Nowak for technical assistance and Ms M. Kasamasch for typing the manuscript. Drs June Dunnick and Juana Wietzerbin provided the anti-mouse IFN-α and -β antiserum and anti-mouse IFN-γ antiserum respectively.

Herpesvirus-transformed cytotoxic T-cell lines

Donald R. Johnson & Mikael Jondal

Department of Tumor Biology, Karolinska Institutet,
S-104 01 Stockholm, Sweden

Investigations of cellular cytotoxicity of the immune system are hampered by the lack of continuously growing, transformed cell lines which express a cytotoxic potential. Here we describe cytotoxic cell lines from the cotton-topped marmoset monkey, transformed by Herpesvirus Ateles (HVA) or Herpesvirus Saimiri (HVS), which can kill certain target cells in a short-term *in vitro* test. HVA/HVS-transformed cells have earlier been classified as belonging to the T-cell lineage[1–3] in contrast to Epstein–Barr virus (EBV)-transformed cells derived from B lymphocytes[4]. We suggest that the HVA/HVS-transformed killer cell lines described here represent an effector population resembling, or corresponding to, marmoset natural killer (NK) cells and that they may be used to define the cytolytic mechanism involved in cellular cytotoxicity and possibly also effector cell receptors and target cell antigens, as well as regulatory mechanisms of general biological interest.

Peripheral blood lymphocytes from adult cotton-topped marmosets were separated on Ficoll–Isopaque and transformed by cell-free supernatants from HVA-infected marmoset kidney fibroblasts[3]. The resulting cell lines were propagated as suspension cultures in RPMI 1640 media supplemented with 10% fetal calf serum and antibiotics. A 6-h ^{51}Cr release cytotoxicity assay was performed in microplates as described in Table 1 legend, using various target cells. Cytotoxicity assays in which HVA-carrying cell lines were used as effector cells, were compared with cytotoxicity expressed by marmoset and human NK cells isolated from the peripheral blood of normal healthy donors. Five different HVA-transformed cell lines and two HVS-transformed cell lines were tested for cytotoxic activity against the human T-cell line Molt-4 (Table 1) derived from acute lymphocytic leukaemia[5]. All seven HVA/HVS-transformed cell lines, and human NK cells, were cytotoxic in contrast to human fetal thymocytes and marmoset B-cell lines. Both *in vitro*-transformed cell lines and lines transformed *in vivo*, that is, tumour-derived cells, were cytotoxic, which indicates that the cytotoxic

Table 1 Cytotoxicity by HVA/HVS-transformed cell lines from cotton-topped marmoset monkeys

Effector cell	Transforming virus	Origin	Type	Age	Cytotoxicity against target cell Molt-4 (specific ^{51}Cr release)		
					25:1	12.5:1	6.3:1
Experiment I							
77-DI-2	HVA	*In vitro* transformed	T	6 months	68.4	59.9	48.9
70-KI-1	HVA	Same	T	3 yr	60.1	49.6	38.2
22-CM-37	HVA	Same	T	4 yr	11.4	9.8	7.9
22-CM-61	HVA	Same	T	4 yr	32.2	29.6	19.8
1022	HVA	Tumour-derived	T	6 yr	62.3	52.1	44.8
70-N-2	HVS	Same	T	8 yr	52.1	40.8	33.8
MLC	HVS	Same	T	9 yr	19.2	15.3	10.7
Human NK	—	Peripheral blood	—	Fresh	68.7	48.3	28.4
Human thymocytes	—	Fetal thymus	—	Fresh	0.2	−0.1	0.0
Experiment II							
77-DI-2	HVA	*In vitro* transformed	T		66.2	48.7	39.4
77-DI-2	EBV	Same	B		3.1	0.6	0.1
70-KI-1	EBV	Same	B		0.2	0.1	0.2
Human NK	—	Peripheral blood	—		75.4	63.6	54.1

Cytotoxicity assay was performed in V-shaped microtitre plates using 10^4 ^{51}Cr-labelled target cells. RPMI 1640 with 10% fetal calf serum was used as testing medium, giving a total volume of 150 μl per well. After 6 h, 50 μl was collected from each well and cytotoxicity calculated as follows: test release − spontaneous release/80% of maximum label − spontaneous release × 100. Values are means of duplicate wells; two representative experiments are shown.

potential of these cell lines is a stable characteristic that does not change even after many years in tissue culture (note particularly the old cell lines 1022, MLC and 70-N-2).

As the Molt-4 cell is a standard target for human NK cells[6], and as the HVA/HVS cells are spontaneously cytotoxic (that is, no special triggering is needed), we investigated whether they would have the same target specificity as human NK cells when tested against an extended panel of cells (see Table 2). HVA/HVS cell lines were found to kill most efficiently target cells derived from T-cell malignancies, such targets are also readily killed by human NK cells[7]. The marmoset lines killed K562 but to a lesser degree than human NK cells (K562 is also a standard target for the human NK system[6,8]). HVA/HVS cell lines killed B-cell lines from non-EBV (as opposed to EBV-containing) malignancies. In contrast, human NK cells seem to kill malignant as opposed to non-malignant cells, as previously shown[9]. Neither HVA/HVS lines nor human NK cells kill normal mitogen-transformed T cells—this was also confirmed using T blasts from concanavalin A and MLC cultures (data not shown). Finally, the HVA/HVS cell lines did not kill the standard NK target in the mouse system, YAC-1, a Moloney leukaemogenic virus (MLV)-transformed cell line of thymic origin[8,10].

Comparison of NK cells from cotton-topped marmosets with human NK cells (Table 3) showed that marmoset NK cytotoxicity resembled that of the 77-DI-2 cell line as both predominantly killed the Molt-4 target and, to a much lesser degree, the Raji and K-562 targets. In contrast, human NK cells demonstrated highest activity against the K-562 target. These results indicate that the difference in target cell specificity between the 77-DI-2 cell line and human NK cells (Table 2) reflects minor differences between the human and marmoset NK systems.

To ascertain that the cell line-mediated cytotoxicity is a true membrane-mediated event (as are conventional T- and NK-cell killing) and not dependent on secreted lymphotoxin-like molecules, we investigated cytotoxicity on the single cell level using a recently described technique in which separate effector–target cell conjugates were embedded in agarose[11]. We also compared the number of active killer cells in the 77-DI-2 cell line with those present in normal marmoset lymphocytes propagated by T-cell growth factor (TCGF). TCGF was prepared from supernatants of phytohaemagglutinin (PHA)-stimulated human lymphocytes, usually pooled from three different donors, as described elsewhere[12]. Table 4 shows that 38.5% of the HVA-transformed killer cells were able to bind to the target cells but

Table 2 Target cell specificity of the 77-DI-2 effector cell line

Target cell	Origin	Characteristics	EBV	Effector cells (specific ^{51}Cr release)	
				77-DI-2	Human NK
Molt-4	Acute lymphocytic leukaemia	T cell	−	68.9	68.7
1301	Same	Same	−	49.3	66.4
CCRF-CEM	Same	Same	−	71.2	68.9
HSB-2	Same	Same	−	71.6	79.7
HD-Mar	Hodgkin's disease	Same	−	36.5	94.8
BJAB	Burkitt's lymphoma	B cell	−	29.1	94.0
Ramos	Same	Same	−	15.9	20.6
K562	Chronic myelocytic leukaemia	CML cell	−	17.3	87.5
DHL-9	Diffuse histiocytic lymphoma	B cell	−	29.4	52.8
Daudi	Burkitt's lymphoma	Same	+	−0.3	42.8
P3HR-1	Same	Same	+	0.1	65.4
B95-8	Normal marmoset B cells	Same	+	6.3	41.8
LCL(IE)	Normal human peripheral blood	Same	+	0.4	1.2
Human T-cell blasts	Normal human T cells stimulated by PHA	T cell	−	0.2	1.6
YAC-1	Mouse line, MLV-transformed	Same	−	0.7	9.9

Cytotoxicity assay was performed as described in Table 1 legend. The data represent three different experiments performed in identical conditions using an effector/target ratio of 25:1.

only 18.3% of these were active killer cells. These values were comparable with those found for the two TCGF-maintained cultures, which demonstrates equivalent cytotoxic potential for these two effector cell types.

TCGF has been shown to sustain proliferation of antigen-specific T killer[13] cells but also to generate NK-like activity[14], and it has been suggested that specific killing and NK killing may be expressed simultaneoulsy in activated T cells at certain stages in T-cell differentiation[15]. Thus, because of uncertainties about the true nature of TCGF cultures and their instability, it seems that HVA/HVS-transformed cytotoxic cell lines are useful, as viral transformation probably freezes effector cells in a defined stage of differentiation representative of the cytotoxic potential expressed by the corresponding non-transformed cells. An analogy could be drawn here between HVA/HVS and EBV because EBV only transforms B lymphocytes in a defined stage of their differentiation[4].

We found marked variation in the number of active killer cells in the 77-DI-2 cell line when tested at different time points (data not shown), the results in Table 4 being of average activity. The explanation for these variations is unclear, suggesting that regulatory mechanisms occur during tissue culture, but we know only that fast growing cultures maintained in roller bottles show the highest activity. The possibility of artificial killing by mycoplasma was excluded by comparing the activity of 77-DI-2 cells kept in mycoplasma-free conditions with that of cells in ordinary tissue culture—similar cytotoxic activities were recorded (data not shown).

Table 3 Natural cytotoxicity by peripheral blood lymphocytes from cotton-topped marmoset monkeys

	Cytotoxicity against target cell (specific ^{51}Cr release)		
Effector cells	1301	K-562	Raji
Monkey 1	43.4	12.1	11.2
Monkey 2	53.8	9.2	10.6
Monkey 3	33.9	8.2	6.2
77-DI-2 cell line	56.2	5.6	4.1
Human NK cells	31.5	72.3	9.3

Cotton-topped marmoset peripheral blood was obtained from Dr L. Wolfe of the Rush Medical Center, Chicago, USA. Lymphocytes were isolated on arrival and tissue-cultured overnight before testing. The cytotoxicity assay was performed using an effector/target cell ratio of 10:1 as described in Table 1 legend. Similar results were obtained in three separate repeat experiments.

Table 4 Cytotoxicity by the 77-DI-2 effector cell line and by TCGF-propagated normal marmoset lymphocytes

	Cytotoxicity (specific ^{51}Cr release)				
	3.0:1	1.5:1	0.8:1	TBCs* (%)	Cytotoxic TBCs† (%)
77-DI-2 (HVA)	50.2	40.7	31.6	38.5	18.3
77-DI-2 (TCGF)	58.6	52.5	50.7	28.7	23.1
77-EC-1 (TCGF)	72.9	65.6	56.2	31.8	30.4

Cytotoxicity was performed as described in Table 1 legend. Molt-4 was used as the target cell.

* Target binding cells (TBCs) were assayed as described elsewhere[17,18].

† Cytotoxic TBCs were tested by the agarose single cell cytotoxicity assay[11]. Briefly, effector and target cells were conjugated at a ratio of 1:10 using carboxyfluorescein-diacetate-labelled target cells, and layered in agarose on to plastic Petri dishes. TBCs were estimated at 0 h and cytotoxicity at 6 h.

Morphological analysis of the 77-DI-2 cell line revealed that a substantial part of the cells resembled large granular lymphocytes (LGLs) and that this fraction seemed to be conjugated to susceptible target cells (data not shown). This may be significant as human NK cells have been reported as having LGL morphology[8]. Electron microscopy of 77-DI-2 cells showed immature cells with abundant endoplasmic reticulum and uropod formation. This indicates a secretory function and a high degree of mobility (data not shown).

Results from electron microscopy and the high cytotoxic activity on some target cells in ^{51}Cr release assays compared with the number of active killer cells found in the agarose single cell cytotoxicity assay, led us to ask the question whether 77-DI-2 effector cells were able to recycle, that is, to kill more than one target cell in the given test period. We previously found this to be a characteristic of interferon-activated human NK cells[16,17]. Using the same technique as for the latter to demonstrate recycling, we found a marked recycling capacity in the 77-DI-2 cell line (data not shown). This recycling capacity is also characteristic of immune cytotoxic T cells[18].

In conclusion, we have found that HVA/HVS-transformed T-cell lines from cotton-topped marmosets can kill predominantly human T-cell lines and non-EBV B-cell lines of malignant origin. This reactivity is clearly a cell-mediated event requiring cell contact and not caused by lymphotoxin-like molecules. The specificity of HVA/HVS cell line killing resembles that of the marmoset NK system, and may be due to these viruses transforming marmoset NK cells or a subpopulation of them. If so, the low reactivity against EBV-induced tumours could indicate that marmoset NK cells differ from human NK cells in their target cell specificity. The selective EBV target deficiency of the marmoset NK system could possibly explain the high degree of susceptibility to EBV-induced lymphoproliferation/lymphomas in these animals[4]. We are now investigating this question.

Alternatively, the HVA/HVS cell line killing could be unrelated to the NK system and represent either a hitherto undefined effector population or possibly a T-effector population which is continuously generated in an autoreactive MLC type of culture. In either case, we consider that the HVA/HVS-transformed cytotoxic cell lines described here are the first immortalized cell lines of lymphoid origin reported which have the capacity to kill by cell contact, without added cell agglutinants, and which display a defined specificity. Possibly they represent an immune function of biological significance and will be useful for studying the finer mechanisms of cell-mediated cytotoxicity reactions.

We thank Maj-Britt Alter for technical assistance, Dr L. Wolfe for a continuous supply of marmoset blood and Dr L. Falk for supplying several of the investigated HVA/HVS cell lines. We also thank Dr G. Klein for discussing the data and manuscript. This work was supported by funds from the Swedish Cancer Society, Karolinska Institute and Karolinska Hospital and by contract NO1-CP-33316 from the Division of Cancer Cause and Prevention, NCI. D. R. J. is a recipient of a fellowship from the Cancer Research Institute, New York.

N-acetoxy-acetylaminofluorene reacts preferentially with a control region of intracellular SV40 chromosome

Peter Beard*, Motohisa Kaneko† & Peter Cerutti†

Departments of *Virology and †Carcinogenesis, Swiss Institute for Experimental Cancer Research, 1066 Epalinges, Switzerland

Many chemical carcinogens or their metabolites react with DNA[1,2]; thus it is of interest to determine what effect chromosomal structure has on these reactions. The chromosome of simian virus 40 (SV40) is well suited for such studies; like chromatin of eukaryotic cells, it is organized into nucleosomes. The nucleotide sequence of SV40 is known[3,4], together with much about the pattern of viral gene expression and DNA replication[5], and the structure of the viral chromosome[6–14]. We have investigated the binding of the ultimate carcinogen, N-acetoxy-acetylaminofluorene (AAAF), to specific regions of the SV40 chromosome *in situ* in the intact infected cell. The results, reported here, indicate that a region containing regulatory functions on the intracellular SV40 chromosome has unique structural properties which render it more susceptible to attack by AAAF than the rest of the SV40 genome. The preferential binding of AAAF to regulatory regions of chromatin may have implications for the mechanism of action of this and similar carcinogens.

AAAF binds covalently to DNA both *in vitro* and in cells growing in culture[15–18]. Over 95% of the reaction products involve guanine residues[15,16,18]. Like other carcinogens which introduce bulky substituents to DNA bases, AAAF reacts more extensively with internucleosomal linker DNA than with nucleosomal core DNA[18–22].

We infected monolayer cultures of the monkey kidney cell line BSC-B with SV40. In the late phase of the lytic cycle, during viral DNA replication, the medium was replaced with medium containing ^{3}H-AAAF (see Table 1 for details). After labelling for 15 min at 37 °C the cells were washed and SV40 DNA selectively extracted[23] and purified by centrifugation in gradients of CsCl–ethidium bromide[24]. As a control we treated protein-free SV40 DNA *in vitro* with ^{3}H-AAAF in the following way. SV40 DNA was extracted from infected cells by the method described above. The supercoiled DNA was then treated with DNA topoisomerase[25] to relax superhelical turns.

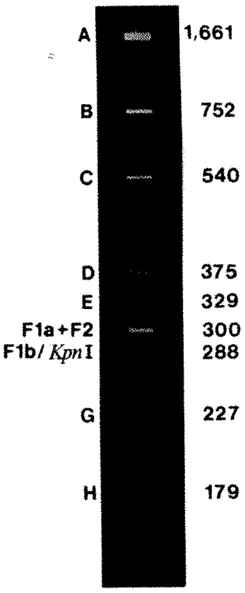

Fig. 1 Low-gelling-temperature agarose gel electrophoresis of SV40 DNA after digestion with restriction enzymes *Hae*III plus *Kpn*I. DNA was electrophoresed in a 3% gel of low-gelling-temperature agarose (Sigma) in Tris-phosphate–EDTA buffer, *p*H 7.8, for 6 h at 4 V cm^{-1}. The gel was stained with ethidium bromide (1 µg ml^{-1}) and photographed in light of 254 nm wavelength. Fragments resulting from cleavage by *Hae*III alone are named according to Lebowitz *et al.*[38]. The larger fragment produced by *Kpn*I cleavage of *Hae*III fragment F1b is marked *Hae*III F1b/*Kpn*I; the smaller product of this cleavage is too short to be detected in this gel (see Fig. 2*c*). Fragment lengths in base pairs are from ref. 5.

Table 1 Distribution of radioactivity in SV40 DNA restriction fragments after labelling of DNA *in vitro* or intracellularly with ^{3}H-AAAF

SV40 *Hae*III fragments	Per cent of total guanines in each fragment	Per cent of total radioactivity in each fragment: Labelled as free DNA	Per cent of total radioactivity in each fragment: Labelled *in situ*
A	30	29	27
B	15.9	18.1	16.1
C	11.1	11.6	9.7
D	7.4	6.5	8.6
E	7.4	6.5	6.6
F1a+F2	12.0	12.3	12.7
F1b/*Kpn*I	7.2	7.6	11.5
G	4.9	4.6	4.4
H	3.9	3.5	3.3

Intracellular SV40 DNA was labelled by addition of ^{3}H-AAAF (9 µM, 878 mCi mmol^{-1}, Midwest Research Institute, Kansas City) to virus-infected cell cultures during 15 min at 40 h after infection. SV40 DNA was then extracted and purified[23,24]. Free DNA (100 µg ml^{-1}) was labelled in solution in 10 mM Tris-HCl, 1 mM EDTA *p*H 7.5. Unincorporated AAAF was then removed by repeated extractions with ether and precipitation of the DNA with ethanol. Labelled DNA (2–10 × 10^3 c.p.m.) was digested with endonucleases *Hae*III plus *Kpn*I (New England Biolabs) and electrophoresed in preparative gel in conditions described in Fig. 1 legend. To determine the radioactivity in each restriction fragment, a simple and reliable procedure was developed. Slices of low-gelling-temperature agarose containing the DNA bands were cut, and water added to 1 ml. The agarose was melted at 70 °C for 5 min and 15 ml Aquasol (NEN) were added and the suspension mixed briefly until homogeneous. Samples were cooled in the dark for several hours, then counted in a scintillation spectrometer. Gel slices with no DNA gave the same background values as Aquasol alone (30 c.p.m.). The radioactivity in each fragment after subtraction of the background is given as a percentage of the total radioactivity. The percentage of total guanines in each fragment was determined from the SV40 nucleotide sequence[3,4].

Relaxed circular DNA is a more appropriate control than supercoiled DNA as SV40 chromosomes contain topoisomerase activity and are themselves thought not to be under torsional stress[26,27]. The free DNA was reacted with ^{3}H-AAAF as described in Table 1. The adduct concentration in SV40 DNA which had been exposed to the carcinogen *in vitro* or *in situ* in the infected cell was estimated from the specific activity of the ^{3}H-AAAF and the radioactivity content of the DNA. SV40 DNA labelled *in vitro* contained an average of about 10 adducts per molecule, whereas SV40 DNA labelled *in situ* contained on average 2 adducts per molecule.

AAAF-modified SV40 DNA was digested with a mixture of the restriction endonucleases *Hae*III and *Kpn*I. This combination gives a set of fragments of convenient size which can be separated by electrophoresis in gels of 3% low-gelling-temperature agarose (Fig. 1). In no case was the AAAF-modified DNA seen to give an altered restriction enzyme digestion pattern compared with normal SV40 DNA. Table 1 shows, for each fragment, its proportions of the total guanine content (calculated from the nucleotide sequence[3,4]) and of the incorporated radioactivity after *in vivo* or *in vitro* labelling. The amount of radioactivity in fragments labelled as free DNA followed the guanine content; when the specific activity was determined as a function of guanine content (Fig. 2*b*), all fragments were labelled equally within experimental error. This result is expected if no region of SV40 DNA shows preferential binding of AAAF because over 95% of AAAF–DNA adducts are formed with guanine residues[15,16,18]. In contrast, the results obtained with SV40 DNA isolated from ^{3}H-AAAF-treated cells indicated non-random distribution of AAAF–guanine adducts. In four determinations the fragment *Hae*III F1b/*Kpn*I was always labelled to a specific activity 1.5–2 times higher than that expected from the guanine content (Fig. 2*a*). The adduct concentrations in the restriction fragments from the rest of the SV40 genome were proportional to their guanine content.

0028-0836/81/190084—02$01.00

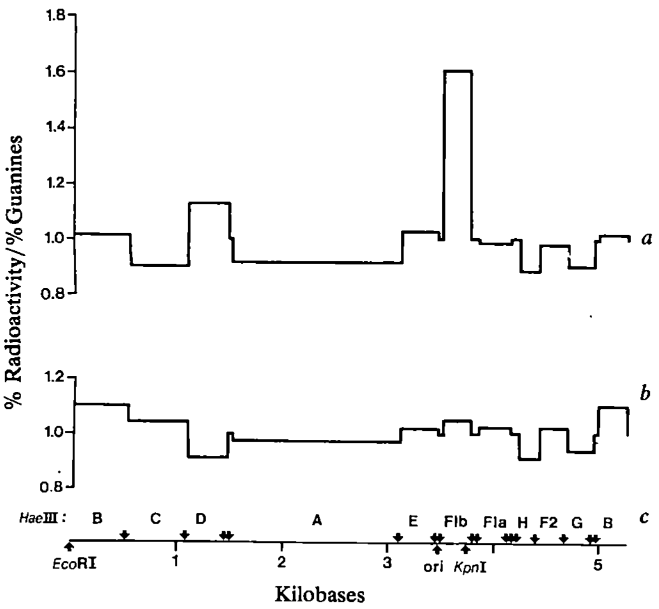

Fig. 2 Preferred reaction site for AAAF on the intracellular SV40 chromosome. The percentage of total guanines present in each SV40 restriction fragment, and the percentage of total ^{3}H-AAAF radioactivity in each fragment were determined as described in Table 1 legend. The ratio of the percentage of total radioactivity to the percentage of total guanines was calculated for each fragment. *a*, SV40 DNA labelled *in situ* in infected cells; *b*, labelled as free SV40 DNA; *c*, the abcissa is a *Hae*III endonuclease cleavage map of the circular SV40 DNA interrupted at the *Eco*RI site. The map is based on Lebowitz *et al.*[38], as is the SV40 nucleotide sequence[3,4]. DNA fragments too small to be analysed have been assumed to be labelled at the average value for the whole DNA.

Thus in the intracellular SV40 chromosome, a stretch of DNA within ~300 base pairs of the 'late genes' side of the origin of replication (Fig. 2*c*) is preferentially-reactive with AAAF. We do not know whether the region just to the 'early genes' side of the origin is also specifically overlabelled with AAAF, as the restriction fragment containing this region is too small (43 base pairs) to be analysed in these experiments. The next distal fragment to the early side, *Hae*III E (329 base pairs) was labelled normally.

The level found for AAAF modification of the hyper-reactive region is a minimum estimate because we do not know the exact limits of this region on the SV40 genome. If the exposed region is much shorter than the DNA fragment *Hae*III F1b/*Kpn*I which we characterized as containing it, then the level of modification would be correspondingly higher than the value we obtained, which is the average for the whole of that fragment. The level would also be greater if the hyper-reactive region were present in only a fraction of the SV40 chromosomes in the cell.

Why should AAAF react predominantly with a certain region of chromosomal DNA? The higher reactivity of AAAF towards nucleosomal linker compared with core DNA[18–22] suggests that the hyper-reactive region of SV40 chromosomes may represent DNA free of protein, or associated with less tightly bound protein. Electron microscopic observation[11,12] showed a nucleosome-free region on a fraction of isolated SV40 chromosomes; it was unclear to what extent this region already existed *in vivo* or was created by loss of nucleosomes during isolation of nuclei or of the viral chromosomes[11,12]. From our results, it is likely that a nucleosome-free stretch of DNA exists on SV40 chromosomes also *in situ* in the infected cell. The reaction of AAAF with DNA is also known to favour denatured DNA over native[28]; it is therefore possible that the hyper-reactive region has an unusual secondary or tertiary structure (reviewed in ref. 29). This region is not, however, simply the most readily denatured part of SV40 as detected by electron microscopy or S_1 nuclease sensitivity[30,31]. It also remains possible that AAAF induces an alteration of chromosomal structure in the SV40 origin region. However, modification of DNA by AAAF has been reported not to interfere with the *in vitro* reconstitution of apparently normal nucleosomes[32].

The region of the SV40 chromosome which reacts preferentially with AAAF contains regulatory sequences controlling the origin of replication of DNA[33], T-antigen binding sites[34] and likely promoters for late transcription[35,36]. SV40 uses cellular enzymes for its replication[5], and SV40 chromatin probably resembles certain regions of cellular chromatin in structure[37]. Therefore, regulatory sequences of some cellular genes may likewise be particularly susceptible to modification by AAAF and similar carcinogens.

Location of domains in globular proteins

Alexander A. Rashin

Institute of Biological Physics, Academy of Sciences of the USSR,
142292 Pushchino, Moscow Region, USSR

Although it has become widely accepted that domains are the basic units of structure, function and evolution in proteins[1] and it is thought that proteins with complex functions evolve by fusion of genes coding for individual domains[2,3], the domains are not uniformly defined. Most commonly, domains are simply the compact and more or less loosely connected areas[1,4] apparent from a visual inspection of protein models; to avoid subjectivity and ambiguities inherent in visual inspection, certain computer algorithms for location of these 'structural' domains have

0028–0836/81/190085—03$01.00

recently been proposed[5–7]. An alternative interpretation is that domains are stable protein fragments found in biochemical experiments[8–17]. I regard them as 'globular fragments' which may refold autonomously and carry specific functions[1], and I propose here a method for location of these globular fragments based on surface area[18] measurements. Applied to several proteins the globular fragments found often coincide with structural domains or are contained within them. In particular the globular fragments found in globins correlate with the two structural domains proposed previously[4,19], and do not correlate with the three coding sequences separated by introns in the haemoglobin genes[20–22].

It has been shown that the surface area buried in a native fold is proportional to the gain in free energy of dehydration and hydrogen bond formation due to folding[23,24]. As surface area is proportional to the number of interatomic contacts[25], it may also serve as a crude estimate of van der Waals' interactions, which are very sensitive to errors in interatomic distances and therefore are usually averaged by counting the number of contacts. These findings are used here to define globular fragments.

A globular fragment may be defined as a segment of a protein chain which, when the rest of the protein is removed, buries a maximum of surface area within its fold. As the contribution of the free energy (estimated as 24 cal mol^{-1} Å^{-2} of buried surface area[24]) to its stability is maximal, such a fragment is more likely than others to be autonomously stable.

The surface area buried in stable globular proteins follows the law[24]

$$\begin{aligned} B_G &= 0.859\mathrm{MW} + 0.774\mathrm{MW}^2 \times 10^{-5} \\ &= 94.49L + 93.654L^2 \times 10^{-3} \qquad (1) \end{aligned}$$

which relates buried areas, B_G (in Å^2), to the molecular weight, MW, or the number of residues, L ($\mathrm{MW} \approx 110L$) in proteins of 50–320 residues. Non-globular structures have smaller buried areas (B) than those given by equation (1), the ratio B/B_G giving a measure of their globularity. Thus, we may calculate the buried surface areas of all chain fragments in a protein, removing the rest of the structure but assuming that the native conformation is retained, and analyse their B/B_G values. A maximum of B/B_G close to unity indicates the presence of a globular fragment.

Buried surface areas may be calculated from atomic coordinates[18]. The use of the simplified geometry[25,26] and the fast algorithm[7] allow such calculations to be made with efficiency equal to those for interatomic distances (see refs 5, 27). The buried areas thus determined are within a few per cent of those calculated using the all-atom algorithm[24]. Figure 1*a* shows, for the haemoglobin β chain, a significant difference in buried areas between globular and non-globular fragments of the same length. Fragment 19–68 has the buried area $B = 4{,}800$ Å^2 and $B/B_G = 0.97$, which indicates its globularity. The fragments of 50 residues beginning at residues 1–10 and 33–55 have $B = 3{,}500 \pm 250$ Å^2 and $B/B_G = 0.71 \pm 0.05$—these are non-globular. It has not been determined whether equation (1) is valid for $L < 50$. However, I found that conversion of the difference $B_G - B$, calculated for a number of α helices, to the equivalent free energy yields values only a few kcal mol^{-1} higher than the experimental stability of an α helix. Thus I used equation (1) for all chain lengths ($L \leq 320$), bearing in mind that it is less justified for $L < 50$. Figure 1*b* shows a typical B/B_G plot.

A summary of my results (Table 1) shows that globular fragments found here often coincide with structural domains or are contained within them. Ribonuclease is a notable exception: S protein (residues 21–124), found to be a globular fragment, was never listed previously among structural domains[4–7]. Table 1 also shows that my locations of globular fragments agree well with those determined experimentally. Note that location of the two independent globular fragments within the previously proposed entire discontinuous domain in hen lysozyme agrees with significant mutual displacements of these fragments on denaturation shown by X-ray crystallography[14]. A relatively low value of B/B_G for the C-terminal globular fragment of elastase is an artefact due to the unusually large number of small residues in this fragment—this means that the expression MW110L in equation (1) is invalid. The use of the dependence on MW in equation (1) yields $B/B_G = 0.98$ for this fragment, indicating

Table 1 Structural domains and globular fragments

Protein	Structural domains	Globular fragments: Calculated limits	B/B_G	Experiment
Pancreatic trypsin inhibitor	1–58*	1–55	1.10	
Immunoglobulin light chain	1–109†	4–109	0.96	Two globular fragments
	110–214†	110–209	0.96	similar to domains (refs 8–11)
Ribonuclease S	No continuous domain*	23–124	0.99	Globular fragment in 21–124 (refs 12–13)
Hen lysozyme	(1–38)+(101–129)*	8–29‡	1.05	8–29, 108–116 (ref. 14)
	39–87	39–98	0.97	42–99 (refs 14, 15)
		105–116‡	0.97	
T_4 lysozyme	1–74§	13–67	1.01	
	75–164§	78–154	1.05	
Papain	10–111*	17–100	1.11	Two independently melting
	113–207*	112–208	1.03	fragments (ref. 8)
Elastase	27–127*	27–120	1.07	
	128–230*	130–229	0.93‖	126–245 (ref. 16)
Thermolysin	1–157†	4–151	1.09	
	158–316†	203–316	1.06	206–316 (ref. 17)
Myoglobin	1–85*	21–70	1.03	
	86–153*	86–152	0.99	
Haemoglobin α chain	1–74*	20–63	0.91	
	75–141*	80–140	0.94	
Haemoglobin β chain	1–79*	19–68	0.97	
	80–146*	81–145	0.99	

Globular fragments are detected as maxima of B/B_G, where B is the buried surface area of a fragment and B_G is given by equation (1). If there are several maxima of B/B_G within the same chain region, only one fragment corresponding to the highest B/B_G value is listed.

$B = B_T - B_N$, where B_T is the total inaccessible area of all the spheres representing residues[25,26] in a given structure and B_N is the area of the spheres made inaccessible by their covalent neighbours along the chain in the same structure. Coordinates used in the calculations are from Brookhaven Protein Data Bank[28].

* Taken from ref. 4, haemoglobin chains are aligned to myoglobin. † Taken from ref. 35. ‡ Globular fragments much shorter than 50 residues (see text). § Located from stereodrawing in ref. 36. ‖ Low value due to an artefact; equals 0.98 when corrected (see text).

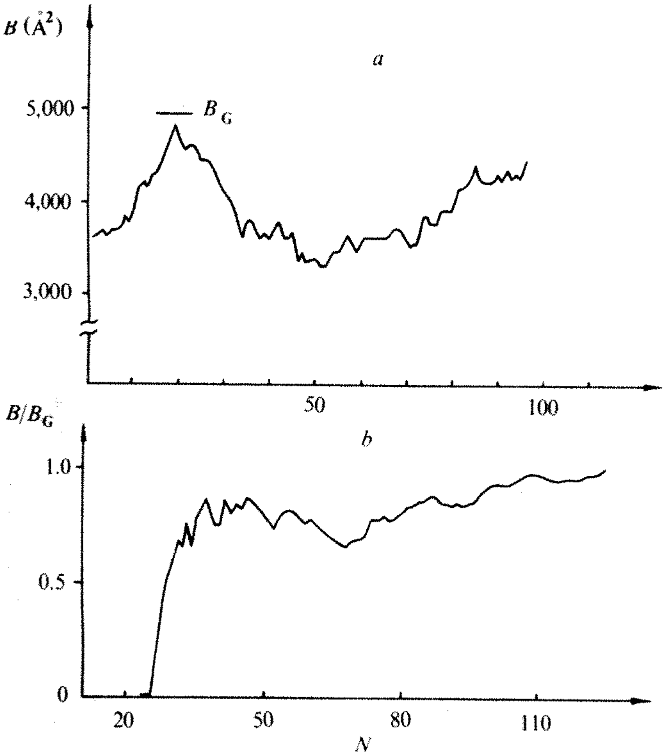

Fig. 1 *a*, The buried surface area B of each segment of 50 residues, beginning at residue N, is calculated for human β chain haemoglobin, assuming that the isolated segment retains its native conformation. The value B_G expected from equation (1) is almost reached by the segment beginning at $N = 19$. *b*, The ratios of the buried area values B of all segments of ribonuclease, beginning at residue 23 and ending at residue N, to the corresponding values B_G expected from equation (1). Two maxima with B/B_G values close to unity at $N = 110$ and $N = 124$ can be seen, the latter being slightly higher.

that this use may be preferable. B/B_G values for globin fragments calculated here using the simplified geometry corresponding to the time-averaged positions of the side chains[25,26] are higher than those calculated with the all-atom algorithm[18,24] (or the simplified geometry fitted to the actual positions of the side chains[7]). This effect of the change in side chain positions agrees with the necessity for small changes of the structure to gain more stability found in the model-building studies of globin fragments[29]. The lowest B/B_G value listed (which may be supposed to correspond to the lowest stability) is that for the N-terminal globular fragment of haemoglobin α chain. This reflects the lack of D helix in the α chain, which is the major difference between the latter and the β chain or myoglobin, and correlates with the drastically different conformation of the apo-α chain compared with the apo-β chain or the apomyoglobin[30].

It was recently proposed, by analogy with immunoglobulins, that translation products of the three continuous sequences or exons in haemoglobin genes correspond to domains[19–21]. Exon products for the β chain are fragments 1–30, 31–104 and 105–146. Table 1 shows that they correspond to neither structural domains[4,19] nor globular fragments. Exon products have low B/B_G values of 0.68, 0.85 and 0.81, indicating their nonglobularity. They do not seem to correspond to functional domains as the latter are conventionally viewed as being composed of few structural domains (or globular fragments)[1]. However, it was shown that fragment 31–104 binds cyanomethaemin but lacks any detectable structure even when bound to haem[31]. Alternatively, it has been proposed[32] that the function of each globular fragment in myoglobin is recognition of the haem. It may be speculated that residues 31–63, part of the N-terminal globular fragment, possess marginal stability sufficient to recognize the haem. We found that its B/B_G was 0.94 in the β chain, but this was not confirmed by the all-atom calculation, suggesting some rearrangement of the structure. This distorted structure may have low helicity undetectable by circular dichroism measurements. These results seem to indicate that at present the domain structure of globins cannot be unequivocally correlated with exons; therefore the problem needs further study.

Algorithms using surface area criteria have been successful in prediction of tertiary[33,34] and quaternary[25] structures of proteins and in location of structural domains (ref. 7 and Wodak and Janin, personal communication). I have shown here that they detect the presence within globular proteins of fragments that may be autonomously stable. Such fragments are likely candidates for intermediates in folding. The folding schemes based on surface area measurements can be derived[32] and compared with results obtained experimentally.

I thank B. H. Yudman for help in programming; M. Yu. Pavlov for control calculations using the all-atom algorithm; P. L. Privalov for useful discussion, and J. Janin and S. J. Wodak for useful discussions and for drawing my attention to the domain/exon hypothesis.

O_2 binding properties of the product of the central exon of β-globin gene

Charles S. Craik, Steven R. Buchman & Sherman Beychok*

Departments of Biological Sciences and Chemistry,
Columbia University, New York 10027, USA

The hypothesis that the exons of eukaryotic structural genes code for functional domains and that the partitioned arrangement of coding information may thus serve to mediate the rapid evolution of new and unique proteins from pre-existing exons[1–3] is also supported by our recent studies which demonstrate that the product of the central exon of the human β-globin gene is a complete functional domain capable of binding haem tightly and specifically[4,5]. Moreover, an analysis of the structure/function

---

* To whom correspondence should be addressed.

changes induced by mutations in different parts of the haemoglobin molecule suggests that each of the three exon-encoded segments is primarily associated with different functions of haemoglobin (for example, haem-binding, haem–haem interaction)[6]. We have now extended our studies to determine whether the central fragment is sufficient for maintenance of a stable complex of ferrous haem with molecular oxygen and, if not, what are the minimal requirements for the expression of this activity. The results of our reconstitution experiments indicate that the isolated central exon peptide is unable to maintain a ferrous haem–dioxygen complex unless the side exon products and the complementary haem-containing subunit are present. A conformational change which accompanies the noncovalent association of fragments may account for the restoration of reversible oxygen binding.

Haemoglobin and myoglobin in their ferrous states reversibly bind oxygen—this makes them unique among haem-binding proteins and different from most ferrous haem compounds, which are rapidly oxidized in the presence of molecular oxygen. They are the only molecules known, other than the biomimetic model systems (for example, haem–polystyrene matrices[7] and 'picket fence' porphyrins[8]) that allow O_2 and Fe(II) haem to combine and dissociate freely without concomitant oxidation of the iron. The stability of the oxygenated derivative seems to be achieved in substantial part by accommodation of the haem group in a hydrophobic pocket into which the side chains from the surrounding helices project. These side chains provide the fifth ligand (His F8), modify the binding of the sixth ligand (O_2, CO, CN^-, etc.) and lock the haem into a specific spatial arrangement with respect to the rest of the protein[9,10].

The distinctive spectral characteristics of various ligand derivatives of haemoglobin have been well documented and provide a sensitive means of evaluating the environment and ligation state of the prosthetic group in the protein[11]. The method used to investigate the oxygen binding properties of the globin central fragment (see Fig. 1) was based on spectral analysis; its application to the isolated intact globins, after reconstitution with haem, was used as a control. Figure 2*a* shows spectra resulting from a typical oxygenation experiment in which the intact β-globin chain (β^0) was combined with haemin dicyanide to form the cyanmet subunit derivative, reduced with sodium dithionite and subsequently oxygenated. Spectra for α-subunits of haemoglobin, native or reconstituted, are almost identical to those presented for β, differing only slightly in the absolute value of the extinction coefficients and having a 1–2 nm difference in position of the absorbance maxima.

Table 1 Far UV circular dichroism and secondary structure characteristics

Protein or peptide	$[\theta]_{222\,\mathrm{nm}}$ (deg cm^2 per dmol)	Calculated % α helix*	Calculated no. of helical residues†
β^h	21,600	73	106
β^0+h	21,600‡	73	106
$\beta^0_{digest}+\alpha^h+h$	18,200		
	(14,800)§	52§	76

α^0_{digest}	7,200	28	39

α^0 or β^0 indicates that the chain has no haem attached; α^h or β^h indicates that the chain has bound haem. The subscript 'digest' refers to unfractionated clostripain-treated globin; the subscript 'rec' refers to a fully reconstituted sample prepared by mixing together equimolar concentrations of the various arginyl peptides, and the subscript 'cf' denotes the isolated central fragment of β-globin. $[\theta]_{222}$ values are means of at least three determinations, except for β^0_{rec} which is the mean of two determinations. The estimated uncertainty in $[\theta]_{222}$ is ±5%. In the cases of the β^0_{rec} samples, the second digit in the calculated α helix may not be significant due to uncertainty in concentration determination.

* Calculated according to Chen *et al.*[21].

† Calculated by multiplying the fraction of helical residues of the third column by 146 and 141 for α- and β-globins, respectively, and 74 for β^0_{cf}.

‡ Reconstitution of α- and β-globins with haemin dicyanide to give the same $[\theta]_{222}$ requires dialysis into 0.1 M potassium phosphate buffer, 1 mM EDTA, *p*H 7.4.

§ These values refer to the β components after subtracting the contribution made by α^h.

To follow oxygen binding to the haem-binding domain, by itself and in combination with other components of haemoglobin, the α- or β-globin chain was first proteolytically cleaved with the arginine-specific protease into the fragments corresponding to the exon-encoded regions of the protein (Fig. 1). The visible and Soret spectra of these samples after their reconstitution with haemin dicyanide were then obtained along with their reduced and oxygenated derivatives. Comparison of Fig. 2*b* with the intact control shown in Fig. 2*a* reveals almost identical spectra for haem-reconstituted β-globin and β-globin digest. However, whereas reduction with dithionite produced a deoxyhaemoglobin spectrum for the reconstituted β-globin, a haemochromogen spectrum (hexacoordinate ferrous haem iron axially bound to two histidines) was obtained with the reconstituted digest and with the isolated central fragment. Subsequent removal of the dithionite produced an oxyhaemoglobin spectrum for the undigested samples; in contrast, the spectrum of the digested sample or the central fragment was that of a haemichromogen (hexacoordinate ferric haem with two histidines serving as the axial ligands), diagnostic of a haem complex that does not reversibly bind oxygen. Similar results were found for α-globin.

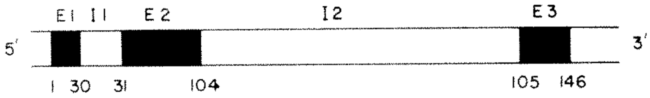

Fig. 1 Diagrammatic representation of the β-globin intron/exon structure. The black boxes E1, E2 and E3 represent expressed DNA sequences (exons); the white boxes I1 and I2 represent intervening sequences (introns)[16]. The open-boxes at the 5′ and 3′ ends are untranslated regions of indeterminate length. The numbers below the exons denote amino acid sequence positions of the β-globin. E2 represents the central exon that codes for the haem-binding polypeptide consisting of amino acids 31–104. The 5′→3′ orientation is indicated. A similar arrangement exists for the α-globin gene[17,18]. The small intron (I1) for α-globin occurs between codons 31 and 32 whereas the large intron (I2) interrupts the coding sequence at 99 and 100. When the amino acid sequences of α- and β-globin are aligned to maximize functional homology[19], their intron/exon junctions coincide; α-globin residue 31 is an arginine but residue 99 is a lysine, thus limited clostripain digestion yields only two fragments of residues 1–31 and 32–141. Cleavage products were separated by a modification of the procedure used elsewhere[4] and involved gel permeation high performance liquid chromatography in 6 M urea, 0.2M formic acid, using a recycle purification mode[20]. This procedure is much more rapid and gives higher purity than molecular sieve chromatography in 9% formic acid.

Comparable experiments were carried out on a fully reconstituted sample of β-globin digest (β^0_{rec}), prepared by mixing equimolar concentrations of the various arginyl peptides then combining the mixture with haemin dicyanide. Although the mixture showed a substantial Soret extinction coefficient, haemochromogen and eventual haemichromogen spectra resulted from dithionite addition and its subsequent removal. However, when the complementary haem-containing subunit, α^h, was combined with β^0_{rec} or the β^0_{digest} before haem addition, the typical oxy spectrum presented in Fig. 2*c* resulted. By subtracting the contribution to this oxy spectrum due to the native α^h, it was established that 86% of the β^0_{digest} produced an oxy spectrum, with the other 14% haemichromogen. The β^0_{rec}

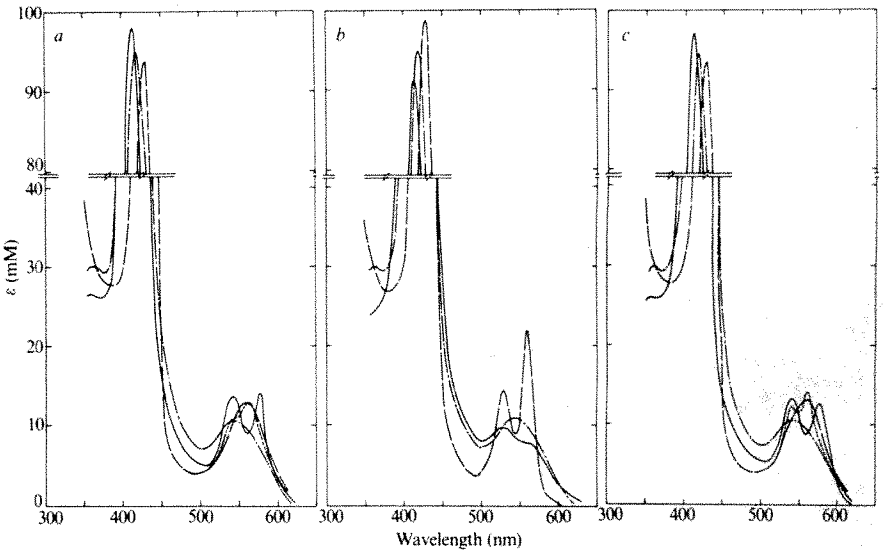

Fig. 2 Spectral properties of cyanmet-, deoxy- and oxy-derivatives of undigested and digested globins. *a*, Cyanmet-spectrum (— — —) of an equimolar mixture of *β*-globin and haemin dicyanide; transient ferrocyanide spectrum (---------) immediately after sodium dithionite addition and the eventual deoxy-spectrum (— — —); oxy-spectrum (———) after dithionite removal. The transient ferrocyanide spectrum and the deoxy-spectrum are coincident below 500 nm. Solutions of the ferricyanide derivatives showed an absorption spectrum in the visible with a broad band centred at 540 nm and a barely discernible shoulder at 560 nm. The Soret band lies near 420 nm, and has an extinction coefficient about 10-fold greater than that at 540 nm. Ferricyanide derivatives of haemoglobin react directly with dithionite, leading to reduction of the haem iron with ligand still bound, the transient ferrocyanide derivatives then dissociating into cyanide and deoxygenated ferrous haem-protein. The latter transition from ferrocyanide to deoxyferrohaem could be monitored for the separated *α*- and *β*-subunits, as the ferrocyanide spectrum, with a maximum at 562 nm and a smaller peak at 541 nm, only gradually coalesced to the deoxyferrohaem spectrum, characterized by a single, broad asymmetric band in the visible region with a maximum at 556 nm and a Soret band in the near UV at ~430 nm. After removal of dithionite by dilution, dialysis or gel filtration, and exposure of the haem–protein solution to oxygen, the characteristic oxyferrohaem spectrum appears. The two visible absorption bands are quite distinct from each other, with one peaking at 577 nm and a broader one of slightly lower intensity peaking at 541 nm. The Soret band is at 415 nm. *b*, Cyanmet-spectrum (— — —) of an equimolar mixture of 60-min clostripain digested *β*-globin and haemin dicyanide; haemochromogen spectrum (— — —) due to dithionite addition and a haemichromogen spectrum (———) after dithionite removal. For *α*-globin, this spectrum also contains a 9.3% oxy-component presumably due to the small amount of undigested globin present. *c*, Cyanmet-spectrum (— — —) of an equimolar mixture of 60-min clostripain digested *β*-globin, the complementary haem-containing *α*-subunit and haemin dicyanide; transient ferrocyanide spectrum (---------) immediately after dithionite addition and the eventual deoxy-spectrum (— — —); oxy-spectrum (———) after dithionite removal. The transient ferrocyanide spectrum and the deoxy-spectrum are coincident below 500 nm. Measurements were made at 4 °C in 20 mM potassium phosphate, 1 mM EDTA buffer, *p*H 5.7 or 0.1 M potassium phosphate buffer, 1 mM EDTA buffer, *p*H 7.4. Although not essential for α^0 reconstituted with haem, 0.1 M potassium phosphate *p*H 7.4 buffer was required to develop reversible oxygen binding activity for the haem-reconstituted *β*-subunit. To reduce undesirable side effects, dithionite reductions were achieved with a 10-fold excess of dithionite in a nitrogen atmosphere. Dithionite removal was by gel filtration through a Bio-Gel P-2, dialysis or dilution.

sample yielded a lower value of 74%. This discrepancy was probably due to irreversible denaturation of the fragment produced by the separation procedures.

No appreciable oxy spectrum was observed when the experiment was repeated with the central fragment alone mixed with α^h. It is therefore clear that the reversible O_2 binding abilities of the central exon haem-binding fragment, incapable of reversibly binding O_2 on the time scale (min) and in the conditions of the above experiments, can be restored by the presence of the side exon fragments and the complementary haem-containing subunit.

To determine whether reversible O_2 binding is correlated with secondary structure, the far UV circular dichroism spectra of the haem-free globins, the fractionated, unfractionated and reconstituted digestion products, the central fragment of *β*-globin and their haem-reconstituted mixtures were determined; the results are presented in Table 1. The helix contents of both *α*- and *β*-globins, which are half those of the haem-containing chains, or lower depending on conditions, were reduced further by digestion with clostripain to the extent of an additional 10% loss in helicity. Both α^0 and β^0 digests, as well as β^0_{rec}, showed some recovery of helix content on recombination with haemin dicyanide: ~20% (or 30 residues) refolding in the case of α^0_{digest} and ~10% in the case of β^0_{digest} and β^0_{rec}. The addition of the complementary haem-containing subunit α^h to β^0_{digest} or β^0_{rec}, and β^h to α^0_{digest} induced some refolding, ~10% in the case of α^0_{digest} and 15% in the case of β^0_{digest}. These changes are smaller in magnitude than those seen when α^h is added to *β*-globin or β^h is added to *α*-globin, perhaps reflecting the limitations imposed on refolding by the interruption of covalent bonding in the linear sequence of residues of the native helices. Neither addition of haemin dicyanide or α^h affected the circular dichroism of the isolated β^0 central fragment.

The loss of structure of the globins on clostripain cleavage, as seen from the circular dichroism measurements, seems to be sufficient for coordination of the distal histidine with the haem iron, thus preventing oxygen binding and resulting in haemichromogen formation. Once the ability to restore the native three-dimensional structure of the haem-binding cavity has been lost, the maintenance of a stable ferrous complex in the presence of oxygen is prevented. This is clearly the case for haemoglobin or myoglobin where the stability of the oxygenated derivative is lost on denaturation, linking the integrity of the conformation of the protein to its O_2-binding capabilities.

The possibility that the structural features defining the haem pocket are induced by haem-binding to the central fragment and can be made more precise when the side fragments are present, even if not covalently joined, has been suggested from Soret extinction coefficient measurements of haem-reconstituted β^0, β^0_{digest}, β^0_{rec} and the central fragment. However, this was not sufficient to restore secondary structure or reversible oxygen binding to the haem-binding fragment. Only by introducing equivalent amounts of the complementary haem-containing subunit before reconstitution with haem could an oxyhaemoglobin spectrum result. This was accompanied by a 14% increase in helix content (20 residues) which suggest a restructuring of the haem pocket to allow reversible O_2 binding. The phenomenon is reminiscent of the refolding observed in complementation studies on ribonuclease[12] and staphylococcal nuclease[13].

These results, taken together with our earlier studies, demonstrate that the exon-encoded central fragment has the structural potential of providing a tight and specific binding site for haem, and that the fit is sharpened by the addition of the N- and C-terminal fragments, but that formation of a stable dioxygen complex requires, in the conditions of our experiments, the presence of the side fragments and the complementary subunit.

We are investigating, by stop-flow methods, whether transient reversible oxygen binding in the absence of the complementary subunit occurs, to elucidate the mechanism by which the distal histidine becomes irreversibly bound to the iron. Obviously, the requirement of a complementary subunit cannot be general, as shown by the reversible oxygen binding of the *α* subunit and myoglobin, both monomeric. In this case, the added subunit served to overcome the tendency for the distal histidine to be bound to haem in the deoxy state. However, it is precisely a difference in bonding tendency of the distal histidine that distinguishes the globins from the *b*-type cytochromes[11]. The central exon product, isolated or in noncovalent association with the side peptide fragments, accordingly has spectral characteristics reminiscent of these cytochromes, and undergoes a similar reduction–reoxidation cycle with dithionite and molecular oxygen.

The finding of a haem-binding (or, more generally, porphyrin-binding) domain encoded by an exon that can combine with other gene elements to generate a multiplicity of haem-binding proteins of diverse function, would be very fundamental. Thus we have begun to define the essential features of a haem-binding site and have shown similarity in the nature and spatial distribution of haem contact residues in haemoglobin chains and several *b*-type cytochromes[5,14,15]. We will provide details of these similarities elsewhere and suggest that the evolution of the globin genes from earlier cytochrome-like ones involved combination of an exon coding for a haem-binding domain with others not derived from cytochrome genes.

This study was supported in part by NSF grant PCM 80-05614. We thank Drs Alex Tzagoloff and Jonathan Greer for critical reading of the manuscript and constructive advice, and Drs Jeremy Luchins and Yvonne Leutzinger for their interest and support. The authors also thank Ms Jill Macoska for preparation of the text, table and figures.

Correlation of DNA exonic regions with protein structural units in haemoglobin

Mitiko Gō

Department of Biology, Faculty of Science, Kyushu University 33, Fukuoka 812, Japan

The discovery of intervening sequences (introns) in DNA led Gilbert and Tonegawa[1,2] to suggest that a new protein could have been produced by bringing together certain segments of pre-existing ones. However, Blake[3] argued that if DNA was so organized that coding sequences (exons) correspond to structural as well as functional units of proteins, then combinations would be much more likely to yield a stable globular conformation through being 'sums of parts'. In immunoglobulin heavy chain, four separate exons encode four different units[4], all with distinct functions and three of which have clear domain structures. However, in haemoglobin, which has no obvious domain structure, no clear conformational characteristics have so far been recognized for the segments encoded by exons. From a close inspection of their conformations by drawing various stereodiagrams and the C^{α}–C^{α} distance map, I now propose a conformational characterization of the segments as structural units.

In the mouse α- and β-globin genes, the three coding sequences correspond to amino acid residues 1–31, 32–99 and 100–141, and 1–30, 31–104 and 105–146, respectively[5–8]. These two subunits of haemoglobin are structural homologues. The central coding sequence has been shown to correspond to the function that interacts with and binds haem[9,10]. Do exonic regions of DNA correspond to structural units of protein conformation in haemoglobin? It is well known that the globin monomers do not show domain or supersecondary structures[11] such as those observed in immunoglobulin or dehydrogenases. A domain can be regarded as a part of a protein which forms a compact, continuous globular region separated from the rest of the molecule[12,13]. The joints at residues 30–31 (31–32 in the β chain) and 104–105 (99–100 in the β chain) between adjacent segments encoded by different exons are located in the middle of B and G helices, respectively. Thus the exonic regions do not correspond to simple secondary structures. Therefore, the conformations of the segments are not characterized as domains, supersecondary or secondary structures.

The folding structure of the whole β chain and those of its three segments encoded by the exons are shown in Fig. 1*a–d*. The segment coded by the right exon consists of two helices connected by several residues forming a reverse turn (Fig. 1*b*). This segment is in slight contact with the haem group. The segment encoded by the central exon compactly encloses the haem group; 14 out of 17 side chains in contact with the haem are part of this segment (Fig. 1*c*). This correspondence of haem binding to the central coding region has been reported elsewhere[9,10]. The segment encoded by the left exon is a helical arc and is less compact than the other segments (Fig. 1*d*)—this segment is not in contact with the haem group. The mutual arrangements of the segments in Fig. 1*a* are such that they lie, and are thus exposed on, the surface of the molecule. They may thus be regarded as a surface layer of the molecule. There is no core in haemoglobin subunits, that is, the subunits consist solely of the surface layer, which is due to the small size of the subunits. Note also that in Fig. 1*a* the joints between adjacent segments occur relatively close to the centre of the molecule. In fact the residue accessibility to water molecules is extremely small at these joints[14].

Protein folding can be presented on a two-dimensional plane by the so-called C^{α}–C^{α} distance map[15] first used by Rossmann and Liljas[13] to locate folding domains. By careful inspection of various patterns on the distance maps, Kuntz[16] showed that the square and trapezoidal patterns represented the simplest and smallest units of the tertiary structure consisting of the three segments that are situated close together in space. Folding of the haemoglobin β chain is shown on this distance map in Fig. 2. The pairs of residues separated by >27 Å are shown by dark shading: these regions are grouped into seven major continuous areas. In Fig. 2 solid lines are drawn at the joints between the polypeptide segments encoded by different exons, that is, between residues 30 and 31 and between 104 and 105. It is remarkable that these lines scarcely cross the dark regions on the map.

This fact together with the characteristics observed in the stereodiagrams leads to a clear characterization of the conformations of the segments encoded by the exons. To describe this characterization, consider the following problem. Given the three-dimensional structure of each subunit of haemoglobin as shown in Fig. 1*a*, when cut into three or four segments consisting of 30–50 residues, in such a way that they are as little extended as possible, it is obvious that all conformations of such segments cannot be very compact. One or two must be rather extended. A possible algorithm for solving this problem in such small one-layer proteins as haemoglobin subunits uses pairs of residues

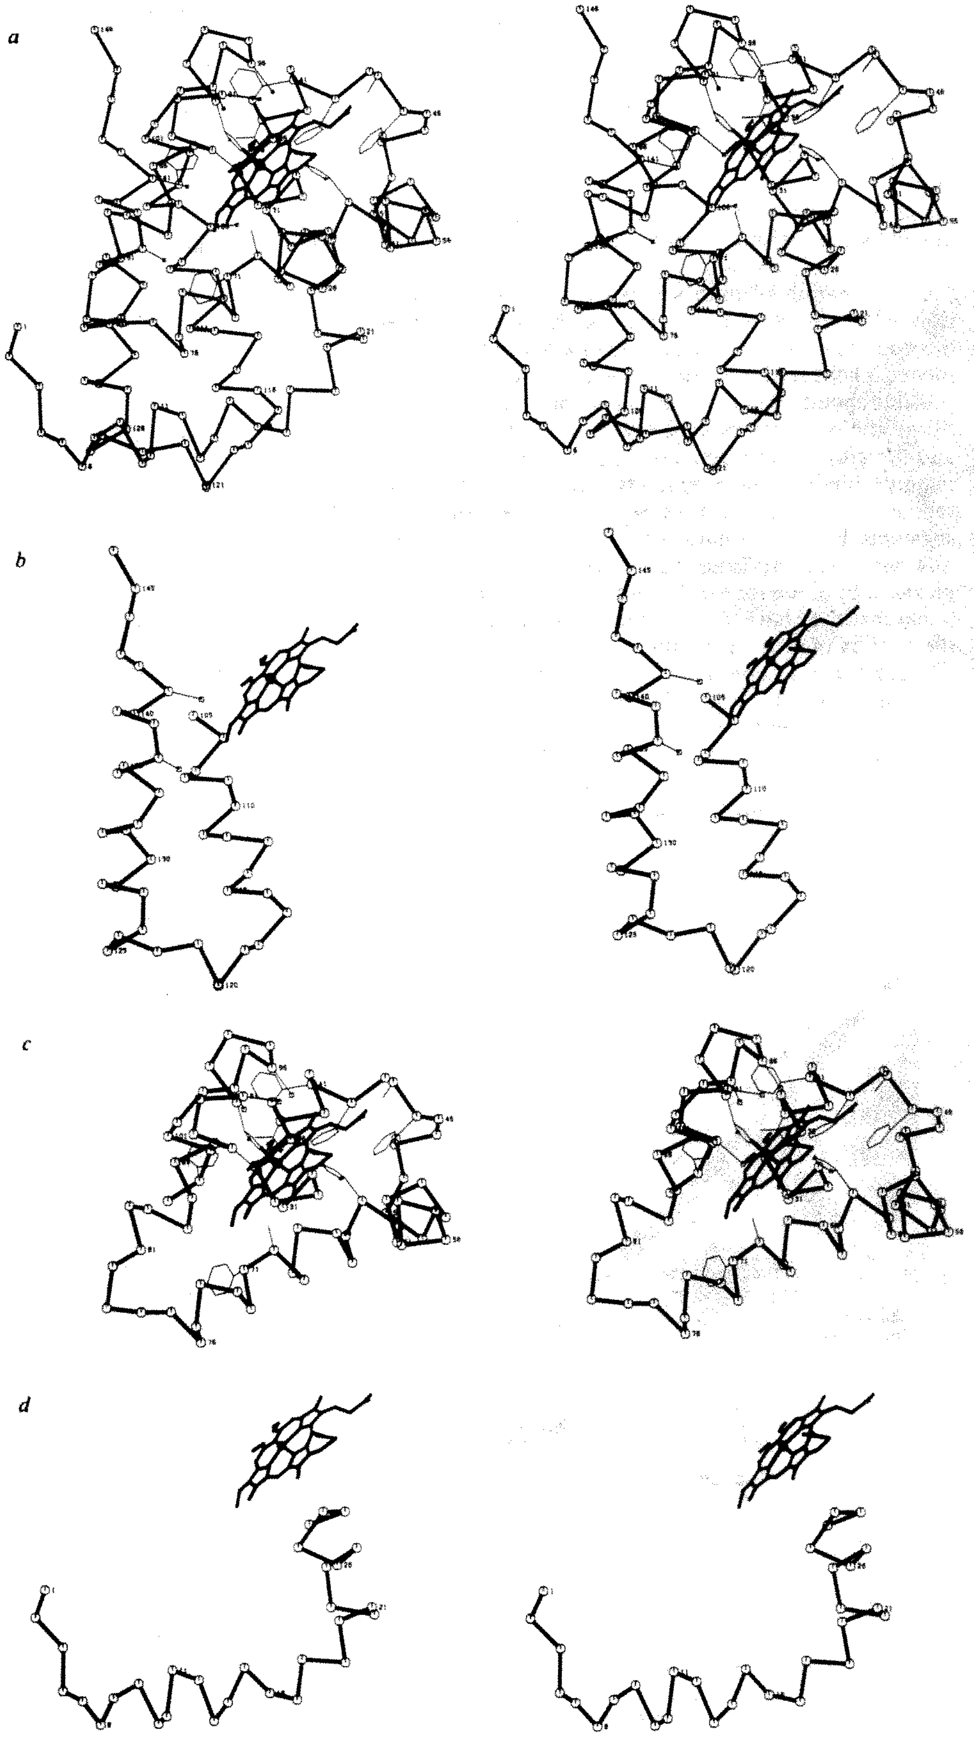

Fig. 1 Stereodiagrams of the whole β chain (*a*) and of the segments corresponding to the right (*b*), central (*c*) and left exons (*d*). The α-carbon backbone is represented. The haem group is shown with each segment to give the relative three-dimensional position. The side chains in contact with the haem group[20] (located within ~4 Å) are drawn symbolically.

which are very far apart in space and cut the polypeptide chain in such a way that pairs of residues that are far apart are not included within each individual segment. This is exactly the situation seen in Fig. 2 if we introduce one more cut somewhere between residues 66 and 71. A set of four segments, F1–4, presents a solution to our problem. F1, F2+F3 and F4 are encoded by exons. From inspection of Fig. 1*a* the central segment itself is seen to be very little extended. Thus, conformations of segments encoded by exons are characterized by the fact that they are the least extended of all possible choices of cuts in the polypeptide chain consisting of three or four segments of 30–50 residues. Pairs of residues which are far apart usually occur at two opposite sides of a globular structure. Therefore, cuts which are introduced to separate them tend to occur close to the centre of the molecule (Fig. 1*a*).

The structural units can be defined by the present algorithm for proteins whose X-ray data are available. Lysozyme is one of these proteins—its gene sequence has been reported by Jung *et al.*[17]. It will be reported elsewhere that three out of four junctions between adjacent structural units of lysozyme determined by the present algorithm correspond to the exon–intron junctions.

Conformation of each segment would not be stable when isolated[18] but the ability to assume 'the native format', when incorporated into a globular structure together with other segments, is kept at a maximum by 'being least extended' among all possible choices. In a small one-layer protein molecule, one side of the conformation of each segment is exposed to the surface and therefore should be mainly polar; the other side should be mainly nonpolar. The probability of forming a new protein from segments of old proteins is expected to be fairly high, when segments have the characters described above. The conformational characteristics now recognized for the segments encoded by the exons in haemoglobin subunits make it more likely that they have a structural, as well as a functional role in the process of protein evolution.

From the structural point of view it is more natural that the structural units F2 and F3 are encoded by separate exons. However, no intervening sequence has been found in the DNA at a position corresponding to the F2–F3 junction. One possible explanation for this absence is that selection pressure eliminated the intervening sequence that was present in an ancestral protein[19]. This is likely because the structural units F2 and F3, when put together, fix the haem group in its functional position, and because unnecessary exon shuffling promoted by presence of the intron would be harmful. In connection with this, note that an interesting feature of the amino acid sequences is observed when rather arbitrary cuts between F2 and F3 are introduced between residues 61 and 62 in the α chain and between 66 and 67 in the β chain (Fig. 3). The last residues of F1 in both chains, and of F3 in the α chain are common in many species—these are arginine or lysine. Arginine is the main residue at the last position of F3 in β chain—lysine is less common. The last residue of the F2 in both chains is commonly lysine. Furthermore, the first two residues of F2 and F4 are hydrophobic, which is again the case for the first two residues of F3. Although it is not known why lysine and arginine, followed by hydrophobic residues, are found at the joints between the segments encoded by exons, the common character of the amino acid residues at the three joints of the segments supports the possibility of the presence in, and subsequent elimination from the ancestral globin, of an intron between DNA sequences encoding the structural units F2 and F3.

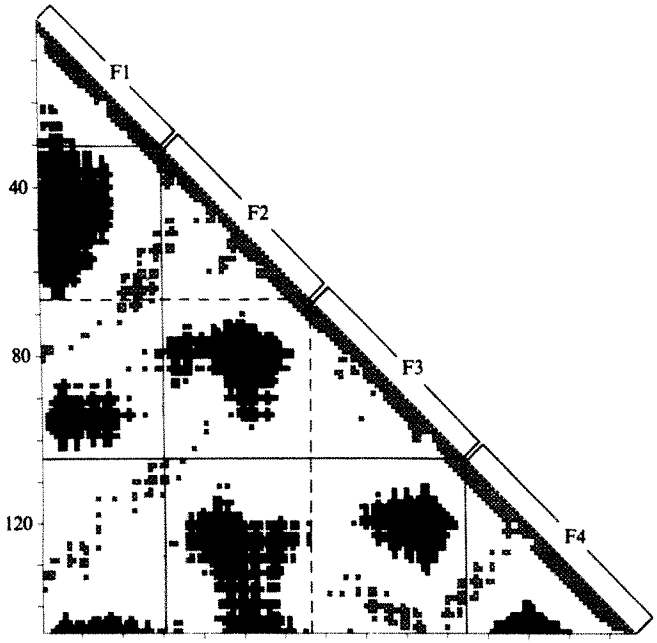

Fig. 2 Distance map of haemoglobin β chain. The distances between the *i*th and *j*th α-carbon atoms are plotted in a triangular space, in which both ordinate and abscissa are the residue sequence number. The grey region represents the pairs of C^{α} atoms within 9 Å, the open area the pairs whose distances are 9–27 Å, and the dark region the pairs separated by >27 Å. α-Helices are represented by a series of interactions along the diagonal. The structural units F1–F4 are defined by considering the exonic regions, this map and the amino acid sequences near the joints of the units. The units F1, F2+F3 and F4 are encoded by the three exons, respectively. The atomic X-ray data used are of horse deoxyhaemoglobin (provided by the Protein Data Bank at Brookhaven National Laboratory).

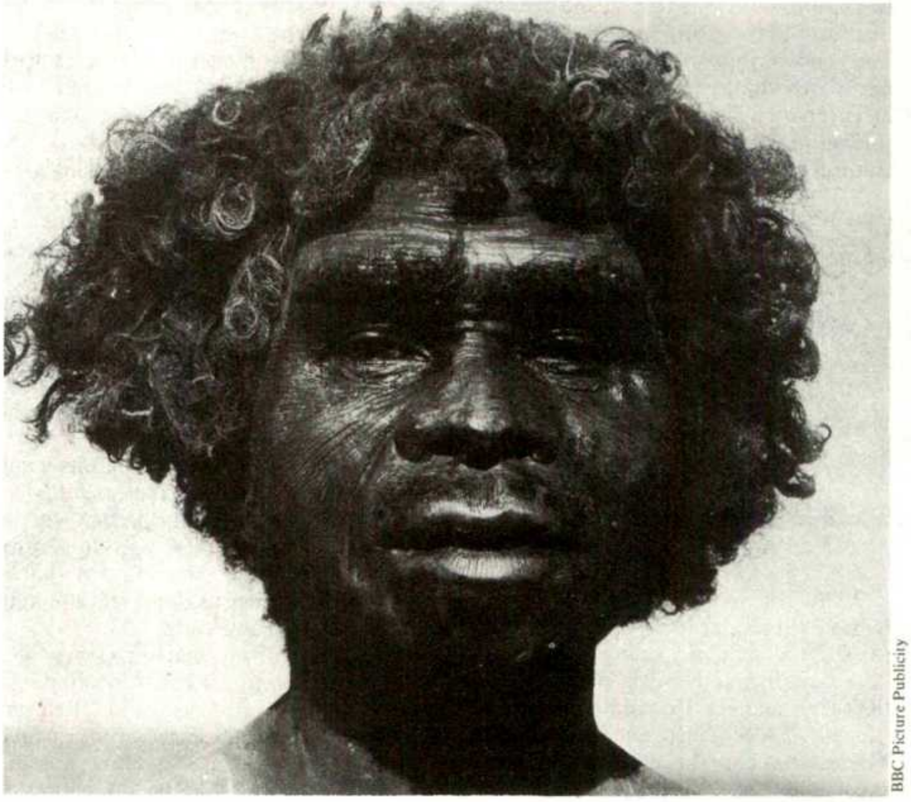
BOOK REVIEWS

Not by bones alone: "The Making of Mankind"

Barry Cox



BBC Picture Publicity

Face from the past — an actor wearing the *Homo erectus* mask.

The Making of Mankind. By Richard E. Leakey. Pp. 256. ISBN 0-7181-1931-2. (Michael Joseph: 1981.) £9.95. Dutton will publish the book in the USA in September, price $25.75. The first programme in the seven-part television series was shown on BBC 2 on 4th May and the remainder will appear on successive Mondays at 9.50 pm.

IN the now common double-barrelled "Let 'em have it in the eyes and ears together" approach, the publication of Richard Leakey's book has accompanied the beginning of the seven-part BBC TV series of the same title — *The Making of Mankind*. After seeing a preview of the first and third programmes, reading the book allows one to make a reasonable guess at the nature of the complete series. I think, on the whole, that Richard Leakey deserves a high mark for balance, content and style.

The linkman of a series of programmes of this kind has an immense opportunity. Taken wherever there is something worth filming, with researchers to help in identifying and gathering relevant material, he can usefully indulge that desire to read and think beyond the boundaries of his own specialist research that lies in many scientists. Leakey has grasped this opportunity with both hands; he quotes Alan Walker's words: "If all we were to learn from prehistory was a list of species in time and space, then we should give up". *The Making of Mankind* is not, therefore, merely an anatomical/stratigraphical account of how one type of leg-bone evolved into another, but is an attempt to weave together all the different threads of evidence that may help us to understand the pathway that led to man today. This approach also has the advantage for the television viewer that he does not have the uneasy feeling that he must, from week to week, remember what went before or risk misunderstanding later programmes.

The beginning of such a series is always the most difficult to design, since one has to capture the interest of the audience and at the same time give an idea of the scope of the whole and provide some of the inevitably rather unglamorous chunks of basic background. Leakey starts with attractive film of exploration and discovery in East Africa, and then back-tracks to explain the processes of evolution and fossilization, and the geological time-scale. I think it was unnecessary to start with the stock sequence (photographs of volcanic activity — origin of the world — origin of life — metazoa — life on land etc.), and I also cannot see that the current debate over graduated evolution versus punctuated equilibria throws any light on human evolution. But the animation–explanation of the process of fossilization was extremely clear, and well integrated with a real-life simulation of rain-water revealing a fossil skull. The programme ends with an account of the earliest hominoid fossils, the forest dryopithecines and the woodland ramapithecines, and suggests how climatic change and consequent environmental change may have moulded this stage of human evolution. On the whole, I felt that this programme negotiated the initial problems very well.

The second programme looks at the African discoveries of fossils of *Australopithecus* and early types of *Homo*, and at the evidence that at least two species of hominid were apparently able to co-exist. It therefore includes the problematical Hadar fossils and the differing interpretations of Leakey and Johansen over their nature: do they all belong to one species of *Australopithecus*, or do some belong to an early species of *Homo*? Though Leakey has been accused of giving a one-sided view of the debate, that is certainly not true of this section of the book, while Don Johansen himself presents his own case in the TV programme, so I feel that the accusation is quite unfair — and the more regrettable for encouraging the layman's view that scientists cannot hold differing theories without becoming personally involved.

It is the third programme that Leakey starts to widen the scope of the series, emphasizing the new experimental approach to the problems of understanding the making and use of flint tools and the social significance of the camp-sites of early man. Here, too, he introduces his main message: that the fundamental social characteristic of man is that he is a *sharer*, his camp-sites being the locations to which food was brought to be shared. This theory, explained by Glynn Isaac, suggests that it was the contribution of both sexes to the food-sharing group (the males scavenging for meat while the females collected plant foods) that provided the basis for the eventual evolutionary superiority of *Homo* over *Australopithecus*. This way of life is presented dramatically by the use of actors made to resemble *Homo erectus* by wearing startlingly life-like masks, and by film of the modern !Kung bushmen who today follow the hunter–gatherer way of life into which this food-sharing habit may have evolved.

In later chapters and programmes, Leakey outlines recent work on the ability of apes to use signs and, by implication, to classify objects and concepts, and on the brain casts of fossil man. (The tendency to suggest that a larger brain *allows* more complex behaviour surely puts the morphological cart before the functional horse?). Neanderthal man leads on to Ice Age art; film cameras were allowed inside Lascaux for the first time in 20 years, and we are promised "staggering and beautiful images of horse, deer, bison and stags". It also seems as though horses and cattle may have been domesticated far earlier than had been thought. Leakey ends with a consideration of the implications of the agricultural revolution.

Richard Leakey at work.

What, then, of the whole? Leakey himself comes over as a sympathetic and relaxed linkman, whose own personality does not obtrude between the viewer and the story, and the TV series is beautifully filmed by Alec Curtis and John Record. The scope of both the series and the book is satisfyingly broad and, as we shall see, there is a message of hope. The book is well written and illustrated, though I could not help feeling that a figure showing the relationships of the hominids to one another in time and their possible evolutionary relationships would have been helpful. Though there is a good index, there is no bibliography of any kind, not even to other popular books.

The culmination of Leakey's message comes in his consideration of the origins of human aggression. He suggests that it was only after the agricultural revolution, about 10,000 years ago, that the possession of settled and accumulated property made its gaining by aggression profitable and its defence therefore necessary. So, Leakey concludes, "Warfare is a social and political response to changed economic circumstances. Humans are essentially cultural creatures capable of responding in many different ways to the same prevailing circumstances". For him, the ills of the modern world are not the ultimate result of the irrevocable crystallization of our social nature during some early man-the-hunter phase of evolution, but are a comparatively recent adaptation — and therefore reversible. Let us hope that history will prove him right. □

Glimpsed behind the curtain

Vera Rich

The Social Context of Soviet Science. Edited by L.L. Lubrano and S.G. Solomon. Pp.245. ISBN 0-8919-0712-9. (Dawson, Folkestone, Kent/Westview, Boulder, Colorado: 1980.) £10, $26.25.

ALTHOUGH the average Western scientist may well have numerous contacts with Soviet colleagues, and may himself have visited the Soviet Union, he will not necessarily have an overall view of the structure of Soviet scientific life. This is not for lack of information — as Susan Gross Solomon observes in her introductory essay, the Western study of Soviet science is now entering its fourth decade, with a proliferation of research projects addressed to governmental as well as academic audiences. That this information fails to reach those scientists who would benefit from a better understanding of the milieu in which their Soviet counterparts live and work, is perhaps due to its being published primarily in the sociological literature. The merit of the present work is not so much that it provides any fundamentally new material, but that it presents the consensus of present thinking in a readily available form.

This is not to say that the essays have been written with scientists in mind. As Loren R. Graham observes in "Reasons for Studying Soviet Science", the principal reason for compiling this book was the desire to understand better the nature of the Soviet Union as a whole. The emphasis given to the Lysenko affair (which, in Mark Adams's "Science, Ideology and Structure", occupies a major place in the book), or the controversy over the pollution of Lake Baikal of the mid 1960s, is thus not so much because of the scientific importance of the issues, but as examples, on the one hand of how political influence can effectively destroy a whole scientific discipline, and, on the other, of a rare case of public disagreement within Soviet society over a major policy issue. Indeed, at times this emphasis may prove enlightening to the scientist. As Thane Gustafson points out in his essay "Why doesn't Soviet Science do better than it does?", the simple answer which jumps to mind — "political interference" — is not necessarily the whole truth. "Crude ideological or political interference", he says, is the "exception not the rule"; the hierarchical structure and centralized planning system in the Soviet Union, the educational system which is stronger on theoretical than practical training and the uniting of administrative and research decision-making powers in the same individual must all be taken into account. Whether or not one wholly agrees with his conclusion that the "arrangements developed in the United States are more effective in creating a favorable environment for rapid scientific advance than those of the Soviet Union", his ideas are a useful counter-balance to émigré writers such as Mark Popovsky who attributes the Soviet short-fall in, say, Nobel prizes to political considerations.

Volume 3 of *True Visual Magnitude Star Atlas, Northern Stars,* by C. Papadopoulos and C. Scovil (for review see *Nature* **284**, 680; 1980) has been published by Pergamon.

How valid it is to judge scientific productivity by such methods is a moot point. Linda L. Lubrano in her essay on scientific collectives does not commit herself; she simply reproduces a number of Soviet tables, assessing productivity in terms of papers written and candidates trained, to illustrate the Soviet concern with norms and output. When she goes on to review Soviet studies on scientific motivation and the psychology of research workers, her exposition lapses into a turgidity and dullness typical of much of the Soviet writing on the subject.

Unfortunately, Professor Lubrano's article was written before the launching of the current press debate in *Literaturnaya Gazeta* on the prestige of pure, as opposed to applied research, many contributions to which have dealt with precisely the same problems of motivation and performance assessment in a far more lively form. This gives a slightly dated air to Lubrano's article, as — although to a lesser extent — it does to the two essays on applied research: Bruce Parrott's "The Organizational Environment of Applied Research" and Kendall E. Bailes's "The Technical Specialists' Social Composition and Attitudes". The latter is almost entirely sociological in content; the former, much wider in scope, ranges over such issues as the changing role of the Academy of Sciences in promoting applied research, the amalgamation of R&D units with production enterprises in the 1970s, and even the degree to which Soviet scientists are alienated from the bureaucratic system.

Taken individually, the seven essays cover a wide range of topics essential to a better understanding of Soviet science. Unfortunately, they remain seven essays, rather than becoming a book in their own right. There is no index, nor are there any useful aids such as a glossary of Soviet acronyms and organizations.

For a scientific audience, the main deficiency of the book is that it was not primarily intended for scientists. Yet, in the absence of a more suitable work, it is to be recommended as background reading to anyone who has dealings not only with individual Soviet scientists, but also with the Soviet scientific establishment. □

Tumour as parasite

P.B. Medawar

The Interaction of Cancer and Host: Its Therapeutic Significance. By Michael F.A. Woodruff. Pp.467. ISBN 0-8089-1265-8. (Grune & Stratton/Academic: 1980.) $46.50, £26.20.

Sir Michael Woodruff, FRS, is one of a small and important group of surgeons that was brought into being by transplantation therapy: a man equally at home in ward and laboratory who has contributed to both the science and the arts of transplantation. The range of topics under discussion here and the depth of their treatment are such as we normally associate with symposium proceedings or multi-author volumes. Neither is a satisfactory genre for scientific communication, for multi-author works usually have a rootless and untidy character because each author busies himself with the part of the business entrusted to himself, often to the neglect of more general considerations.

The volume under review is open to no such reproaches. It is the work of a single mind — and a very good mind it is too: spaciously well informed, critical where criticism is called for (witness Woodruff's treatment of the so-called "autonomy" of tumours and the discussion of the notion of the immunological surveillance), but sanguine too in its appraisal of the contribution laboratory science may make to the prophylaxis or treatment of tumours.

A majestic list of references citing titles and first and last page numbers occupies pp.289–419. Over a long period of time such reference lists repay their authors for some of the time and trouble that goes into them but we readers are beneficiaries right away.

In the preparation of a work of this scale and unified structure the time must be set when copy is all packed up and sent to press: no useful purpose is served by delaying publication in the hope that someone will come forward with a revelation without which the book would be incomplete. Woodruff's work is conceptually up to date and its character is such that it matters not the least that it does not include every contribution to tumour biology up to the date of publication of this issue of *Nature*. No reference is made, for example, to the anti-tumour action of retinoids nor to recent epidemiological evidence pointing to the complicity of vitamin A in resistance to tumours. These very recent advances were known only as premonitory rumblings to those who were listening for them. □

Sir Peter Medawar is Head of the Transplantation Biology Section of the Medical Research Council's Clinical Research Centre and is currently engaged in research on tumour prophylaxis.

IQ: the environmentalist position

Richard Lynn

Race, IQ, and Jensen. By James R. Flynn. Pp.313. ISBN 0-7100-0651-9. (Routledge & Kegan Paul: 1980.) £10.50, $27.50.

Hitherto, the environmentalist case on the race and IQ issue has been characterized more by emotion and ideology than by reasoning and science. This deficiency is to some degree remedied by the present volume in which Dr Flynn gives a cogent and reasoned exposition of the environmentalist position.

The author recognizes that the chief problem for the environmentalist is to find an environmental factor capable of depressing the mean Negro IQ by one standard deviation or 15 IQ points. He recognizes also that many of the possible candidates frequently advanced by environmentalists do not begin to stand up to examination. This is particularly true of both poverty and discrimination. Among other problems these possibilities collapse in the light of the experience in the United States of the Jews and the Chinese. Both of these ethnic groups arrived as penniless immigrants and suffered initially from the handicaps of poverty and discrimination. Yet both minorities have mean IQs at least as high as those of Caucasians of north-west European descent.

It remains possible, however, that there is a more subtle environmental factor depressing the Negro IQ, or perhaps a set of factors each exerting a relatively small effect. The author proposes low parental IQ, poor nutrition during the mother's pregnancy, lack of stimulation in early childhood, family dislocation, low self-image and poor education. Taken together the author argues that these could be sufficient to account for the phenomenon. The difficulties with these arguments are twofold. First, as the posited deleterious effects are small they are hard to detect. Second, there is a chicken and egg problem in so far as the proposed factors are mainly functions of low IQ in Negro parents.

While there are manifest weaknesses in the environmentalist position, there are also problems in the genetic hypothesis. Two of these are particularly important. In the first place, the genetic hypothesis requires that in individuals of mixed Negro and Caucasian ancestry the IQ should be positively related to the proportion of Caucasian genes. There is contradictory evidence on this point and it is certainly by no means clear that this is the case. Secondly, there is a study of the children of German mothers and American Negro servicemen, in which it was found that the IQ of these children differed little from the mean of the German population.

It is a pity that the author has largely confined his discussion to the American data. The results of intelligence testing of racial and ethnic populations in other parts of the world are an important dimension of the problem and should be considered in any comprehensive discussion. Thus, for instance, if there were a Negro population somewhere in the world with a mean IQ of 100 the environmentalist case would be considerably strengthened. There is a substantial amount of evidence on this question from Negro populations in London, Jamaica and a number of countries in Africa, but in all cases their mean IQ is either about the same as that of American Negroes or else lower. These results cannot be readily explained in terms of test bias, because Mongoloid populations in Japan, Singapore, Taiwan and Hong Kong obtain about the same mean IQ as those of Caucasians in the United States, north-west Europe, Australia and New Zealand. This consistency of intelligence levels across many different nations would appear to suggest a significant genetic determination.

While the present volume is limited in so far as it does not come to terms with this important set of data, it has to be welcomed as a scholarly and informed presentation of the environmentalist position. □

Richard Lynn is Professor of Psychology at the New University of Ulster, Coleraine.

Einstein refined — just in time

W.B. Bonnor

Exact Solutions of Einstein's Field Equations. By D. Kramer *et al.* Pp. 425. ISBN 0-521-23041-1. (Cambridge University Press: 1981.) £30, $72.

PROGRESS in theoretical physics consists largely of formulating equations and solving them. For instance, the equations put forward by Newton, and by Maxwell, are still being solved for application to special problems; and theorists have been seeking solutions of Einstein's equations since general relativity was discovered in 1915.

Solutions, yes — but why *exact* solutions? Aren't approximate solutions good enough? E. Schrödinger wrote (about Einstein's unified field theory) that "the exact solutions, involving strong fields, have disclosed the ingenuity of the mathematicians who discovered them, but nothing more". Approximate solutions are certainly good enough when a theory is well understood, like Newton's mechanics, and there is no danger of series failing to converge. But in a mathematically complicated theory like general relativity one does not always trust approximations. For example, after half a century of approximate work on motion, there is still no agreement on whether freely falling bodies radiate gravitational waves. A suitable exact solution could settle this once and for all.

A vast number of exact solutions of Einstein's equations have been discovered since 1915. With the half-dozen or so exceptions to be found in nearly all textbooks, these have lain buried in the literature. A warm welcome will therefore be given to this book. The magnitude of the authors' task is indicated by the bibliography which contains about 1,000 references; and these have been sifted from a list of twice as many. Most of the solutions given have been checked, which must have been a monumental task. Indeed, perhaps the work has been done only just in time: had it been left any longer it might not have been possible at all, because papers on exact solutions are appearing at the rate of over 100 per year.

It is possible to use the book simply as a catalogue in which to search for an exact solution, knowing to begin with some of its properties. However it is much more than this. It was essential to impress some order on the plethora of exact solutions obtained by a variety of methods. The authors choose as their principal methods of classification, first, symmetry groups and, second, Petrov types. They give an excellent introduction to both these topics, including much not easily found in other books. Part I, General Methods, also includes chapters on differential and Riemannian geometry, and on the Newman–Penrose formalism.

The authors have done such a fine job that it is important to realize what the book does *not* include. First, as stated in the Introduction, the exact solutions given are those arising from the following energy–momentum tensors: vacuum, electromagnetic fields, pure radiation, dust and perfect fluids. Although all the really important exact solutions fall under these headings, it should be noticed that some areas of physical interest are excluded, for example, charged matter and viscous fluids. It must also be remembered that nearly all solutions in the book are purely local, and no consideration is given to their global existence. Nor are boundary value problems within the authors' terms of reference, so the matching of different solutions is not considered; this leads to the somewhat bizarre omission of a famous solution, that of Einstein and Strauss for a star embedded in the expanding Universe. Another possible source of misunderstanding for the unwary reader lies in the quite forgiveable practice of giving the general form of a solution wherever possible, and omitting reference to special cases, even where these may be of physical importance.

All seriously interested in general relativity should get this book. They should also take advantage of the authors' invitation to inform them of omissions and of new solutions. In this way we may hope that the catalogue will be kept up to date and re-published from time to time. ☐

W.B. Bonnor is Professor of Mathematics at Queen Elizabeth College, University of London.

Les sciences bien vulgarisées

Alan Isaacs

Concise Encyclopedia of the Sciences. Edited by J.-D. Yule. Pp.590. ISBN 0-87196-491-0. (Facts on File: 1981.) $29.95.

BEING able to praise one's competitors is an indulgence not frequently available to those of us who earn a living by what the French call the *vulgarisation* of science. However, this is an excellent book, well written, expertly edited and lavishly illustrated mostly in full colour — or rather color, for this is the American edition of a book one version of which has already been published in the UK (Phaidon, 1978; £9.95). At $29.95 the American edition is undoubtedly good value — for the youngster with an interest in almost any branch of science it will certainly be a most acceptable gift. Uncles (and aunts) please note. It will also be a valuable asset for any library and for readers with no specialized knowledge of science.

Broadly speaking it does exactly what it says it will do — supplies both a dictionary of the most commonly encountered words of science as well as the encyclopaedic background material necessary for understanding their use in a wider context. The 400,000-word text is competent, accurate and jargon-free; for a book of this size it is difficult to see how it could be improved. One third of the text area is devoted to illustrations, almost all of which are a pleasure to look at, both because they communicate the information they are intended to communicate and because they are either well-chosen photographs or well-drawn diagrams. Particularly effective are the historical panels that summarize the history of some subjects and the "context panels" that illustrate the interrelationships between branches of other subjects.

If one has to criticize, one could say that it is perhaps unwise to have claimed (as the jacket does) to have covered philosophy and medicine. In both these fields the coverage is rather less than adequate. In philosophy, for example, the extent of the lacunae can be judged from the fact that there are no entries for ethics or existentialism, nor are Duns Scotus or Aquinas to be found. As Lady Bracknell might have said — to lose one scholastic doctor may be regarded as a misfortune; to lose two looks like carelessness!

In medicine the coverage is more thorough but it is perhaps surprising to find an entry for lymphoma but not one for the more common but less ominous papilloma. Some of the more recent techniques, such as tomography and thermography, are also omitted, as is the now ubiquitous Emiscanner.

If no attempt had been made to cover either philosophy or medicine there would perhaps have been room to deepen the treatment of the growing points of physical science. Quarks, for example, get only a one-sentence mention under subatomic particles, the state of play in nuclear fusion and fast-breeders is not explained, and the alternative energy field is not very well covered (nothing on wave or wind power or biomass energy).

It is, however, uncharitable to dwell on these gaps; so much is included and treated so well. This is undoubtedly an excellent reference book. ☐

Alan Isaacs is editor of the Macmillan Encyclopedia, *the* Penguin Dictionary of Science, Longman's New Dictionary of Physics, *and science editor of* Collins English Dictionary. *He has contributed to many other dictionaries and encyclopaedias.*

nature

14 May 1981

Will Mitterand be free to change?

What happens when one of the most conservative countries in Europe, perhaps even in the world, elects a socialist as a president? Revolution? Or nothing much? Or a mixture of the two? This is what people outside France are asking now that M. François Mitterand has beaten the incumbent president more handsomely in last Sunday's election than even the optimists of the left had been hoping. Frenchmen, however, know the truth.

The new president will be more tightly contained by economic and social constraints than his ardent supporters will be wishing. (M. Mitterand himself, on the other hand, may relish the lack of absolute freedom that he will discover when he takes over in ten days or so.) For the French economy, like others in Western Europe, is balanced on a narrow ledge separating the disasters of inflation and of slump. The temptation of any socialist government to cure unemployment by spending borrowed money is not a cure but a recipe for another kind of disaster. The new president will also find that even his most radical supporters are as firmly wedded to the preservation of familiar institutions as die-hard conservatives. This is why France in the 1980s is so obviously an amalgam of the recent past and the seventeenth century. The plastic bodied automobile on the once-Roman road now lined by poplars is as good a symbol as any.

The influence of the past quarter of a century, since the creation of the Fifth Republic, is nevertheless crucial both for France and for M. Mitterand. With the ending of the neo-Gaullist era, it will be tempting to forget how much has been accomplished. At the beginning of the period, French science and technology were not much to be proud of. There were a few nuclei of industrial innovation, the nuclear energy industry and the new plants for exploitation of natural gas and petroleum in the south and in North Africa, but the telephone system hardly functioned. University research was in the doldrums, chiefly from lack of funds even for teaching the huge numbers of students flocking to the universities. The CNRS was making modest experiments with its scheme for supporting members of staff within university departments, but neither the universities nor the council had begun to appreciate the importance of this device. The university system was hardly equipped to do so, as the upheavals of 1968 demonstrated all too clearly. Yet with the passage of time, French research has prospered. For some reason, imaginative laboratory work has flourished while the government machine has been occupied with the design of frequently artificial programmes built around specified technological goals — the building of an aircraft, or the exploitation of technologies with made-up names, *l'informatique,* for example. Now and again, this peculiarly French system of dual support for research runs into trouble (see page 101). But on the whole, it has functioned better than could have been expected.

How will M. Mitterand change all this? Nobody at this stage can be sure. Part of the explanation for the new president's success is that he has kept his cards close to his chest during the election campaign. And some of the things he has been saying no doubt owe much to the need to appeal to particular groups of electors. Thus the promise that there will be a "pause" during which the future of the previously ambitious French nuclear power is re-examined may have been designed to win round the ecologists, who captured four per cent of the vote in the first round of the elections. The political cost of reviewing the plans for building nuclear power stations (and for the development of the fast reactor called Super-Phénix) would not be high. Deciding to cut them back would not merely offend a large number of French workers but would run headlong into conflict with the traditional French conviction that self-sufficiency comes above prudence, economic or otherwise. If the doctrine of self-sufficiency is to be challenged, there are other fields in which the battle could be fought more profitably.

The most obvious opportunity for change is in the not entirely unrelated field of arms control. Since the collapse of the old scheme for a European Defence Force in the mid-1950s, France has been the stumbling block in a long series of arms control negotiations. Once President de Gaulle had accepted the arguments of his generals, General Gallois in particular, that national security required self-sufficiency in nuclear weapons, France has stood aside from sensible arrangements such as the Non-Proliferation Treaty and the Partial Test-Ban. In recent years, French policy has been obviously ambivalent. Thus France has resolutely refused to accede to the Non-Proliferation Treaty while behaving — in dealings with India, for example — as if it had done so. A moderate Gaullist government such as that of President Giscard d'Estaing has inevitably been the prisoner of the true Gaullists to its right, and thus politically prevented from throwing over the foolish doctrines of the 1950s. M. Mitterand will have no such inhibitions. On the contrary, his policies towards the world outside France predicate change. We shall soon find out how resolutely he seeks to amend the French position on nuclear self-sufficiency — and whether in the process he discovers that after a generation, the doctrine of comprehensive military self-sufficiency goes deeper than merely Gaullism.

The prospect that there will now also be a further acceleration of the growth of public spending on research and development is less secure, if only because there are both financial and structural limitations on what the new government can hope realistically to accomplish. French expenditure on research and development, by government and private industry, now amounts to 1.7 per cent of the Gross National Product. M. Mitterand has promised that this will increase by more than a half in the next five years. He has not explained how. And he would find it hard to do so even in the post-election euphoria. Channelling close on an extra one per cent of the national wealth through the government machine, earmarking it for spending on research and development, would be a formidable task if there were a decade in which to do the trick. To attempt it in five years would send inflationary ripples about the place. When he and his advisors start in earnest planning how to implement this promise, they will be driven to conclude that what is true elsewhere is also true in France — that the only basis for spending more money profitably is to begin by improving the quality, and increasing the scale of, university training in science, technology and research. And changing universities is slow work.

The proposal that there should be a minister of cabinet rank with responsibility for research and development is, on the other hand, more than merely sensible. In the circumstances that the new president will inherit, the most immediate danger is that organizations conceived of by bureaucrats and given life by politicians will become so powerful and set in their ways that they are at once wayward and uncontrollable. For all its virtues, the CNRS is in danger of becoming such a law unto itself. The practice of putting university researchers on the payroll, necessary though it may have been a generation ago, now threatens the autonomy of universities and impairs the flexibility of the research enterprise. The first task for the holder of this post (if and when appointed) will be to look again at the relationship between the universities and the rest of publicly supported

0028-0836/81/200097-02$01.00

research and development. In doing so, he or she will find it necessary to ask whether the condition of the French university system is entirely suited to present needs. In the past seven years of the presidency now ending, much has been done pragmatically to improve the lot of the universities, but very little is written down on paper. The new president seems to have been offering the nearest that France would accept to an American way of administering science. The question still to be answered is whether he will discover, in this connection too, that tradition goes deeper than voting behaviour.

Calculating flop

The British government, always ready to seek to demonstrate that water can be made to run uphill by a sufficient display of determination, has been in trouble for several weeks because it insists on willing that Britain, like the United States, should enjoy the benefits of an indigenous, productive, competitive and profitable mainframe computer manufacturer. The trouble came to a head on Monday, when the chairman and managing director of the company called International Computers Limited (ICL for short) resigned, after the Department of Industry had put a pistol to their heads and asked that they should accept a new way of working. Mr Phillip Chappell, the part-time chairman for just over a year, will go back to being a full-time merchant banker. His managing director, Dr Christopher Wilson, will remain a director of ICL (and will be paid an executive director's salary). Mr Chappell and Dr Wilson are replaced by two outsiders — Mr C. C. F. Laidlaw, vice-chairman of British Petroleum Ltd, as chairman and Mr Robert Wilmot (now managing director of the British end of Texas Instruments) as the new managing director. The government's headhunters have done well; the new management has at least as good a chance of succeeding as the old. But the chances are not high, and it is in the (British) public interest that everybody concerned should acknowledge that to be the case.

ICL has a long distinguished history, going back to the end of the Second World War. That was when people straight out of the design of radar systems settled down to making electronic versions of the old electromechanical calculating "engines". For a time, at least in Britain, it seemed that success exceeded all reasonable expectations. A private company called Ferranti was closely involved with the development of a computing system at the University of Manchester, linked with the names of people such as Thuring and F. C. Williams. The first prototype of this computer was frequently inspected by admiring visitors from other computer companies, many of them from overseas. In due course, when it seemed likely that an electronic computing machine of some kind might sell and make money, the then British government negotiated with Ferranti an arrangement under which there would be a public subsidy to help put this new machine on the market. The amount concerned, just over £1 million, was tiny in comparison with the task. But Ferranti chose to spend this pittance not on the development of a commercial market but on the development of a more advanced and less successful machine.

With the passage of the decades (almost exactly two of them), it became plain that the promise of the immediate post-war period had not been fulfilled. By 1968, the turnover of IBM World Trade (the overseas arm of IBM Inc.) probably exceeded the annual exports of the United Kingdom. Enthused by a vision of a brave new technical world, however, Mr (now Sir) Harold Wilson, then the British Prime Minister, set up an organization called the Industrial Reorganisation Corporation to effect the merger of companies judged too small to compete on their own with the giants overseas. In 1968, Ferranti's computer interests, together with those of the other British manufacturers eager to build mainframe computers, were welded together with the help of public money. The stage was set for the emergence of a giant to complete with IBM *et al.* The snag was that nobody thought, knew or seemed to care what kind of company ICL should be so long as it was big.

This week's announcement that the management must be changed yet again is therefore a sign that water is still steadfastly refusing to flow uphill. The attempts by successive British governments to give ICL an inside track in the supply of computers for the public sector has most often been defeated by the preference of the intended customers for somebody else's machines. ICL shares with the most successful of its overseas competitors, even IBM, the fault of not having judged just when small computers would come into their own. Unlike some of them, it has been too insecure to ride this tide. Now, it seems, ICL is hoping to make up with its flair for distributed computer networks for its failure to make much money on the huge machines that are its pride and joy. British taxpayers in particular will wish it luck. In the next two years, the company will survive with the help of a loan of £270 million from the commercial banks, £200 million of which is underwritten by the government on behalf of the taxpayers.

In retrospect, what went wrong at ICL was not the decision (in 1968) that there should be a unified computer company, nor the British government's repeated reappointment of new managers, but the failure to acknowledge at the outset that in a novel field of technology, it is impossible to design by means of a committee the commercial enterprise that is certain to carry off the prize. The best that can be hoped for is to send several arrows at the target.

The irony in all this is that British government's stake in ICL is now much less than it used to be a year ago. Technically, the company is much more directly under the control of its private shareholders than of the Department of Industry since the government and some other big shareholders sold out to the general public at the top of the market. But ICL will remain in hock to the department so long as the £40 million public loan arranged some years ago remains unpaid. For the whole of that time, British governments will find it necessary to worry about the strategic value of companies such as ICL. Some of them may be able to stomach pulling out of old industries such as shipbuilding, but pulling out of computer manufacturing may seem like turning the back on the future. In ICL's present crisis, all kinds of interests are seeking to persuade the British government of that truth. But it is not a truth at all, of course. Consistently unprofitable companies serve no purpose and should be put to sleep, whatever they happen to be making.

Tokenism again

Public officials, who necessarily spend their waking hours in committee meetings, naturally believe that appearance is reality. For the past several years, but especially since the appearance of the Finniston Report on engineering education eighteen months ago, the British government and the whole company of its officials have been dedicated to the belief that the status of engineering as a profession and of engineers as people must somehow be enhanced. Otherwise, the argument goes, British manufacturing industry will continue to be uncompetitive and will go out of business.

Dr Duncan Davies, until last month Chief Scientist and Engineer at the Department of Industry, and Sir Geoffrey Allen, the chairman of what used to be the Science Research Council, have shown what can be done. Dr Davies has rechristened himself "Chief Engineer and Scientist". Allen's research council, with the help of Queen Elizabeth II, has been renamed the Science and Engineering Research Council. Everybody concerned proclaims that the change of name does not mean a change of function. But engineers (as distinct from scientists) will walk a little taller. And the only cost will be that charged by the suppliers of printed stationery to public agencies and corporations. Nobody seems alarmed that the chief recommendation of the Finniston Report — that there should be an Engineering Council to regulate the profession of engineer — has still not been set up.

At a meeting on Thursday this week, the unions claiming to represent professional engineers will be throwing yet more sand in the works. Tokenism, not the best policy, may be the only one.

Congress will battle against proliferation

Senate split confirmation of Malone

Washington

Democrats in the US Congress are shaping up for what is expected to be a major confrontation with the new Republican Administration over proposals to loosen controls on the export of nuclear technology and materials. Already they have tried, albeit unsuccessfully, to block Mr Reagan's nominee for the position of Chief Nuclear Advisor to the State Department — Mr James Malone — as a warning shot to the Administration that it can expect fierce opposition if it tries to relax existing controls too far or too fast.

Mr Malone had previously been the General Counsel of the Arms Control and Disarmament Agency (ACDA) under President Nixon. Shortly after Mr Reagan's election last November he was appointed to head the transition team for ACDA. And his nomination for the State Department post, officially known as Assistant Secretary for Oceans and International Environmental and Scientific Affairs, has been warmly supported by the conservative Republican, Senator Jesse Helms of North Carolina.

Last week his nomination was formally approved by the Republican-dominated Foreign Relations Committee in the Senate, and confirmation by the full Senate remains a formality. However, five of the fifteen members of the committee voting cast their ballots against Mr Malone, expressing concern that the type of proposals he was supporting for speeding up nuclear exports would increase the risk of the proliferation of nuclear weapons.

Several Democrat members of the Senate committee, including Senator John Glenn of Ohio, a strong supporter of stiff anti-proliferation measures, also raised concerns about possible conflicts of interest. During the Carter Administration Mr Malone has been a member of a Washington law firm, Doub and Muntzing, which includes among its clients groups in Japan who have been seeking permission to export nuclear technology from the United States.

During the committee hearings on his nomination, Mr Malone was reluctant to provide much detail of the extent to which his company had been involved in furthering the goals of such clients. His reluctance provided Mr Glenn with an excuse to hold up his nomination for several weeks, and the committee members unhappy with his appointment are proposing strict procedures to prevent any conflict of interest.

Their main concern, however, is a broader one, namely, that Mr Malone seems keen to dismantle many of the nuclear export controls introduced during the Carter Administration, in particular parts of the Nuclear Non-Proliferation Act of 1978. This act requires countries to accept international safeguards on their nuclear installations before they can receive US-produced nuclear technology or materials, and to obtain US permission before these are transferred to a third party, for example, for the reprocessing of spent fuel.

The transition team report on ACDA suggested that a new office be created within the State Department that would centralize all aspects of nuclear export policy — including the assessment of whether the receiving country was obeying international safeguards, a role at present performed by the Nuclear Regulatory Committee. The nuclear industry, already facing the prospect of a major slump in domestic demand, favours such centralization in order to expedite the licensing of exports; but Senator Glenn and others reply that the Nuclear Regulatory Committee (NRC) was given control of export licensing specifically so that decisions on safeguards would be made on technical rather than political grounds (as happened when NRC refused to allow to the export of nuclear fuel to the Tarapur nuclear plant in India, a decision later overruled by President Carter).

The nuclear industry is hoping for more sympathetic support for its international trade from the new Administration than from its predecessor. The Atomic Industry Forum points out that Secretary of State Alexander Haig has already called nuclear energy "imperative" for Western industrialized nations, and also notes that the appointment of ex-NRC commissioner Richard Kennedy as Under-Secretary of State for Management places "a nuclear supporter in Haig's inner circle" — even though the post has no nuclear responsibility. The industry would welcome a return to the "reliable supplier" doctrine as a device for limiting the misuse of nuclear technology which Mr Malone is expected to promote, but which critics claim has in the past proved ineffective in preventing nuclear exports claimed necessary for energy programmes being used for military purposes.

Ironically, the major threat may come from a very different direction, the Administration's desire to reduce public spending substantially. Among the agencies expecting major budget cuts is the Export-Import Bank, which provides loans to US companies to subsidize their exports, particularly to Third World countries. Virtually all US nuclear exports have been paid for with loans from this bank. If the source of the loans dries up — as seems possible — the nuclear industry will find itself facing a new set of hurdles to cross.

David Dickson

Science Adviser appointment revived

Washington

The appointment of a Presidential Science Advisor, on the back burner for most of the time since Inauguration Day, has become a live issue again. In the past few days, the name of a potential candidate for the job has been circulating. Earlier this week, it seemed certain that the new man would be formally nominated before the end of May.

The newest candidate is Dr George A. Keyworth, 41-year-old head of the physics division at the Los Alamos National Laboratory in New Mexico, where he has worked for the past 13 years in nuclear weapons research, laser fusion and basic nuclear physics.

Dr Keyworth has already visited Washington to discuss the job with White House officials, but said last week that he has not formally been offered the position — although the offer was widely expected in Washington. He holds a bachelor's degree from Yale University in 1963, and a PhD in physics from Duke University in 1968.

Dr Keyworth is largely unknown in the scientific community; he seems to have had little experience in Washington, although he has served on the Department of Energy's Fusion Data Committee. Dr Keyworth's name is said to have been put forward by the domestic policy staff within the White House, and he is said to have the enthusiastic support of Dr Edward Teller, one of Mr Reagan's advisers when he was governor of California.

The Reagan Administration has apparently had considerable difficulty in finding a candidate prepared to accept the post of science adviser and director of the Office of Science and Technology Policy, partly because of rumours that the role of the office is likely to be downgraded from its prominence during the Carter Administration under Dr Frank Press. Dr Keyworth says that he is in complete agreement with the new Administration's attitude towards science, and attempts to restore "American pre-eminence in industrial technology".

Dr Nunzio J. Palladino, dean of the College of Engineering at Pennsylvania State University, is expected to be named by Mr Reagan as the new chairman of the Nuclear Regulatory Commission. Dr Palladino worked as an engineer with the Westinghouse Electric Company in Philadelphia before joining the National Laboratory at Oak Ridge.

French presidential election

Good for science?

Champagne corks were popping in science departments throughout France on Monday at the news that François Mitterand, socialist party leader, was to be France's next President. Not that most French scientists are socialists; rather, that science will take a leap forward in France if Mitterand sticks to his announced policies.

Mitterand has promised a "national council for science and culture", reporting to the president, and has announced that spending on research and development in France should reach 2.5 per cent of gross national product by 1985, compared with the present 1.8 per cent. Mitterand's goal could only be reached with high government spending, for French industry is notably niggardly in its provision for science; Giscard had a more cautious target of 2.3 per cent by 1988.

The socialist leader has also said he will raise the rank of the minister of science to full cabinet level, so the minister will participate in all major policy decisions. (The current incumbent, Pierre Aigrain, attends cabinet only when matters involving science are under discussion.) Two names are being tipped for the job; François Gros, a biochemist at the Institut Pasteur, who has been active among scientists on Mitterand's behalf; and the career politician Jean-Pierre Chevenement, a member of the chamber of deputies who has taken an interest in scientific affairs. The high level of the post may favour the politician.

Mitterand will also set up a parliamentary special committee for technology assessment, something previously unheard of in France, where technological decisions have been reached in an entirely autocratic manner. The new president is also cool on nuclear power, so France's nuclear lead might be expected to slip unless national pride erodes the president's doubts. He has said he will call for a "pause" in nuclear construction after the reactors now under order, and the fast breeder Super-Phénix, are completed, in order to review the programme. **Robert Walgate**

French oceanography

Pulling together

The outgoing French government completed the last leg of its reorganization of oceanographic research last month with the creation of a joint interdisciplinary programme between CNRS, which is the main funding body for scientific research, and the Ministry of Universities. The new programme is expected to be in full operation early next year. The reorganization, which began at the end of 1979 when an informal Comité d'Océanologie was set up to advise government, reflects the political importance in France of technologies for exploiting the mineral and biological wealth of the oceans.

This attempt to coordinate research supportd by CNRS and the Ministry of Universities through the new Programme Interdisciplinaire de Recherche Océanographique (PIRO) is unusual in French research administration, for with the growth of support for oceanography since the Second World War, two disparate research programmes have grown up within the universities and the CNRS laboratories. Although similar difficulties have arisen in other fields, oceanographic research has been particularly affected, according to the director of PIRO, Roger Chesselet.

PIRO's task of coordination will fall to an eighteen-member scientific committee with an annual budget of 11 million FFr, the Ministry of Universities and CNRS each contributing half. The budget, which will be in addition to the 185 million FFr already spent on oceanographic research, will be used to run and buy equipment for six small research vessels, and to foster collaboration between several research groups working on different aspects of the same problem. PIRO, whose members are CNRS administrators and oceanographers nominated by CNRS and the Ministry of Universities, will be keen to support fundamental research in physical and biological oceanography, leaving mineral exploration and the application of new technologies to the well-established Centre National pour l'Exploitation des Océans (CNEXO). A small amount of the extra 11 million FFr will, however, be spent on research equipment for use by CNRS and university staff on board CNEXO's large, ocean-going research vessels.

The setting up of PIRO follows the definition of three categories of research: research with short-term application supported by the departments of industry, transport and environment; research with medium- and long-term application supported by CNEXO; and fundamental research, the responsibility of the Ministry of Universities.

Under the new arrangements, the different organizations supporting oceanography will report to the Comité d'Océanologie. France is also hoping to collaborate internationally, especially with developing countries, on pollution problems and the exploitation of ocean resources when the Law of the Sea becomes operational. **Judy Redfearn**

Bazan protests

The academic research community in Argentina has been disconcerted by the precipitate sacking of Professor Nicolas Bazan from his posts as Director of the Institute of Biochemical Research at Bahia Blanca and as Professor of Biological Chemistry at the University of the South. Professor Bazan (38) heard of his dismissal only when he returned to Argentina from the United States early in March, but it is held to have taken effect from the end of 1980.

The most puzzling aspect of this development is that Professor Bazan has insisted that he has no connections with political organizations deemed subversive by the military regime. One explanation is that his success has made him the target for influential jealousy, another that his dismissal is intended as a reminder that the influence of the military persists in the universities of Argentina.

Dr Bazan is a neurochemist who has, in the past few months, been able to demonstrate that in rat models of epilepsy, arachidonic acid and other precursors of prostaglandins are released into the brain in large amounts. Professor Bazan had been planning an investigation of the presence of arachidonic acid in the cerebrospinal fluid of human patients suffering from epilepsy, on the assumption that the underlying cause is a membrane deficiency.

Since his dismissal, Professor Bazan has insisted that he will fight for reinstatement. He has been supported by the staff of his institute, which sent a letter of protest to the President of Argentina on 21 March. The Argentinian press has also covered Bazan's dismissal sympathetically.

UK university finance

Truth looms

British universities should know more clearly next week what the future holds. For then the University Grants Committee will put out a circular spelling out the basis on which recurrent grants will be distributed to individual universities in the next few years. This first circular will be followed in June by more detailed information about the proposed division of the recurrent grant for 1981–82 among individual universities.

The committee has been forced to this two-stage approach by the need for detailed consultation with the Department of Education and Science about ways of sweetening what must certainly be a bitter pill. Originally it had been intended that final allocations would be announced this month. One of the concessions wrung from the government is likely to be an assurance that recurrent funds for the universities will be held for the next three years at the levels suggested in the white paper on public expenditure published in March.

British universities may thus know where they stand more clearly than in recent years, when government support has been determined one year at a time. The promised grants will, in the government's opinion, nevertheless require many universities "to review the range and

0028-0836/81/200100-02$01.00

nature of their contribution."

Next week's letter from the grants committee is expected not to go so far as to suggest that some universities should close. The emphasis, instead, will be on financial economies within existing institutions, with the recommendation that universities should think of closing departments which, for one reason or another, do not meet tests of efficiency and effectiveness. Universities and those who work in them will be especially interested in whatever arrangements the committee suggests for dispensing with unwanted members of teaching staffs.

Dr Edward Parkes, chairman of the University Grants Committee, has, however, made it clear in his evidence to a parliamentary committee that the impending cuts will not be made uniformly across the board. Universities will also be affected differently by the still uncertain enrolment of overseas students for the coming academic year. In its *Statistical Bulletin* for April, the Department of Education and Science shows that overseas student numbers declined by 7 per cent between 1979–80 and 1980–81.

Enrolments between the same two years declined by 10 per cent. Although the universities as a whole have more successfully maintained overseas student numbers than other institutions of higher education, some among them are in serious trouble, while all fear that new enrolments next October will decline further.

One part of the government's package of support for the universities has, however, been decided. The equipment grant for British universities will be increased by about 11 per cent to £76.7 million for the academic year 1981–82.

Hungarian research

Cost of elitism

Budapest

Budapest's Eotvos Lorand University is to have a new science building — at a time when the Hungarian government is drastically reducing spending in virtually every sector of the economy.

This is not the first time that the university has been promised such a building, which would unite its 44 small science "chairs" under one roof into four large departments — mathematics and physics, chemistry, life sciences and Earth sciences. Yet, in spite of the economic climate, the academics concerned are confident that this time the plans will come to fruition, because the reorganization can be justified as cost-effective. With all laboratories in close proximity, it will be possible for the various departments to share expensive equipment.

More significant in precipitating the decision, however, was the public debate on the role of the university, begun in May 1979 by the journal *Magyar Tudomany,* in which the reorganization of universities into large departments was favoured.

One of the government's aims is to break the tradition of academic elitism. Young scientists are reluctant to leave cosy academic niches in research institutes to enter the harsher world of industry and the universities. Although the reorganization will be welcome, any real moves to strengthen the role of the universities in research would first have to deal with one of the major grievances of Hungarian scientists, the difficulty of purchasing equipment and reagents from abroad.

Because of the centralization of foreign trade, such purchases have to go through a single import–export company, which means a delay of at least six months for every order. Hard currency is not the only problem — the same delay occurs with purchases from the Comecon bloc. Only in research projects with a government priority rating — such as work on genetic engineering done under contract with the chemical industry — can the purchasing process be accelerated.

Whenever this subject is raised with officialdom, scientists say, the response is always sympathetic — but without visible result. Until the matter is resolved, however, young scientists will have one more reason for seeking a long-term post in one of the Academy of Science's numerous research institutes. For the academy has its own purchasing agency, "Akadimport", and although the delays involved are still of the order of two months, this still gives such researchers a considerable edge.

Vera Rich

Satellite-linked computers

Network planned

Several different groups in Britain are cooperating in an experiment to link computers via satellite. The idea is to demonstrate to home and overseas customers how British technology can help industry and research institutions with their communications problems. Project Universe, as the experiment is called, is being supported to the tune of £3 million for three years by the Department of Industry, the Science and Engineering Research Council, British Telecom and two private companies, GEC-Marconi and the software house Logica.

The experiment is mainly to demonstrate how groups of users such as universities and companies with offices in different centres can communicate with each other through networks of computers linked by land and satellite. Six laboratories will house rings of computers, based on a network designed at the University of Cambridge, and will be equipped with an earth-station consisting of a 3-m diameter dish, a 14-GHz radio transmitter and an 11-GHz receiver. Communications within a laboratory will be via the land system and between laboratories via one channel of the European Space Agency's Orbital Test Satellite. Each computer will be able to communicate with any other in the system initially at a rate of 1 Megabit per second.

The Department of Industry, which is providing the largest sum of money, hopes that the project will help develop technology and demonstrate uses for the network.

The two major demonstrations of the network will be in transmitting large volumes of scientific and industrial data between centres. The Rutherford Laboratory is particularly keen to use the network to transmit mask design for large-scale integrated circuits, developed with its electron beam lithography machine, to universities and industry.

The project is expected to be in operation early next year. It will run for two years throughout the rest of the life of the Orbital Test Satellite.

Judy Redfearn

Research management

Audits go on

Despite the tangle of legal threats, and claim and counter-claim over their previous — and still unpublished — work on Sir Bernard Lovell's radioastronomy at Jodrell Bank, a group of the Science Policy Research Unit (SPRU) at the University of Sussex has been given the go-ahead for its next study: CERN at Geneva.

The group is headed by Keith Pavitt, acting deputy director of SPRU, with principal researchers John Irvine and Ben Martin, who have developed what they call the method of "converging partial indicators" to assess the relative merits of scientific research groups.

Inevitably, this is dangerous territory, normally confined to the secrecy of peer review panels and referees' reports, and the Sussex group's serious attempt to arrive at objective criteria raised hackles as soon as it was applied to real cases, which included a comparison of radioastronomy groups in Britain and abroad and a study of British optical astronomy.

All these studies are now essentially complete, but none has been officially published — largely due to the Sussex group's procedure of checking its figures with the relevant laboratories first. Predictably, laboratories whose work is implicitly criticized object to either the figures or the conclusions.

The SPRU group, however, has been unable to consider such questions because at an early stage it was denied access to research council files under the "40 year rule", which controls the availability of government documents — even though the research councils are not government departments. It therefore could not assess the conditions under which one group, say, received a major grant, while another did not.

Nevertheless, what counts in the end is results, and the SPRU group claims to have a method which gives an objective assess-

0028-0836/81/200101-02$01.00

ment of those results by using the relevant research community's own judgements of scientific value, both directly (through confidential questionnaires) and indirectly (through publication rates and citation frequencies).

A preliminary version of the radioastronomy study was read last year at a closed session of the Organization for Economic Cooperation and Development, and was very well received; but the wide circulation of that paper, particularly in the Netherlands and West Germany, whose own radio telescopes were also assessed (not all favourably) led to recrimination from Jodrell Bank, which did not do so well in the study. And now North-Holland, the publisher of *Research Policy*, in which the final paper was to appear, is said to be refusing to publish the radioastronomy work.

Moreover, the originator of the SPRU study, Sussex physicist Dr Norman Dombey, wishes to have no part in such publication, and says he disagrees completely with the work, mostly done by Martin and Irvine, and its conclusions. Dombey, although a high energy physicist, will not be a member of the group for its study of CERN, and argued with the Social Science Research Council that the CERN work should not be funded. However, after nearly a year's deliberations, the council has given the group a grant for 15 months' work on CERN and its future project LEP, but has insisted this time on extremely strict rules on confidentiality.

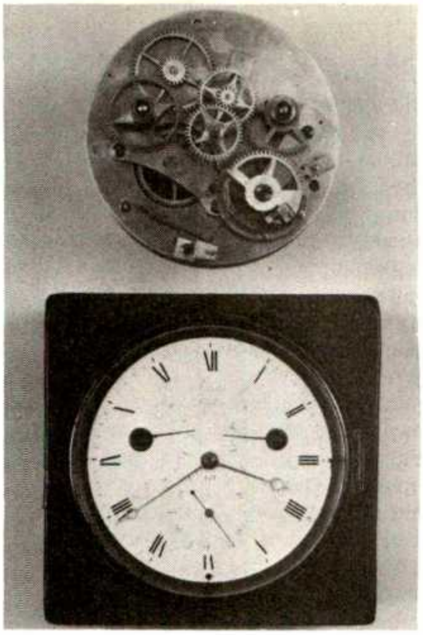
Robert Walgate

Arnold at Christie's

An 8-day marine timekeeper which is being offered for sale on 3 June at Christie's London auction rooms is thought to be a prototype for the modern marine chronometer, and it has been suggested that the spring detent which it employs could be the earliest ever, predating the putative "Earnshaw" pattern by several years. Made by John Arnold in London around 1775, the design of this un-numbered chronometer throws light on the many problems which confronted Arnold in his efforts to construct a timekeeper which would be accurate and reliable and could also be made in quantity at a relatively low price.

His chronometer (a term he himself coined) was designed to keep the same rate of going in every position and it incorporates a mechanism to compensate for changes in temperature. It has a three-armed uncut brass balance 45.2 mm in diameter. Regulation is by flat spiral balance spring, regulated by curb pins carried on a bi-metallic compensation curb, concentric with the balance pivot. The convex enamelled dial bears the signature "Arnold, London". His earliest dials were enamelled, but once commercial production was started, he changed over to silvered dials. The box, 6½ inches square and 3½ inches deep, is of mahogany.

Arnold first started working on marine timekeepers in 1786, about nine years after John Harrison — the carpenter turned clockmaker — had submitted his No.4 timekeeper to the Board of Longitude. This was a body which had been set up by the British government and which in 1714 offered a prize of £20,000 for a machine which would enable longitude at sea to be determined to a specified degree of accuracy. Harrison richly deserved the prize but the board shilly-shallied for many years, and it was only towards the end of his life that he recieved the final instalment of the award.



Had the Board of Longitude a free choice between the Harrison and Arnold timekeepers, the Arnold might well have been chosen on the grounds that it was less complicated and consequently easier to produce. Arnold made chronometers for the Admiralty at 60 guineas a piece, much cheaper than Harrison's which took about 3 years to make.

Arnold deserves much of the credit for introducing into England the manufacture of chronometers on a large scale.

As for the price likely to be reached when the chronometer is auctioned, Christie's are not willing to speculate. But if the device's history can be authenticated it could fetch anything between £20,000 and £100,000.

Arthur Frank

Mr Arthur Frank, the now-retired owner of a Glasgow-based optical business, is a well known collector of optical and scientific instruments. Much of his collection, which includes early telescopes, cameras and eye-glasses, is now distributed among several British museums. Mr Frank will be contributing occasional articles when important scientific instruments change hands or come onto the auction markets.

Indian government policy

Committed to science

New Delhi

The poor coordination between Indian scientists and politicians should improve following long-awaited decisions announced by Mrs Gandhi recently. Mrs Gandhi herself is to preside over a nine-member Cabinet Committee on Science and Technology, dealing with broad policy matters, and two more science committees have also been formed.

India's worsening position on the energy front and a massive bill for oil imports have led to the formation of a six-member Alternative Energy Commission, along the lines of the Atomic Energy Commission, to be chaired by Professor M. G. K. Menon, Secretary of the Department of Science and Technology. The third committee, the Science Advisory Committee to the Cabinet, consists of 20 eminent Indian scientists from all the major disciplines. Dr M. S. Swaminathan heads this body which is to advise the cabinet on science and technology policy.

The Cabinet Committee on Science and Technology will have an important role in deciding how to spend the science and technology budget of more than 30,000 million rupees (£1,667 million) allotted in the country's sixth five-year development plan. Main areas of interest will be in life sciences, oceanography, alternative energy sources and bioengineering as applied to pharmaceuticals.

Naresh Sahajpal

● **Energy alternatives:** The Indian government has given fresh impetus to the development of new and renewable sources of energy. The key point of the plan is reduced dependence on imported oil. The government is investing in systems for utilization of energy from the Sun, wind and biomass.

In photovoltaics, the public sector company, Central Electronics Limited (CEL) of Sahibabad, has begun bench-scale manufacture of single crystal silicon solar cells and panels with capacities of up to 10kW per year. Solar modules developed by CEL are already being used in powering a light beacon at Dwarka port, pumping water for a whole village in Rajasthan and lighting a 20-bed hospital in Ladhak. Solar water heating systems are being installed in many hotels, and a textile mill in Ahmedabad is already meeting its hot water requirements through a large solar heater.

A 120 million rupee (£7 million) project has been drawn up for developing low cost solar-grade silicon material and cheap fabrication techniques and for improving the efficacy of solar cells and solar panels.

A national wind energy centre is being set up at Allahabad Polytechnic to develop a low-cost windmill. A cold storage plant utilizing geothermal energy is being set up in Himachal Pradesh. And a 600 MW tidal power station is planned in the Gulf of Kutch in Gujarat.

UN funds falter

Washington

Frustrated in the United Nations by lack of progress in following up proposals from the Conference on Science and Technology for Development (UNCSTD), held in Vienna in August 1979, a group of developing countries has organized a top-level mission to try to persuade the oil-rich nations that they should be doing more to support technological efforts in the Third World.

In an initiative originating from government officials from Tunisia, Mexico, Pakistan and Guinea, a delegation made up of ministers or other top officials from ten developing countries will visit several major oil-producing countries at the beginning of next month to discuss ways of supporting technical assistance programmes. The countries to be visited include Saudi Arabia, Kuwait, the United Arab Emirates, Nigeria and Venezuela.

The delegation will then move to Paris, where it will report to the Secretary-General of the Organization for Economic Co-operation and Development (OECD). Several OECD countries, in particular the Scandinavians, have already expressed enthusiastic support for the so-called "Tunis initiative", which they see as avoiding some of the road-blocks faced by classical negotiating patterns on North/South economic issues.

Eventually it is hoped that a package can be put together in a form likely to be endorsed by the planned summit meeting between industrial and developing countries in Mexico City in October. President Ronald Reagan has recently agreed to attend the meeting (partly, it is rumoured, because President Lopez Portillo of Mexico has agreed not to invite Cuba's Fidel Castro).

The package could contain a commitment from oil-producing and developed countries to support technological development in the Third World by several hundred million dollars a year by the mid-1980s. The aim is to find a way of using the large cash surpluses being built up by the oil-producing nations to catalyse development efforts, without running into the political tensions which have polarized discussions between the Group of 77 and the industrialized nations within the United Nations.

In the event, the Interim Fund for Science and Technology, set up at the Vienna conference with an initial goal of raising $250 million to cover two years of operation, has fallen far short of its target. Less than $60 million has been received in pledges — and only about a third of this is thought to have been handed over. The interim fund is the responsibility of the United Nations Development Programme, and officials are working closely with the Tunisian government and other members of the so-called group of 10 — in addition to the four countries listed above, the other members are Peru, Senegal, Sudan, Kenya, Jordan and Sri Lanka — to find other ways of financing the projects that they have been assessing.

Although financial aid will be high on the agenda of next month's discussion with the oil-producing nations, equal emphasis is being placed on the need to support science and technology as an integral component of economic development in Third World nations. Even the oil-producing nations themselves are putting increasing emphasis on their need for technical assistance in building an economy which is not totally dependent on oil exports.

Officials from the United Nations Development Programme are also trying to link the efforts which have already been made under the interim fund to any plans emerging from the UN Conference on New and Renewable Sources of Energy, due to take place in Nairobi in August, for encouraging research on new energy sources. They argue that it would avoid unnecessary duplication if any new research initiatives from the Nairobi conference were under the same umbrella.

A second list of projects, totalling $11.2 million, has recently been approved for funding under the interim fund. These include $1.3 million to Brazil aimed at improving carbon fibre technology; $500,000 to Ethiopia for the popularization of science and technology; $670,000 to establish a unit for research on cellulose products in the Sudan; $370,000 for "interregional" courses in Bangladesh and Ghana on the application of modern techniques in physics to development (one on monsoon dynamics, the other on solid state physics); and $30,000 towards a symposium in Ghana on the state of biology in Africa, being organized under the auspices of the International Council of Scientific Unions. Funding has already been offered for the initial stages of each of these projects, although whether the totals are reached depends on how many countries make good their pledges to the interim fund. **David Dickson**

Mary Lindley

Mary Lindley, an assistant editor of *Nature* since 1966, died last Thursday, 7 May, after some months of illness. She was the longest-serving member of the present staff of *Nature*, and during her service with the journal had successively been responsible for most of the journal's separable functions. She joined the staff immediately after graduation from the University of Oxford, where she had been trained at Somerville College as a biologist with inclinations towards botany.

Mary Lindley suffered throughout her life from the consequences of restricted growth. Her method of dealing with this handicap was to behave as if it did not exist. In this spirit she learned to type, to drive a motor car, to live on her own and to travel widely. Between 1972 and 1975 she worked in the Washington office of *Nature*, handling the flow of scientific manuscripts through that office. When she died, Mary Lindley was the chairman of the Association for Research into Restricted Growth, an organization whose formation she had helped to stimulate.

As a colleague, one of Mary Lindley's memorable attributes was her sardonic wit. Always economical with words, she could in half a sentence puncture an overblown argument — or make a joke. For much of her time on *Nature*, she was the chief defendant of the view that whole organisms have a place in biological studies.

She appeared to be indefatigable. To avoid the worst of the London traffic, it was until very recently her habit to set off in her tiny motor car before the rush-hour began. She would leave the office late, not only to avoid the evening rush-hour but because (she would insist) there was still work to do. Her greatest achievement was that her dealings with those whom she met in the course of her work were never compromised by her handicap; to them, she was merely a very sharp lady who happened to be small.

As an editor, Mary Lindley was the most flexible of people. In her time, she had been responsible for the Book Reviews and the News and Views sections of the journal. For more than a year before she died, she had coordinated, edited and written much of the output of the Nature–Times News Service, which appears in the London *Times*. A few days before she died, cheered by her release from an iron lung and apparently indifferent to the discomforts of a tracheotomy, she asked for a typewriter to be taken to St Thomas's Hospital so that she could begin to write again.

Very few knew of her mounting frustration in the past year about her deteriorating health. Her courage was, however, evident to all.

CORRESPONDENCE

Progress in Crete

Sir — The commentary on the current conditions in higher education and research in Greece by Mr E.M. Pantelouris, which appeared in your issue of 1/8 January, came to our attention with some delay. It is, however, instructive to examine the case of the University of Crete as an example of the roadblocks encountered in the actual implementation of innovative ideas and the measure of success that may be expected. This will also demonstrate, we hope, that some of the conclusions of Mr Pantelouris with regard to the University of Crete are not necessarily true.

The operations of the University of Crete started in the academic year 1977–78 with the Department of Mathematics of the School of Sciences at Heraklion and the School of Humanities at Rethymnon. The Department of Physics was added in 1978–79. During this formative phase, instruction was carried out by temporary staff hired on an annual basis and the university was housed in provisional quarters provided in high school buildings.

In spite of these shortcomings, the progress accomplished during the first three years of operation through the efforts of the Provisional Administrative Committee and the enthusiasm of the temporary staff has been remarkable. Some of the major accomplishments include: (1) The organization of a library which already contains about 100,000 volumes in the humanities and 20,000 volumes in sciences. (2) The construction of provisional housing facilities for the schools of science and medicine which are expected to be ready for the academic year 1981–82. (3) The development of a flexible modern curriculum which has been already used successfully. And (4), the organization of student laboratories and the procurement of basic research equipment for the School of Sciences.

Clearly, however, the consolidation of these achievements and the future progress of the university depends critically, at this stage, on the recruitment of a high quality permanent faculty. The Administrative Committee has pushed from the beginning for a departmental structure, in contrast to the chair system, with a high professor to student ratio and a faculty with three professional ranks. The initial appointments will be made by faculty selection committees nominated by the Administrative Committee and consisting of professors from universities in Greece and abroad. These are new and unprecedented features for the Greek university system and it is not surprising that the legislation required for their implementation was time consuming.

This work is now complete and a call for candidacies for 24 positions in the School of Sciences and 14 positions in the School of Humanities has been publicized (see *Nature* classified columns of 29 January). The faculty selection committees have been nominated and the first appointments are expected to be made by late autumn this year. These, of course, are only the first steps in consolidating the structure of the new university and much persistent and enlightened effort will be required especially by the first members of the faculty. The course of the campaign for reforms in the system of higher education in Greece has demonstrated so far that while a diagnosis of flaws and deficiencies is common knowledge, the planning and implementation of effective steps for lasting changes is an agonizing procedure, replete with frustrations but highly rewarding when successful. We hope that the University of Crete will play a significant role in this by setting an example of a high quality modern institution of higher education and research.

A. Kostikas
(Member of Administrative Committee)
Crete University, Greece

Xeroderma list

Sir — The issues raised in Cairns's article "The origin of human cancers"[1] and subsequent comments[2] highlight the importance of studies of rare human disorders as models for human carcinogenesis. In order to gain quantitative information on such questions as the frequency of cutaneous and internal neoplasms in patients with defective DNA repair, we are establishing a registry of xeroderma pigmentosum patients. We welcome correspondence from physicians and scientists who are aware of American patients with xeroderma pigmentosum:

Be nice to NATO

Sir — Mr Roger R.C. New has recently argued in these columns against publicizing the NATO Advanced Study Institutes in *Nature* on the grounds that it implies approval for "the increasing military orientation of our society" (*Nature* 23 April, p.624). I take precisely the opposite point of view (neither of us questions the scientific and pedagogical value of these institutes).

Surely lasting peace can only be established on this planet if a framework of trans-national judicial, political and economic institutions can be developed to cope with the problems plaguing all mankind. In my view the construction of such institutions must begin with those nations sharing a common democratic tradition — basically those encompassed by NATO and/or OECD. NATO has always been intended as more than a military alliance; I note Article 9 of the Treaty, establishing the "North Atlantic Council" for political consultation, and the meetings of the NATO parliamentarians.

Expansion and encouragement of multinational intellectual, economic and ultimately political ties among the citizens of the world's democracies must be urgently pursued, and the NATO Advanced Study Institutes play a small but positive role in such developments.

William M. Irvine
Chalmers University of Technology, Onsala Space Observatory, Sweden

Computer algebra

Sir — I was delighted to see your recent article on "Algebra made mechanical" (*Nature* 19 March p.198). These symbolic math systems will surely revolutionize scientific computation. However, there is one minor correction to the article: muMATH was coauthored by Albert D. Rich and myself at The Soft Warehouse. Also, to redirect the deluge of enquiries, I suggest that they be sent directly to the distributor: Microsoft Consumer Products at 400 108th Ave. N.E., Suite 200, Bellevue, Washington 98004, USA.

David R. Stoutemyer
The Soft Warehouse, Hawaii, USA

Confusing script

Sir — In the debate stimulated by Halstead's[1] criticisms of the Natural History Museum's exhibit on human evolution, there are two main issues which only partly overlap. First, what cladism entails, and what various authors think about it; and second whether the museum's exhibit presents a fair picture of human evolution, as it is known to science.

Those who disagree with Halstead about the former would do well not to prejudge his assessment of the latter, without seeing the exhibit. B.A. Wood's[2] observations that some early hominids have been seriously misassigned should be noted. So far the archaeological side to the exhibit has passed without comment, but one particular example, in which archaeology and physical anthropology are brought together, speaks volumes for the general tone of the exhibit.

First, it is suggested, reasonably enough, that neanderthals have characteristics not shared by modern man, and vice versa. Then the script continues

> "But because the neanderthals and modern man share these two important characteristics
> — an average brain size of 1,330 ml
> — burial of the dead
> . . . they can be grouped together in the same species — *Homo sapiens*".

This confused conjunction of biometrical and cultural criteria is so weird that little more need be said. But other oddities abound. We are told that we are apes, without any reference to the pattern of characteristics which distinguish us as hominids. Then, the whole, vital, subject of chronology is almost totally omitted.

It seems unlikely that the exhibit represents "official" doctrine of the museum concerning cladism. It represents a good visual show, in which unfortunately "educationalese" has taken over to the extent that the children and other visitors who much enjoy the exhibit are seriously and unnecessarily misled by gross oversimplifications. This is a great pity, for in many ways meticulous care has been taken in the preparation of the exhibit. The desire to simplify in order to spread knowledge is understandable, but over-simplification at the expense of accuracy is counterproductive, and does little to further learning.

Interferon: decline and stall

from Peter Newmark

THE good news to come out of a recent gathering in Rotterdam* was that, given to cancer patients, interferon does have some reasonably consistent clinical effects; the bad news was that there are the side effects of fever, malaise and weight loss. As the number of cases in trials of interferon increases from the tiny to the small and as the trials become randomized, controlled and double-blind, it is clear that interferon is no wonder drug. It remains, however, the case that the number of responses in most trials of interferon is above the threshold for declaring it useless. The consensus view is that interferon will eventually find a permanent place in the limited armoury of the cancer chemotherapist.

The evaluation of interferon in cancer, or for that matter as an antiviral agent, has been unconventional for two main reasons. The first is that it has been available in such small quantities; the second that it has such a marked species specificity that it has always been considered necessary to produce human interferon for human therapy and it has generally been thought pointless to test human interferon on experimental animals. Hence the first very impure products of the heroic Finnish effort, led by K. Cantell, to purify interferon from white blood cells were tested on minute numbers of patients and far too much was sometimes read into the occasional, dramatic response.

Although the supplies of interferon are increasing exponentially, many groups are still testing and reporting handfuls of cases without adequate controls. Among the best current trials of interferon are those of the American Cancer Society (ACS), all of which make use of the Finnish human leukocyte interferon (a mixture of α-interferons). In summarizing the ACS metastatic breast carcinoma trial, Dr E. Borden (University of Wisconsin) included the results of a parallel trial of the same interferon at the M. D. Anderson Hospital in Houston. Of the combined current total of 43 cases, 12 have shown a partial response — defined as one in which there is at least a fifty per cent decrease in the sum of the diameters of all measurable tumours — and lesser responses were recorded in another 6 cases. Despite rumours to the contrary, Borden said the ACS trial will continue, although variations in the size, route and schedule of dosage may be introduced.

The ACS malignant melanoma trial appears less promising, with only one partial response and five lesser responses out of a current total of 43 cases (S.E. Krown). And in only 4 of 23 ACS cases of multiple myeloma was there registered a partial regression of disease (E.F. Osserman, Columbia University). Sadly this does not match conventional therapy and the ACS has decided that, henceforth, interferon will only be tried in combination with more active agents. For breast carcinoma there is still hope that interferon will turn out to be as good as any other single agent (but not as good as a combination of such agents) but it is too soon to be confident even of that conclusion.

Another relatively large trial of leukocyte interferon is on about 50 cases of osteosarcoma (H. Sander, Karolinska Hospital). This trial, unlike its promising predecessor, is being properly controlled and is not yet complete. Sander's impression was that interferon was proving to be better than conventional chemotherapy. Most other reported trials contained less than 10 patients except for a 26-case trial of fibroblast interferon (β-interferon) against neuroblastoma on which it is too early to pass judgement (D. Niethammer, University of Tubingen).

It is also too early to discover the results of the larger trials of interferon as an antiviral prophylactic agent. In particular, a proper trial of the ability of Finnish interferon to prevent herpes and papova virus infections of renal transplant patients (M.S. Hirsch, Boston) will take at least another year to complete. Meanwhile there is still guarded optimism for the use of interferon in the treatment of hepatitis B and both R. Sundmacher (University of Freiburg) and E. De Koning (Utrecht) reported that trifluorothymidine, in combination with Finnish interferon, was markedly more effective against herpes virus-induced dendritic keratitis of the corneal epithelium than was trifluorothymidine alone.

As the clinical trials progress, so does the purity of the interferon tested. Purity can mean one of two things. The first is the extent to which contaminants have been removed; good preparations are now over eighty per cent pure and have a specific activity of over 10^7 international units per mg protein. But purity can also mean the separation of one subtype of interferon from a mixture. The only way to obtain a single member of the eight or so subtypes of α-interferon is from bacteria containing the relevant gene. Production by such means has advanced to the point where at least two small clinical trials of different subtypes have commenced with two hopes. One is that different subtypes will have distinct and complementary activities, as suggested by some *in vitro* tests (N. Stebbing, Genentech); the other is that some subtypes will be without side effects. In that respect it was the impression of T. Merigan (Stanford University) that subtype α_2 (from Genentech/Hoffmann La Roche) produced the usual side effects in man whereas H. Schellekens (TNO, Netherlands) claimed that the same subtype (from Biogen) did not produce the fever that leukocyte interferon did when given to the rhesus monkeys and yet was just as effective in the prophylaxis of vaccinia virus in that species.

Of great promise for the purification of individual interferons is the growing number of monoclonal antibodies which can be used in affinity chromatography. The original monoclonal (*Nature* **285**; 446, 1980) has now been joined by another one against α-interferon (L. Montagnier, Institut Pasteur) and several laboratories now have monoclonal antibodies against β-interferon (H. Erlich, Cetus Corporation; J. Trapman, Erasmus University; H. Hochkeppel, GBF Braunschweig).

Much attention is being turned to the most enigmatic of interferons, γ-inter-

feron. Previously known as Type II or immune interferon, this species is produced by cells of the immune system, particularly T cells. Production can be boosted by a variety of inducers and different laboratories have their favourite inducer. For example, R. Falcoff (Institut Curie) favoured anti-lymphocyte serum, H. Kirchner (*Nature* **291**; 79, 1981) uses phytohaemagglutinin or concanavalin A on continuously cultured T cells, J. Vilcek's group swear by a combination of phytohaemagglutinin and phorbol esters (*Proc. natn. Acad. Sci. U.S.A.* **78**; 1601, 1981), most recently mezerein (Y.K. Yip), which has less tumour promoter activity than the one previously used, and others favour protein A from staphylococci (for example, *Nature* **291**; 77, 1981).

Induced cells are beginning to yield sufficient γ-interferon for its purification (or mRNA for its cloning). The big question is whether or not γ-interferon(s) will turn out to be distinct from other species in structure and activity. Conventional wisdom has been that γ-interferon is distinct but in a review of the literature L. Epstein (University of California, San Francisco) expressed caution in view of the impurities of all preparations so far tested. She finds no convincing evidence that γ-interferon has any unique effects on normal cell function and presented evidence that it induced the same 11 peptides in fibroblasts as did α-interferon. There remains, however, the possibility that γ-interferon is quite distinct; it has, for example, at least twice the molecular weight of other interferons (unless this represents polymerization) and is the only one to be unstable at *p*H 2. Unfortunately it also becomes very unstable on purification.

What, then, can be said of the future of the interferons as therapeutic agents? The consensus view appears to be that they will find a place in the treatment and prevention of viral diseases and in the treatment of cancer. For the latter they offer a unique therapeutic approach because they act not as toxins, directly on the tumour cells, but through the immune system, particularly natural killer cells. It is because of this that there is some optimism that γ-interferon, itself from cells of the immune system, will turn out to be a more potent anti-cancer agent than the other interferons. If the problem of side effects (see, for example, G. Scott *et al. Br. med. J.* **282**; 1345, 1981) can be overcome, much larger doses than in the current typical schedule (10^6 units daily for 30 days and thereafter less frequently) may also improve the efficacy of interferons; already some patients have tolerated repeated doses of 100×10^6 units. Although interferon is not the wonder drug that many had hoped, though few had promised, a reasonable, positive view, as expressed by G. Galasso (NIH), is that we should at least be thankful for the arrival of a new drug which is active against diseases for which there are usually few, if any, therapeutic agents. ☐

Palaeoclimates north and south

from M. James Salinger

Following the discovery that changes in Southern Hemisphere sea surface temperatures preceded changes in the Northern Hemisphere by about 3,000 years (J.D. Hays, X INQUA Congress, Birmingham, 1977), research into Southern Hemisphere palaeoclimates has accelerated rapidly. New data, presented at the first CLIMANZ* conference, allow a comparison between palaeoclimatic trends over a large area of the Southern Hemisphere with those of Europe and North America.

In the Northern Hemisphere the last glacial period commenced with a cooling at about 70,000 BP followed by a long period of lower temperatures. This period of cooler climates, continental ice masses and lower sea level was punctuated by a complex series of interstadials, with maximum ice volume at about 18,000 BP. Warming then occurred with very rapid temperature rises between about 15,000 and 12,000BP. A more gradual rise occurred after 10,000 BP with the warmest period in the Holocene at about 6,000 BP.

Oxygen isotope measurements from the Huon Peninsula in northern New Guinea (P. Aharon, Australian National University (ANU)) show that relatively rapid fluctuations occurred in the average annual temperatures between 53,000 and 37,000 BP, with a maximum cooling of about -6°C below present temperatures during a marine regression at 43,000 BP. At 29,000 BP when sea level was relatively high (-45 metres) temperatures were 2.6 ±0.7°C less than at present. These results can be compared with those from deep-sea cores analysed by CLIMAP which suggest a maximum cooling of about 2°C in the western Pacific. Lake data (J. Bowler, ANU) indicate a hydrological regime which was radically wetter than present around 30,000 BP and earlier.

The New Zealand glacial record (T. Chinn, Ministry of Works, Christchurch) suggests that the maximum advance of the Pleistocene occurred around 23,000 BP and continued until after 21,000 BP, with a depression in annual temperatures, deduced from glacial deposits, of approximately 5°C. Corroborative data came from J. Hays (Lamont–Doherty Geological Observatory); faunal evidence from a deep-sea core at 42°S 80°W indicates a sea surface temperature of 8°C below present at 21,000 BP. Hays speculated that the greatest extent of Antarctic sea ice occurred around this time. These results seem to confirm that Southern Hemisphere changes lead those in the Northern Hemisphere by about 3,000 years, at least for the last glacial maxima.

A little later, around 18,000 BP, sand dunes were active in Australia, suggesting a period of increased windiness (J. Bowler, J. Ash and R. Wasson, ANU). Stronger westerlies displaced to the north are indicated by the distribution of quartz grains off the east coasts of Australia and New Zealand (see J. Thiede *Geology* **7**; 259, 1979). These results, together with CLIMAP sea surface temperature data presented by Hays, imply that, at this time when the globe was extremely cold and Northern Hemisphere ice masses were at their maximum extent, the Southern Oscillation, an important feature of the atmospheric general circulation, was much reduced. This would have other implications, not least being a marked reduction in the frequency of upwelling along the South American coast (the El Nino phenomenon).

Comparison of climatic trends in Europe and North America with Australia and New Zealand

Time period (Before present)	Europe and North America	Australia and New Zealand region
40,000–25,000	Fluctuating but cool temperatures	Fluctuating but cool temperatures
23,000–20,000	Cooling	Maximum coldness
18,000–17,000	Maximum coldness	Cold
15,000–12,000	Rapid warming around 13,000–12,000	Rapid warming at about 14,000
10,000–8,000	Warming	Maximum warmth
Approximately 6,000	Maximum warmth	Slight cooling

M. James Salinger is in the Climatic Research Unit, University of East Anglia.

---

*The CLIMANZ (Climatic Change of Australia and New Zealand) conferences aim to bring together groups of workers trying to reconstruct late Quaternary Australia and New Zealand climates.

0028-0836/81/200106-02$01.00

Between 15,000 and 10,000 BP a dramatic change in climate occurred. Geomorphic and palynological evidence from New Guinea indicates that deglaciation started before 14,500 BP with a rise in temperature amounting to 6°C over the entire period (G. Hope, ANU). Glacial changes in New Zealand were extremely rapid, retreating from near-maximum conditions around 17,500 BP to conditions similar to today by 13,500 BP (T. Chinn). At around 15,000 BP there was no substantial area of lowland forest in New Zealand but 5,000 years later both islands were almost completely forested (M. McGlore, Department of Scientific and Industrial Research, Christchurch). In the sub-Antarctic, Hays provided evidence of sea surface temperatures from a deep-sea core at 42°S 80°W. At around 15,000 BP temperatures were near to the glacial minimum and by 10,000 BP they had attained values near to Holocene maximum levels. His data from 42°S suggest that south of the oceanic Polar Front the sea ice regime changed extremely rapidly. Over 300 years at about 14,000 BP there was a sharp reduction in sea ice cover.

The maximum Holocene warming in the CLIMANZ area occurred at 9,000 BP, adding to the mounting evidence that the warmest, most pluvial periods in the past 15,000 years did not occur simultaneously throughout the globe. The warmest period in Europe is thought to be about 6,000 BP. Pollen from Mt Wilhelm and Mt Carstensz in New Guinea (G. Hope) provides evidence that tree-lines there were higher around 9,000 BP than at present. Data from much of southeastern Australia suggest warmer and wetter conditions.

Stratigraphical and pollen records from a number of sites in the southeastern highlands show highest temperatures and precipitation levels at 9,000 BP (A.P. Kershaw, W. Southern, J. Williams and L. Joyce, Monash University), coeval with high lake levels noted at Lake Frome (J. Bowler). At this locality the pollen analyses of G. Singh (ANU) indicate a summer monsoonal rainfall with annual rainfall of perhaps three times the present total. Between 10,000 and 8,000 BP New Zealand had a more complete forest cover than it had at any other time in the past 80,000 years (M. McGlone). The forests in the North Island grew under wet, mild conditions. Maximum forest cover in southern New Zealand, however, coincided with warmer and drier conditions than present. The deep-sea core at 42°S 80°W indicates a minimum of sea ice at this time. Again Southern Hemisphere temperatures in the CLIMANZ area at least seem to lead those in the Northern Hemisphere by about 3,000 years.

The evidence from moisture indicators show striking similarities with anomaly patterns in Australasia associated with an increased Southern Oscillation (Salinger *Mon. Weath. Rev.* **108**; 1892, 1980; Coughlan *Q. Jl R. met. Soc.* **105**; 707, 1979). The suggestion of a high Southern Oscillation Index around 9,000 BP would imply a stronger Walker Circulation and more frequent cold water upwelling off the South American coast and would have other consequences which are open to independent testing at other locations.

Parallels between the spatial patterns of past climates, and those of today, especially associated with important and well defined features of the general circulation such as the Southern Oscillation, provide a relatively simple way of interpreting local changes in a global context and may help us to understand more fully the lack of synchroneity between Northern and Southern Hemisphere climate changes over the past 50,000 years. ☐

Hooked on microtubules

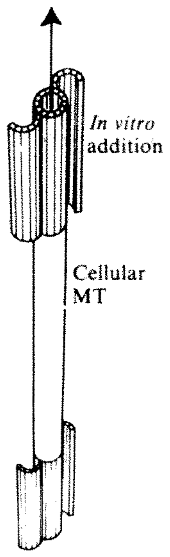
from Jeremy Hyams

In addition to their well documented role in ciliary and flagellar movement, microtubules also participate in many forms of intracellular motility. Phenomena such as the separation of chromosomes at mitosis, the redistribution of pigment granules in fish and amphibian chromatophores and transport along nerve axons are all spatially associated with arrays of microtubules and, in most cases, disrupted by anti-microtubule drugs such as colchicine.

A striking feature of these microtubule-associated movements is their bidirectionality; this property has been taken by many workers to reflect the organization of the underlying microtubules. Briefly, it has been suggested that there exist, in such situations, two families of microtubules with opposed polarities, each capable of exerting force in a given direction. Establishing the polarity of cytoplasmic microtubules has therefore long been regarded as the key to understanding the mechanisms of intracellular motility in much the same way as defining the orientation of the structural proteins of the muscle sarcomere was crucial to defining their interaction during muscular contraction.

Unfortunately for proponents of this view, until now there has existed no unambiguous morphological marker of microtubule polarity analogous to the arrowhead decoration of microfilaments by heavy meromyosin. Experimental dissection of microtubule directionality has therefore progressed only by the less expedient analysis of microtubule elongation *in vitro*. When tubulin subunits are added to a preformed seed (a fragment of microtubule or an organelle such as a flagellar axoneme or basal body), growth is favoured at one end (the fast or plus end) but also occurs to a lesser extent at the other (slow or minus) end (*Nature, News and Views* **284**; 402, 1980).

An important extension of this type of approach was introduced by Heidemann and McIntosh (*Nature* **286**; 517, 1980), who exploited an earlier finding that tubulin, polymerized *in vitro* in a high-ionic strength buffer containing dimethyl sulphoxide, formed not microtubules but sheets of protofilaments (Burton & Himes *J. Cell Biol.* **77**; 120, 1978; Mandelkow & Mandelkow *J. molec. Biol.* **129**; 135, 1979). When Heidemann and McIntosh used existing microtubules to seed this assembly, the polymer formed consisted of whole microtubules to which a C-shaped ribbon of protofilaments had attached, forming a conspicuous hooked appendage. Cross-sectioned images of microtubules grown on *Tetrahymena* basal bodies (see figure), viewed from their plus towards their minus ends, revealed that the hooks had a predominantly right-hand curvature, irrespective of whether microtubules were growing outwards or inwards from the basal body. The method therefore reveals not the direction of growth of these microtubules but, rather, their intrinsic polarity.



In vitro growth of hook-bearing microtubules onto existing seeds. Viewed from the fast-growing or plus end (arrow) the hooks are predominantly right handed irrespective of the direction of growth.

This exciting discovery was limited in its

0028-0836/81/200107-02$01.00

applications to those microtubules which could be elongated *in vitro*. Now, however, by minor modification of their original method, McIntosh and his colleagues have shown that hooks can form directly on existing microtubules (Euteneuer and McIntosh *J. Cell Biol.* **87**; 509, 1980; *Proc. natn. Acad. Sci. U.S.A.* **78**; 372, 1981). In other words, the long-awaited morphological marker of microtubule polarity is at last available.

Application of the new technique to motility-related microtubules has already achieved some notable successes. Decoration of spindle microtubules from both plant and animal cells has sufficiently resolved earlier uncertainties concerning spindle organization to signal the demise of at least one hitherto highly regarded model of mitosis.

Results with other cellular systems have equally demanded that earlier views of microtubules in relation to intracellular motility be reconsidered. In the fish chromatophore, hook curvature was found to be the same for all microtubules and consistent with their plus ends being distal to the cell centre. Thus, even in situations in which transport is clearly bidirectional, the underlying microtubules all possess a single polarity. McIntosh and his colleagues conclude that microtubules do not contribute directly to motility in this system but, rather, form a vectorial framework upon which some other force-generating component is organized. Defining the interaction of microtubules with obvious candidates for this role, such as microfilaments and microtrabeculae, clearly now becomes a major challenge. ☐

Magmatic snap, crackle and pop

from D. H. Tarling

GRAVITATIONAL segregation of crystals out of a magmatic melt has long been considered to be the prime mechanism by which the composition of one or possibly two primary magmas can evolve to account for the observed varieties of igneous rock. This mechanism was originally proposed by Bowen (*Am. J. Sci.* **29**; 175, 1915) as a result of experiments in which olivine glass melts were held for 15 minutes at 1,430°C, before quench cooling, in a pot 2.5 cm high and 1.5 cm wide. The fact that gravitational segregation of individual crystals in a magmatic melt is physically impossible has, however, only been appreciated by a few researchers and the mechanism has only received wide acceptance because there appeared to be no satisfactory alternative.

The actual mechanism by which the fractionation takes place is absolutely vital to any interpretation of the isotopic ratios in igneous rocks. In particular, it is widely accepted that ^{86}Sr/^{87}Sr ratios are low for rocks of mantle derivation. Such a view is based on the assumption that normal oceanic ridge basalts are representative samples of the mantle — that the isotopes themselves have not been partitioned to any significant extent during the formation of the oceanic crust. A recent paper on convective fractionation by Rice (*J. geophys. Res.* **86**; 405, 1981) is therefore critical not only to the understanding of igneous petrological evolution models, but also to the whole basis of geochemical analyses of igneous rock types. It also provides a satisfactory explanation for the occurrence of violent, explosive volcanism associated with the sudden mixing of radically different magma types.

The fundamental objection to crystal segregation is that crystals forming within a cooling magma would take an infinite time to reach the bottom of the magma chamber and so could not accumulate as a crystal mush at the bottom. In any case, the evidence from layered igneous complexes, such as the Skaergaard intrusion of Eastern Greenland, is that the layering takes place on the roof and sides of the chamber as well as on its floor, and it can be repetitive throughout the sequence. To account for such observations, both Hess (*Geol. Soc. Am. Mem.* **80**; 230, 1960) and Wager and Brown (*Layered Igneous Rocks*, Oliver and Boyd, Edinburgh, 1968) proposed that the layering was associated with turbidity currents within the magma chamber, from which individual crystals then segregated. However, although some sedimentary features can be found in some layered complexes, many such features are absent — apart from the intrinsic impossibility of sinking individual crystals through such a viscous medium and the necessity to plate both the walls and ceiling, as well as the floor.

What, then, does Rice propose to replace this widely accepted but impossible model? Essentially he draws on his industrial background in glass and metallurgical processing, combines this with studies by Hurle (*J. Crystal Growth* **13/14**; 39, 1972), and proposes a convective process of fractionation that also explains layering on a range of scales, and shows how magmas of different kinds can be maintained separately and then combined catastrophically to provide explosive volcanism, such as was recently observed in Mount St Helens, and historically at Krakatoa (AD1883) and Santorini (BC1450).

Assuming reasonable physical parameters, the Rayleigh number at which convection would occur within a magma would be obtained in quite small chambers, about 50 m deep, although differences in, for example, viscosity and composition mean that convection could occur on the range of macro- and microscales commonly encountered in geological situations. As the magma convects to lose its heat, there is magma flow past the cooling front at which crystallization is being initiated. Solidification therefore takes place at this front as a function of its temperature and the compositions of the crystallized minerals and the liquid melt. Because the convection is unsteady, there are repeated changes in the composition of the minerals being deposited along the front giving rise to layering. Rice's model predicts that a basaltic magma chamber some 1 km deep would develop layers, each of which would be 5–10 m thick — as observed in the Skaergaard intrusion. One major difference to the previous models is that the layering would occur equally on the floor, ceiling and walls of the magma chamber, as is observed.

Rice's mechanism also explains the apparent close relationship between explosive silicic volcanicity and quieter basaltic eruptions. It has always seemed strange that basaltic lavas can be extruded through the flank fissures of a volcano that was, almost simultaneously, exhibiting violent silicic eruptions at its central cone. (The mechanism may also help to explain the puzzling 'Daly gap' in the range of compositions, between tholeitic and rhyolitic, observed in many oceanic volcanic systems.) In the later stages of the proposed model, there is a high-viscosity, low-density, low-melting point rhyolitic magma overlying a low-viscosity, higher-density, higher-melting point basaltic magma. Rice shows that such a system is stable, apart from some convective intermixing in the boundary zone, until the top of the basaltic magma cools to its crystallization temperature. At this time, the basaltic magma will begin to exsolve volatiles that further reduce its viscosity and its density. This essentially destroys the stability of the system so that there is a near-instantaneous, massive, explosive 'roll-over' of the two magmas, often associated with the generation of super-heated 'flashing', particularly if the magmas are hydrous.

Such a model, if valid, should allow better evaluation of the gestation time of the violent igneous eruptions and clarify how to estimate the potential hazard from the compositions of previously erupted phases. However, one major aspect in this proposed mechanism is that eddy-sized

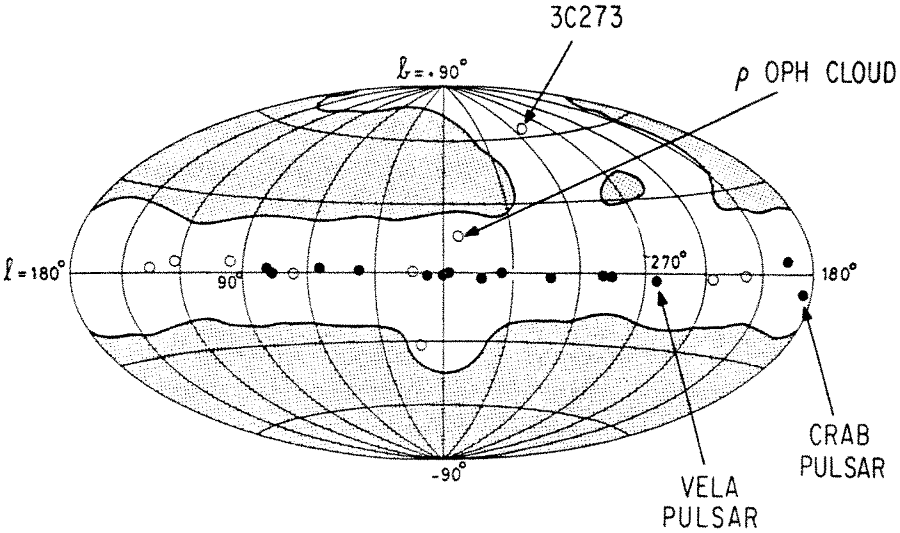
A catalogue of unidentified objects

from David J. Thompson

THE sky seen with a gamma-ray telescope offers a unique view of high-energy astrophysical processes. This uniqueness is emphasized by the second COS B catalogue of high-energy gamma-ray sources (Swanenburg *et al. Astrophys. J. Lett.* **243**; L69, 1981) which documents the remarkable lack of obvious correlation between most of the gamma-ray sources and previously known astronomical objects.

The high-energy gamma-ray telescope aboard ESA's COS B satellite has been in operation for nearly six years and data used in compiling the second COS B catalogue span more than three years. The 25 sources of gamma rays with energies above 100 MeV which make up the catalogue may be either stellar or extended sources (with diameters up to 2°). Although the COS B survey does not cover the entire sky, it does include the full galactic plane, along which most of the sources are clustered. There is also a concentration towards the inner part of the Galaxy. In addition to the simple observation that these sources are galactic, their spatial distribution suggests that they lie within 2 to 7 kiloparseconds of the Solar System and, hence, are radiating on the order of 10^{36} erg s^{-1} in the form of high-energy gamma rays.



The second COS B catalogue of high-energy gamma-ray sources, shown in galactic coordinates. Observations covered the unshaded region. Filled circles denote sources with measured fluxes $\geq 1.3 \times 10^{-6}$ photons (>100 MeV) cm^{-2} s^{-1}, while open circles denote sources below this threshold (from Swanenburg *et al.* 1981).

Despite efforts by a number of investigators, only four of the 25 sources have firm identifications. The Crab and Vela pulsars are recognizable by their time signatures, having the same periods as the radio pulsars. The quasar 3C273 and the interstellar cloud complex near the star ϱ Ophiuchus are identified by positional coincidence, which is meaningful only for these high-latitude sources. An extended source, not appearing in the catalogue, has also been identified by COS B with the molecular clouds in Orion (Caraveo *et al. Astr. Astrophys.* **91**; L3, 1980). The remaining 21 members of the catalogue are distinguished by their lack of counterparts at other wavelengths. In particular, the gamma-ray luminosities of these sources are at least an order of magnitude greater than their X-ray luminosities and several orders of magnitude greater than their radio luminosities. This preferential production of gamma rays indicates an unusual astrophysical setting, dominated by large energy transfers. The fact that the identified gamma-ray sources are not all of the same type suggests that the unidentified sources may themselves not be a homogeneous group. The variety of energy spectra seen for the sources in the COS B catalogue is a further indication that two or more classes of gamma-ray source may emerge from future studies. The intriguing possibility is that at least some of these presently unidentified sources may turn out to be a totally new class of galactic object.

Further results can be expected from COS B, particularly in the area of time variability studies, but positive identification of these mysterious sources depends on future observations. The Soviet–French GAMMA-I satellite (to be launched in the next two years) should give improved position information for some of these. The instruments selected for the Gamma Ray Observatory (now scheduled for launch in the latter part of the 1980s) have the broad energy range, good angular resolution and high sensitivity to provide the next breakthrough in gamma-ray source studies. The importance of the COS B catalogue is that it establishes a sizeable number of gamma-ray sources with astrophysically unique properties.

---

convective systems, particularly those associated with magmatic fluids within cracks, are likely to be characterized by a Soret type of isotopic fractionation (as used to produce enriched uranium) that could drastically modify the ratios of even relatively stable, immobile isotopes. The lack of evidence for significant magma chambers beneath the Atlantic and Indian Ocean ridges certainly indicates that the fractionation of the mantle melt to form the oceanic crust probably operated predominantly within tensional cracks in the lithosphere, rather than in a clearly defined magma chamber. The magma chambers thought to have been identified along the East Pacific Rise could, in fact, be areas of the mantle with intensive fractures filled with magmatic fluid, rather than the conventional concept of a large volume of magmatic liquid. Even if magma chambers do exist in such situations, Rice's model could mean that there is much more isotopic fractionation of mantle materials than has generally been recognized. Thus mantle homogeneities postulated on the basis of variation in elements and their isotopes from mid-oceanic ridges to off-centred volcanoes could merely indicate slight differences in the Soret fractionation system in the different areas. Much of the evidence for or against mantle sources for many magmas could similarly be at least gross oversimplifications.

The implications of Rice's model are far-reaching. His paper highlights our ignorance of the fractionation processes in magma chambers, and demonstrates the inadequacy of widely accepted, but incorrect mechanisms for fractionation. It could also mean that we are only just beginning to understand the ways in which igneous rocks are formed and that all previous geochemical interpretations must be re-evaluated. □

What are mast cells for?

from T. M. Dexter, R. W. Stoddart and S. T. A. Quazzaz

FROM the time that Paul Ehrlich first described the presence of water-soluble, metachromatically staining granules in certain cells after treatment with Toluidine blue[1] to the present day when Astra blue is used to distinguish the same granules[2], staining properties have been the basis for distinguishing tissue mast cells and basophils from other cell types. Indeed for many years these cells were known only as morphological entities whose numbers were increased in certain pathological conditions. Mast cells are present in all mammals so far studied and have a diffuse distribution, being detected in the gut mucosa, peritoneal cavity, subcutaneous tissue lymph nodes and the thymic capsule. Although the precise relationship between circulating basophils and tissue mast cells is unclear, one may be derived from the other.

The origin of these cells has long been a matter of speculation. Burnett suggested[3] that at least some mast cells represent post-mitotic derivatives of T lymphocytes, citing evidence such as the response of mast cells to T-cell mitogens, mast cell reactions during the response to parasitic infections, and the ease with which mast cells can be generated from cultures of lymphoid tissue. As early as 1963, Ginsburg and Sachs[4] showed that mast cells were regularly produced when thymus cells were cultured on fibroblast feeder layers and others[5,6] suggested that mast cells in the gut mucosa are derived from T cells. However, these suggestions are not compatible with the finding that normal numbers of mast cells are present in the subcutaneous tissue of athymic (*nu/nu*) mice which are devoid of T cells[7].

T. M. Dexter is in the Department of Experimental Haematology, Christie Hospital and Holt Radium Institute, Manchester, and R. W. Stoddart and S. T. A. Quazzaz are in the Department of Experimental Pathology, University of Manchester, UK.

Kitamura and co-workers[8] have used the elegant system provided by the bg^J/bg^J mice, where the peripheral blood leukocytes have highly characteristic giant granules (Chediak–Higashi syndrome). Using the granules as cell markers in marrow transplant chimaeras, they showed that mast cells were derived from marrow precursors, and that mice with a genetically determined macrocytic anaemia (W/W^V mice), associated with a defect in the pluripotential haematopoietic stem cell, also lack tissue mast cells[9]. W/W^V mice are useful in that they will accept marrow grafts–which will cure the anaemia–without the need for prior irradiation to ablate the endogenous haematopoietic system. The availability of these two mouse strains with genetic markers has now paved the way for a direct analysis of mast cell development.

In the experiments reported in this issue of *Nature* (p.159), Kitamura *et al.* have exploited the ability of murine haematopoietic stem cells to undergo clonal proliferation and differentiation and form colonies in the spleens of potentially lethally irradiated mice. A mixture of bg^J/bg^J and wild-type stem cells was injected into wild-type mice. The origin of the resulting spleen colonies was determined using the bg^J/bg^J giant granules as a cell marker, and cells from isolated, individual spleen colonies (containing a 'clonally' pure cell population of either bg^J/bg^J or wild-type cells) were injected into W/W^V mice. Several months later, the blood haemoglobin type was used to determine whether the W/W^V recipients had been reconstituted with cells derived from individual spleen colonies. The animals were then killed and the tissue mast cells and granulocytes examined. In many animals, mast cells which were wholly bg^J/bg^J or wild type appeared in the tissue — and in one mouse the mast cells, erythroid cells and some granulocytes were shown to be bg^J/bg^J derived. These data show fairly conclusively that mast cells and myeloid cells have a common origin in the pluripotent haematopoietic stem cells, but note that the long time interval (15 weeks) between reconstitution of the W/W^V mice and analysis of the mast cells leaves open the possibility that thymus processing is an obligatory step for mast cell development.

This possibility has now been excluded, however, by the recent work of Schrader *et al.*[10]. These authors describe a persisting (P) cell (a name which one can only hope will be replaced before it becomes established!) generated in agar cultures of myeloid progenitor cells and which can be grown in liquid cultures for long periods, provided that the cells are supplied with an appropriate stimulating factor (in this case a conditioned medium derived from concanavalin A-stimulated T cells). In the absence of this factor, the cells die. Such cells contain granules which stain with Astra blue, possess histamine and appear to be equivalent to mast cells. They lack lymphoid markers and can be grown from marrow culture of *nu/nu* mice, from

100 years ago

We take the following from the *Colonies and India:* "To say that a train had been stopped by caterpillars would sound like a Yankee yarn, yet such a thing (according to the *Rangitikei Advocate*) actually took place on the local railway a few days ago. In the neighbourhood of Turakina, New Zealand, an army of caterpillars, hundreds of thousands strong, was marching across the line, bound for a new field of oats, when the train came along. Thousands of creeping vermin were crushed by the wheels of the engine, and suddenly the train came to a dead stop. On examination it was found that the wheels of the engine had become so greasy that they kept on revolving without advancing — they could not grip the rails. The guard and the engine-driver procured sand and strewed it on the rails, and the train made a fresh start, but it was found that during the stoppage caterpillars in thousands had crawled all over the engine, and over all the carriages inside and out."

Messrs. Seimens and Halske gave a public trial last week of their new electric railway, which runs between Lichterfelde and the Cadettenhaus, about six miles from Berlin. The trial is stated to have been most successful. It was in a simple tramcar, with an electric battery totally concealed between the wheels, in connection, through the rails it ran on, with the principal battery at the station. The rails are three feet three inches apart, and exactly resemble those of an ordinary railroad, only the gauge behind narrower. The greatest speed obtained on a distance of about one and a half miles was eighteen English miles an hour. Dr Siemens has proved that if necessary a far greater speed could be obtained, but this is not allowed by the German police authorities. It will not be allowed to proceed at more than nine miles per hour. The railway was opened to the public on Monday.

In connection with the subject of "Fascination," Dr. Otto of Schemnitz, Hungary, writes us of a case which came under his notice. In 1859, when the use of firearms was under stringent regulations in Hungary, peasants often killed hares on the Danubian island Creppel in the following way:— Two peasants would drive in a cart over the reaped fields. On spying a hare (say at two to three hundred paces) they proceeded to drive round it some five or six times in succession. One peasant carrying a long stick at length sprang out, at the moment the cart was behind the hare (the cart continuing its course), and coming up to the animal slowly, killed it without difficulty. It was not uncommon to kill thus as many as six or seven hares in one morning.

precursor cells which can also produce granulocytes. These cultured mast cells should allow analysis of the variety of responses in which mast cells are thought to be involved. However, tissue mast cells appear to be functionally heterogeneous and the 'P' cells may represent a developmentally restricted sub-population.

What is the function of mast cells? For many years they have been implicated in hypersensitivity reactions[11] and many parasites, such as schistosomes, are known to stimulate mast cell accumulation. After such infections there is a rapid and dramatic increase in the number of mast cells in the lymph nodes (mainly in the cortical and capsular regions) followed eventually by a decline. The initial accumulation is thought to represent migration of mast cells to the lymph nodes; and the 'disappearance' is believed to be due to degranulation rather than exit via the lymph node hilus[12]. Whether the degranulated cells leave the node in some unrecognized form and recirculate is not known. Normally, mast cells are rather more abundant in the medulla and the deeper paracortex than in the peripheral parts of the node; they are strikingly absent from germinal centres. In some pathological conditions a distribution similar to that seen in parasitic infections is found, again suggesting centripetal migration. What the mast cells are doing in the lymphoid organs is open to speculation.

Most cells contain significant amounts of histamine and many cells, including lymphocytes, have histamine receptors[13]. Histamine inhibits lymphocyte-mediated cytolysis by T cells[14], possibly indicating a role for mast cells in modulating T-cell function. In this context it is significant that T cell- deficient *nu/nu* mice, which have normal or increased numbers of mast cells in subcutaneous tissue, nonetheless show a complete failure of intestinal mast cell response to parasitic infections[15]. However, adequate function can be restored with a thymus graft, perhaps indicating that a T-cell helper function is required. Obviously Schrader's 'P' cells may help to unravel this sort of cooperative response.

Mast cells contain within their granules amines, such as serotonin, and can release large amounts of prostaglandins and leukotrienes. They also specifically produce heparin, a highly sulphated glycosaminoglycan. Heparin has been implicated in the sequestration of lipids by tissue cells and stimulates the migration of capillary endothelial cells[16]. The tissue distribution of mast cells suggests that they may play an important part in the production of heparin and local angiogenesis. Since the successful growth of a tumour depends on its blood supply, this is likely to be of profound importance in the determination of patterns of tumour growth. For example, the growth of spherical tumour masses with necrotic centres might be related to a high density of mast cells immediately around, but not within, the tumour mass.

It is apparent that the careful investigation of the occurrence of mast cells in a variety of pathological conditions is likely to reveal new facets in their role in chronic inflammation, response to injury and the initiation of repair. It is already clear that they are much more than pharmacological time bombs or land-mines simply to be tripped by wandering molecules like IgE. ☐

Leishmaniasis and mouse genetics

from F. E. G. Cox

THE paradox that in some forms of leishmaniasis there is a massive antibody response but not protection, while in others there is no antibody response but excellent protection, is gradually being explained by the use of genetically defined strains of mice.

Leishmaniasis is one of the six diseases selected by the WHO for its Special Programme for Research and Training in Tropical Diseases and is the general name given to infection with any one of some five species or 14 subspecies of the protozoan genus *Leishmania*. Leishmaniasis is transmitted by sandflies and the parasites injected into the human host multiply by repeated binary fission within macrophages in various parts of the body. The manifestations of the disease range from simple, slowly healing cutaneous lesions to fatal disseminated infections involving the viscera. In the Old World the cutaneous form is caused by *Leishmania tropica* and the disseminated visceral form by *Leishmania donovani*. In the New World *L. tropica* is replaced by a number of species that affect not only the skin but also underlying tissues.

At present there are no fully effective drugs or methods of vector control for the prevention of leishmaniasis and no vaccine at all. Fortunately, the parasites can infect mice, so recent studies using these animals have provided a wealth of information that may eventually be useful in the control of leishmaniasis.

Resistance to *L. donovani* and *L. tropica* is genetically controlled — some strains of mice are very resistant to infection while others are susceptible[1-3]. In *L. donovani* infections resistance is controlled by a single autosomal gene on chromosome 1, designated *Lsh*. Differences between resistant (dominant) and susceptible (recessive) mice appear before day 50[4]. Among the susceptible mice some exhibit prolonged infections while others experience a dramatic fall in parasite load. This response is controlled by a gene or genes within or close to the H–2 region of chromosome 17 which allows some innately susceptible mice to recover[5].

L. tropica infections, similarly, are under genetic control with some mice, such as the C57BL, being resistant and others, in particular BALB/c mice which experience fatal disseminated infections, being susceptible[6]. Resistance to *L. tropica* is controlled by a single autosomal gene which is neither the *Lsh* gene involved in *L. donovani* infections nor the H–2 complex, although H–2 genes may be involved late in the infection[6]. Immunity to *L. tropica* involves an antibody-mediated immune response of the delayed hypersensitivity type (DTH) in which the main cells concerned are T lymphocytes (T_D). In susceptible BALB/c mice the lack of immunity is due not to a failure to elicit a DTH reaction but to the induction of suppressor T lymphocytes (T_S), cells which impair the DTH reaction[7]. Early in the infection, DTH is detectable but later it is suppressed. The pattern of events has been elegantly investigated by Howard, Hale and Liew[8]. They subjected BALB/c mice to sublethal irradiation at levels known to delete the precursors of T_S cells and found that the infection, instead of progressing to a fatal conclusion, began to resolve at the same time as those in genetically resistant mice.

Immunity to *L. tropica*, therefore, depends on a DTH reaction which in certain mice can be suppressed by T_S cells. What role, if any, does the humoral immune response play? In the experiments using irradiated mice[8], irradiation at levels that ablate antibody production but not T_S cells had little effect on *L. tropica* infections. Antibody levels in both

irradiated-healing and non-healing mice were similar. A more direct approach to the role of antibody has involved the use of Biozzi high- and low-responder mice. In Biozzi high responders (Ab/H) antibody levels are high and macrophage activity low while in low responders (Ab/L) the reverse is the case[9]. In Ab/H mice infected with *L. tropica,* large, progressive, ulcerating lesions are produced in the presence of high specific antibody titres while in Ab/L mice the lesions are small and healing and antibody levels are minimal[10]. These results confirm unequivocally the widely held belief that in *L. tropica* infections the main protective mechanism is a DTH response and that antibody plays little or no part in recovery. The actual outcome of the infection depends on the interplay of T_p and T_S cells and in due course this information should give us some insight into why some human patients easily overcome the infection and experience only an insignificant lesion while others suffer from spreading and sometimes fatal infections. These findings are relevant not only to *L. tropica* but also to other species. There are indications that similar mechanisms may be involved in infections with the New World species, *Leishmania mexicana*[11], and it may be that the failure to overcome *L. donovani* infections also involves a defect in the DTH mechanism. □

Interstellar grains: models and measurements

from David A. Williams

INTERSTELLAR GRAINS are small solid particles mixed with the interstellar gas which reveal their presence to astronomers in various ways: by causing extinction and polarisation of starlight, or by emitting in the infrared (IR). Extinction is caused by absorption, which heats the grains, or by scattering, which gives rise to an observable, diffuse radiation. Grains also have chemical effects on the interstellar gas, being responsible for conversion of atomic to molecular hydrogen by surface catalysis, and for heavy element depletion. Although grains have been discussed for more than forty years, a recent conference* showed that the questions astrophysicists ask about them have not greatly changed: what are they made of, how are they formed and destroyed, and what is their interaction with gas and radiation?

Astrophysicists have traditionally relied on the curve showing variation of interstellar extinction with wavelength as a pointer to grain identification. In reviewing visual and UV observations Wolstencroft (Royal Observatory, Edinburgh) emphasised the remarkable constancy of the extinction curve in different regions of the Galaxy, especially in visual wavelengths. Some variation does occur in the UV suggesting that (at least) the grain size distribution may vary. Whittet (Preston Polytechnic) showed from a study of the ϱ Oph cloud that, contrary to previous reports, such variations are not accompanied by significant changes in the gas to dust ratio. Measurements of the diffuse (scattered) light in the visual and UV place conflicting constraints on grain properties. Duley (York University, Toronto) and Williams (UMIST) offered a solution in terms of an additional UV component arising from H_2 fluorescence that is not normally allowed for.

Participants were excited to hear from Scarrott (University of Durham) of several peculiar emission features longwards of 5,700Å from the mysterious Red Rectangle. The origin of these features caused much speculation and Greenberg (Rijksuniversiteit te Leiden) suggested an answer based on the laboratory simulation of grain mantles. Ices of simple gases (such as water, methane and ammonia) in approximately cosmic proportions are irradiated by UV and dramatic changes in the material are observed. Flashes of light may be emitted as warm-up occurs and the residue has optical features which Greenberg proposes are the diffuse bands.

Unidentified spectral features associated with grains also abound in the IR. Whittet reviewed recent observations of emission features from HII regions, planetary nebulae, galactic nuclei, and the absorption features in the cool interstellar gas. Most participants were convinced that the prominent 9.7 μm feature (seen in emission at high temperature and in absorption) is to be attributed to the SiO bond in refractory material such as amorphous silicates or oxides. The 3.1 μm feature, seen only in absorption in dark clouds, was generally attributed to molecular mantles accreted by cold grains.

A number of other IR absorption and emission features in the range 3–12 μm are known and two alternative interpretations were given. Allamandola (Rijksuniversiteit te Leiden) presented results of laboratory measurements of absorption features from ices such as H_2O, CO and CH_3OH, and identified them with observed absorption features at 3.4, 3.5, 6.0 and 6.8 μm. Duley and Williams suggested that radicals bound at reactive sites on amorphous carbon grains produce these and other absorption features, and also emission features from warm grains. The precise spectral properties of such grains will change according to their environment. Clearly, the flood of IR observations is providing a set of tight constraints on grain composition.

These and other constraints were discussed by Greenberg, who suggested that all observations so far were consistent with models of amorphous silicates or oxides, carbons, dirty ice mantles and photoprocessed material. The interaction of gas and grains can be studied in detail when the grain material is specified, for then the vast surface chemical literature can be tapped. Duley showed how effectively this can be done. He described a consistent model, including depletion, chemical reactions and optical properties, with the attractive feature that the chemical and optical nature of grains change as grains move from one environment to another. Apparent changes in grain properties may merely reflect their physical state.

The formation of grains is indicated astronomically in a number of sources: late-type giants and supergiants, other special stars, planetary nebulae, novae and supernovae. Some problems remain in understanding nucleation processes. Mechanisms of destruction (sputtering, evaporation and shattering in collision) seem able to account for the life times of grains. Evans (University of Keele) reviewed observations of a nova exhibiting grain formation. There are some difficulties in explaining why the grain temperatures increased after the nova had already started to decline in brightness. There are also some quite puzzling observations of ejection in WR stars in which optical and IR intensities decline with time but the measurement at 3.4 μm remains high.

The Durham group, in work described by Smith, demonstrated that sophisticated modelling of optical polarisation in reflection nebulae is particularly rewarding in understanding the nebulae and the grains. Robinson (Queen Mary College, London) convinced the workshop that in such modelling, especially of IR sources, workers must account correctly for radiative transfer or quite spurious interpretation concerning grains and source properties may result.

The meeting ended in a mood of some optimism. Although much controversy remained it was felt that new observations, particularly in the IR and UV, allied to sophisticated modelling, will enable significant progress to be made in the next few years. □

David A. Williams is in the Department of Mathematics, University of Manchester Institute of Science and Technology.

Episodic granite plutonism in the Scottish Caledonides

Otto van Breemen

Scottish Universities Research and Reactor Centre, East Kilbride, Glasgow G75 0QU, UK

Brian J. Bluck

Department of Geology, The University, Glasgow G12 8QQ, UK

Boulders from a Lower Devonian conglomerate complete the record of a phase of Ordovician plutonism associated with island arcs and blue schist metamorphism, indicating high angle subduction. Following a phase of sedimentary accretion, late Silurian plutonism was the result of low angle subduction. The two granite suites have distinct isotopic trends.

BOULDERS of two-mica granite which occur as clasts in the Lower Old Red Sandstone conglomerates along the Highland Boundary Fault (Fig. 1) have yielded Rb–Sr muscovite ages of ~460 M yr confirming the existence of a widespread suite of subduction-related Ordovician granites south of the Great Glen Fault. A voluminous suite of late Silurian to early Devonian granites can be related to the subduction of comparatively younger, thinner, hotter and more buoyant oceanic crust. The intervening hiatus in plutonism coincides with the peak of subduction accretion in the Southern Uplands, further demonstrating the necessity of subducting wet sediments to generate granitic magmas. For the Ordovician suite, the sedimentary record completes an isotopic trend of increasing $^{87}Sr/^{86}Sr$ ratios away from the trench which can be related to the increasing involvement of upper crust. The later granites show a trend towards more unradiogenic lead away from the trench which can be attributed to the increasing involvement of lower crust.

The Lower Old Red Sandstone rocks of the Midland Valley of Scotland comprise a thick sequence of late orogenic alluvium and intercalated volcanic rocks[1]. The sequence at Stonehaven (Fig. 1*a*), possibly exceeding 8 km in thickness, contains abundant conglomerates which are dominated by igneous clasts[2] (Fig. 1*b*). Andesitic and basaltic clasts are particularly abundant and often less well rounded than accompanying granite clasts of similar size. Granite which locally makes up ~25% of the clasts, ranges from microgranite to pegmatites and is invariably primary muscovite bearing. These clasts have generally been considered to have been derived from the late Silurian–early

Devonian granites to the north[3,4]. However, the muscovite-bearing granite clasts become less abundant upwards in the succession.

Isotope analyses

Rb–Sr isotope dilution analyses (Table 1) follow analytical methods described elsewhere[5]. Rb–Sr muscovite ages for the four muscovite biotite granites RC 1916, 17, 19, 20 are concordant at 459 ± 5 Myr. The Rb–Sr muscovite age for pegmatitic sample RC 1913 may be slightly older at 465 ± 5 Myr. Rb–Sr biotite ages scatter down to 421 ± 5 Myr. The biotite age for sample RC 1917 is, however, concordant with the muscovite ages.

The Rb–Sr muscovite ages are here interpreted in terms of the time of emplacement of these underformed granites and pegmatite for two reasons. First, in the central Highlands and within the axial region of the Caledonian orogen, Rb–Sr muscovite systems have survived all phases of Caledonian deformation and associated amphibolite facies metamorphism[6]. Second, the concordance of the biotite and muscovite ages for sample RC 1917 indicates that regional temperatures in at least some of the host rocks could not have greatly exceeded 300°C, the estimated blocking temperature for the Rb–Sr isotopic system in biotite[7]. The younger, scattered biotite ages are believed to have been caused by alteration to chlorite during deposition in lower Devonian time.

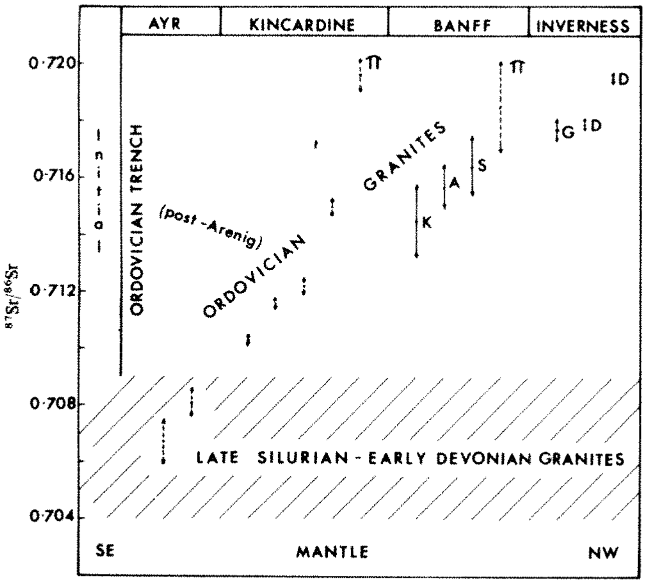

Fig. 2 Cumulative frequency plots of initial ^{87}Sr/^{86}Sr ratios for post-Arenig Ordovician granites in Scotland. From left to right regions have been arranged from the Ordovician trench into the interior of the continent. Dashed lines indicate uncertainties on individual whole rocks: clasts, granodiorite dykes (D) or pegmatities (π). Solid lines indicate uncertainties on whole rock isochrons. See Fig. 1.

The wide range in initial ^{87}Sr/^{86}Sr ratios obtained is interpreted in terms of increasing upper crustal involvement. The chemistry of the rocks bears little systematic relation to the initial ^{87}Sr/^{86}Sr ratios which suggests that the magmas sampled by the boulders did not involve simple mixing between two end members. Concentrations of SiO_2 range from 71 to 74 wt%, Na_2O from 3.1 to 3.9 wt%, K_2O from 3.5 to 4.8 wt% and normative corundum from 0.1 to 2.6 wt%. The wide range in ^{87}Sr/^{86}Sr ratios combined with the lack of evidence for a mixing pattern suggests that the boulders came from more than one intrusion. Thus the tight grouping of Rb–Sr muscovite ages at ~460 Myr supports the evidence from the Stonehaven clast profile (Fig. 1) that these late Ordovician granites represent a distinct pulse of magmatism.

Granite clasts

The provenance of the ~460 Myr granite clasts is not known. The conglomerates in which they occur thicken onto the north-west limb of the Strathmore Syncline suggesting a source to the north-west, a view supported by the presence of Highland-type rocks in the conglomerates. In terms of durability during transportation, schists and volcanic rocks would probably break down quite quickly, granite less quickly and quartzite least of all[8]. On this basis it is estimated that granite formed some 10–15% of the exposed ground in the source at about the time the Dunnottar Group (near Dunnottar Castle) was laid down. The present areas to the north of Strathmore (in southern Aberdeenshire) contain some 43% granite bedrock by area (taking a strip of country 20 km to north-west of the Highland Boundary Fault for 60 km south-west from Stonehaven). These Silurian–Devonian granites have not been found in the Devonian conglomerates. The nearest rocks of ~460 Myr age are found some 60 km to the north in Banff[9]. In view of the size of the granite boulders (up to 80 cm) transport over this distance is unlikely, and a more proximal source either in the Midland Valley or in the southern Highlands is envisaged. Given no substantial lateral movement on the Highland Boundary Fault and accepting the stratigraphical evidence, we suggest that these early plutons were emplaced high into the Dalradian cover to the north, among rocks which were largely in greenschist facies metamorphism. These greenschist rocks provided some of the

associated clast materials in the conglomerates. As with other plutonic bodies and as suggested by the clast profile, convergence of the margins downwards would result in a balloon shaped plutonic mass[10], which might almost disappear as the land surface was eroded down.

Granite clasts dated[11] at ~470 Myr and associated with an influx of andesitic fragments[12], both derived from the southern Midland Valley, have been related to the late Ordovician two-mica granites in the Dalradian of Banff and Aberdeenshire. In the latter region ages range from 475±5 Myr for the Stichen Granite (U–Pb on monazite[13]) to 453±4 Myr and 444±9 Myr for the Kennethmont and Aberchirder granites (Rb–Sr whole rock isochrons[9]). A regional suite of tourmaline-bearing pegmatites have been dated at 463±6 Myr (Rb–Sr muscovite isochrons[14,15]). All these intrusions are post-tectonic. Further north-west, in the Moine schists below the Dalradian metasediments, late tectonic pegmatites and a small two-mica granite (the Glen Kyllachy Complex) have been dated at 445±5 Myr and ~443 Myr (Rb–Sr muscovite and whole rock isochron ages[5]). If the Rb–Sr isotope data are taken alone, there seems to be a ~30 Myr, decreasing age trend from the south-east to the north-west away from the trench. The Stichen Granite in north-east Aberdeenshire with a reliable U–Pb monazite age of 475±5 Myr seems to be older. Even so, the age of this pluton falls within the ~35 Myr range of late Ordovician granite emplacement.

Discussion

As the Ordovician granites extend south-east of the Highland Boundary Fault where there is no evidence for the Grampian orogenic event, this suite has been interpreted in terms of being related to subduction[11]. Yet high initial $^{87}Sr/^{86}Sr$ ratios and various geochemical features have been presented as evidence that the two-mica granites of north-east Aberdeenshire and the Glen Kyllachy complex have been derived from metasediments[5,9,16]. The new data from the denuded granites along the Highland Boundary Fault provide evidence for a common origin of all the middle to late Ordovician granites and andesites and a link between subduction and high level melting.

The ~460 Myr granites are clearly younger than those migmatites north of the Highland Boundary Fault which are of ~510 Myr Grampian age[17] or older[18]. In view of their proximity to the Highland Boundary Fault it would be difficult to envision their generation through burial metamorphism of Grampian age[19]. Also these granites slightly predate the Caradocian marginal basin closure along the Highland Boundary Fault (Fig. 3, see ref. 20). Their generation and rise past the present erosion level almost certainly required a subcrustal heat source.

Burnham[21] has shown that mantle-derived basic magma can produce extensive partial melting and assimilation of hydrous rocks of felsic composition. Such a process is analogous to the mechanism of magma ascent and country assimilation as developed by Bowen[22,23]. Thus the rise of a magma continues while a net balance of heat is maintained from that lost by melting and or assimilation of country rocks and gained by the latent heat of crystallization of a more basic residuum. The assimilation crystal fractionation process is not unique to the original magma and as the magma bores its way upwards, the major element chemistry will approach that of a partial melt of the country rocks.

Initial Sr isotopic ratios for all the late Ordovician granites are plotted in Fig. 2. Ratios from each area are presented as cumulative frequency plots for increasing values and the north-west is represented by the right-hand side of the diagram. The granites show a systematic increase in $^{87}Sr/^{86}Sr$ ratios as one passes from the Ordovician trench to the interior of the continent. The age and initial ratio pattern of the late Ordovician granites thus seems to be systematic. Although the effects of ultrametamorphism may have been significant, it is reasonable to conclude that the process which relates all these granites, on both sides of a marginal basin, is subduction. The north-westwards increasing $^{87}Sr/^{86}Sr$ ratios could then be attributed to the increasing thickness of older continental crust above the Benioff zone[24].

Clearly the high temperatures of metamorphic rocks in a post-tectonic setting when geotherms are raised in the early stages of uplift[25] should by the above heat balance mechanism allow the magmas to rise high into the upper crust as well as increase the proportion of melt derived from the upper crust. Also, in view of the westward orogenic diachronism across the Grampian region[5] magmatism may have persisted later in the north-west. In the latter region earlier magmatism may be represented by late tectonic 'discordant migmatite'[26]. Also the apparent westward migration of plutonism is probably partly the result of the time constant of subduction.

Variations in the nature and extent of plutonic and volcanic activity have been related to differences in characteristics of the ocean plate being consumed at the trench[27–29]. In Recent to Jurassic examples, where adjacent ocean lineation patterns allow reconstructions of this type, the relationship between characteristics of ocean plate and plutonic activity is still equivocal[30]. In the Caledonian cycle, changes in the characteristics of the Iapetus plate can only be inferred from the stratigraphical record in southern Scotland. Criteria for the recognition of these changes are given in Fig. 3. Vlaar and Wortel[31] and Molnar and Atwater[32] have shown that a relationship exists between angle of subduction and age of plate–older plates are thicker, colder and denser and therefore dip more steeply than the younger. These authors also suggest that island arcs and accompanied marginal basins are produced by the steeply dipping subduction zones.

The geological record in southern Scotland suggests the presence of volcanic arcs and marginal basins in Arenig to Llandeilo times[33] together with possibly older blue schist, from which it might be inferred that the Iapetus plate was cold and steeply dipping. It was during this interval that the early granites (discussed here) were emplaced. These are high level, relatively low volume granites showing much upper crustal involvement. At this same time, despite evidence for rapid uplift in the Midland Valley source[11], the volume of trench accretion does not seem to have been substantial[34]. Some of this sediment may have been consumed in the subduction zone.

In the interval Caradoc–Ashgill, the beginning of sedimentary accretion coincides with decreasing granite magmatism moving away from the trench. The following Llandovery and Wenlock stages are typified by a major accretionary prism and during this

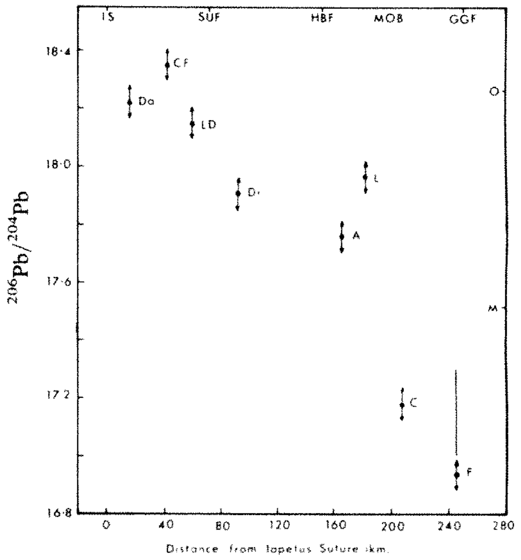

Fig. 4 Plot of age corrected $^{206}Pb/^{204}Pb$ ratios for feldspar separates from Silurian–Devonian granites of Scotland[45] versus distance from the Iapetus Suture. See Fig. 1. Doe and Zartman's[47] mantle and 'orogene' values of $^{206}Pb/^{204}Pb$ 400 Myr ago are represented by M and O. These authors estimate Upper and Lower crustal values at 18.71 and 16.67 respectively. Lewisian rocks yield values in the range 13.41–16.91 (ref. 48).

time, no granite intrusions have been recorded south of the Great Glen Fault. Abundant calc-alkaline plutonism at this time north of the Great Glen Fault can be explained in terms of separate subduction histories before the opposing Highland regions were juxtaposed by sinistral movements along this transcurrent fault[5,35].

The next period of major plutonism south of the Great Glen Fault took place between ~415 and 390 Myr. (Fig. 1)[13,36–39]. There is no record of any sediment accretions at this time in the south of Scotland. Although there may be many reasons for this absence of sediments north of the Iapetus suture, it is possible that they were taken down the subduction zone as in the former period of major plutonic activity. Indeed, the patterns of granite plutonism and sedimentary accretion observed in California[40], Alaska[41] and Scotland support continuous crustal recycling[42,43].

At this stage it is possible that together with the sediments on the ocean floor, part of the accretionary prism was also abraded into the subduction zone. A hypothesis of a mixed derivation of sedimentary and mantle material to make up the voluminous Silurian–Devonian granites is consistent with the Sr (ref. 37) and O isotope data[38,44]. However, common lead isotope data from feldspars show that lower crustal materials were also involved in the formation of these granites[45]. As lower crustal rocks generally have low $^{87}Sr/^{86}Sr$ ratios, the absence of a geographical trend in this parameter (Fig. 2) is not diagnostic. The common lead isotope evidence is supported, however, by more recent Sm–Nd isotope evidence[46].

With the separate history of the later granites on either side of the Great Glen Fault, the Pb isotope trend[45] for the granites to the south can be shown to be surprisingly consistent. On Fig. 4 the $^{206}Pb/^{204}Pb$ ratios of the later granites south-east of the Great Glen Fault have been plotted against distance from the Iapetus suture. More data would be desirable. However, note that four $^{206}Pb/^{204}Pb$ ratios from the Foyers complex (in the range 17.0–17.3) reported by Pankhurst[39] and showing the internal variability in a single pluton are consistent with the trend of northwestwardly decreasing ratios. The consistent downward trend of this ratio away from the Iapetus suture is best interpreted in terms of an increasingly unradiogenic (Pb) lower crustal input into the granites. In view of the relative Pb concentrations of upper and lower crustal rocks, only limited amounts of upper crustal rocks are likely to have been assimilated[47].

The trend of upper crustal (radiogenic Sr) involvement of the Ordovician granites seems to have been repeated with respect to the lower crust (unradiogenic Pb) in the case of the Silurian–Devonian granites. This feature can be partly explained by the large amount of Highland uplift, erosion and cooling which occurred in the intervening (Silurian) time. At the same time, the greater volume of the later granites, which may have swamped the upper crustal contribution, argues for high temperatures in the lower crust and the mantle[49]. The voluminous nature of these granites combined with the abundance of andesitic volcanism, often directly relatable to the plutons, suggests that in the final stages of closure of Iapetus the continent over-rode comparatively young, hot ocean floor at a low angle of subduction. This interpretation is also consistent with the absence of island arcs in the Silurian.

We thank J. Hutchinson for help with the analyses and A. N. Halliday who contributed to discussions on granite volume in relation to angle of subduction. The Isotope Geology Unit of the Scottish Universities Research and Reactor Centre is supported by the NERC.

Expression in *E. coli* of maize and wheat chloroplast genes for large subunit of ribulose bisphosphate carboxylase

Anthony A. Gatenby, Judith A. Castleton & Michael W. Saul
Plant Breeding Institute, Trumpington, Cambridge CB2 2LQ, UK

Synthesis of the large subunit polypeptide of ribulose bisphosphate carboxylase can be detected in Escherichia coli *cells containing the chloroplast genes from maize and wheat. The chloroplast DNA sequences contain a 'promoter' that, in* Escherichia coli, *initiates transcription and translation of the genes. This synthesis of large subunits has been substantially increased using the powerful λ promoter, P_L, to drive transcription of the maize gene.*

0028–0836/81/200117—05$01.00

ALTHOUGH much effort has recently been devoted to constructing plasmids in which the expression of mammalian genes can be directed from prokaryotic promoters[1–7], there have been no reports of the expression of plant genes in *Escherichia coli*. Chloroplast genes from higher plants would seem to be particularly favourable candidates for expression in bacteria because of the similarities already established between chloroplasts and prokaryotic organisms. Thus, in both there are 70S ribosomes containing 23S, 16S and 5S rRNA[8], there is strong sequence homology between maize chloroplast and *E. coli* 16S rRNA genes[9] and *N*-formylmethionyl-tRNA is used for the initiation of polypeptide chain synthesis[10]. Furthermore, chloroplast genes have been transcribed and translated successfully *in vitro* using *E. coli* cell-free extracts[11]. Accordingly, we have investigated chloroplast gene expression in bacteria using the maize and wheat genes for the large subunit polypeptide of ribulose bisphosphate carboxylase (RuBPCase).

Our choice of this gene was favoured by the extensive knowledge of both the structure and function of the gene and the enzyme. RuBPCase [3-phospho-D-glycerate carboxy-lyase (dimerizing), EC 4.1.1.39] holoenzyme is a major soluble protein in green plants and fixes CO_2 in the photosynthetic pentose phosphate pathway[12]. It is present in the stroma of chloroplasts as an oligomer with 16 subunits and a molecular weight (MW) of ~560,000 (ref. 13). Eight of these subunits are small (MW 12–18,000) and the remaining eight are large (MW 50–55,000). The large subunit contains the catalytic sites for the carboxylase and oxygenase reactions[12] but the function of the small subunit remains undetermined. The small subunits are nucleus encoded[14] and synthesized on cytoplasmic ribosomes as a precursor which passes through the chloroplast membrane and is processed to its final size[15,16]. It is assembled with large subunits that are encoded by chloroplast DNA[17] and synthesized on chloroplast ribosomes[18]. The DNA sequence of the maize large subunit gene[19] and a pea small subunit cDNA clone[20] have been established.

We describe here the synthesis of the large subunit polypeptide of RuBPCase in *E. coli*, apparently under the control of chloroplast sequences that function as promoters in this bacterium. The synthesis of the plant protein can also be manipulated using promoters from bacteriophage λ during lytic infection. The demonstration that chloroplast genes from higher plants are expressed in *E. coli* provides many new opportunities in plant and bacterial molecular biology.

Construction of λ and plasmid molecules containing RuBPCase large subunit gene sequences

The chloroplast chromosome of all characterized species contains a single copy of a gene for the large subunit of RuBPCase (RuBPCase LS), and the position of this gene has been mapped for maize[21] and wheat (C. M. Bowman, B. Koller, H. Delius and T. A. Dyer, personal communication). The gene from both species can be isolated intact on a fragment generated by digestion with the restriction endonuclease *Bam*HI; 4.3 kilobase pairs for maize and 9.7 for wheat. Both these fragments have been cloned directly into the *Bam*HI site of pBR322. The maize fragment has the additional advantage of being a suitable size for cloning into the *Bam*HI λ insertion vector NM570-BV2 (ref. 22). Our approach in the construction of λ and plasmid recombinants containing the RuBPCase LS sequences is detailed in Fig. 1 legend.

The orientation of the maize gene in λ was determined using the asymmetric location of *Eco*RI sites within the chloroplast DNA fragment[21] and the phage vector[22]. Clones were identified in which the RuBPCase LS gene is transcribed either from the *l*-strand of the phage chromosome using the promoter P_L(λ*Zm*B1^l), or from the *r*-strand using the promoter P'_R(λ*Zm*B1^r). The maize gene was transferred to the *Bam*HI site of pBR322 and the two possible orientations (p*Zm*B1A and p*Zm*B1B) distinguished by the asymmetric location of *Pst*I sites within the chloroplast DNA fragment[21] and the plasmid[23]. The plasmid p*Tac*39 contains the wheat RuBPCase large subunit gene on a fragment inserted into the *Bam*HI site of pBR322 and we derived the plasmid p*Tac*518 from p*Tac*39 by reversing the orientation of the chloroplast fragment (Fig. 1).

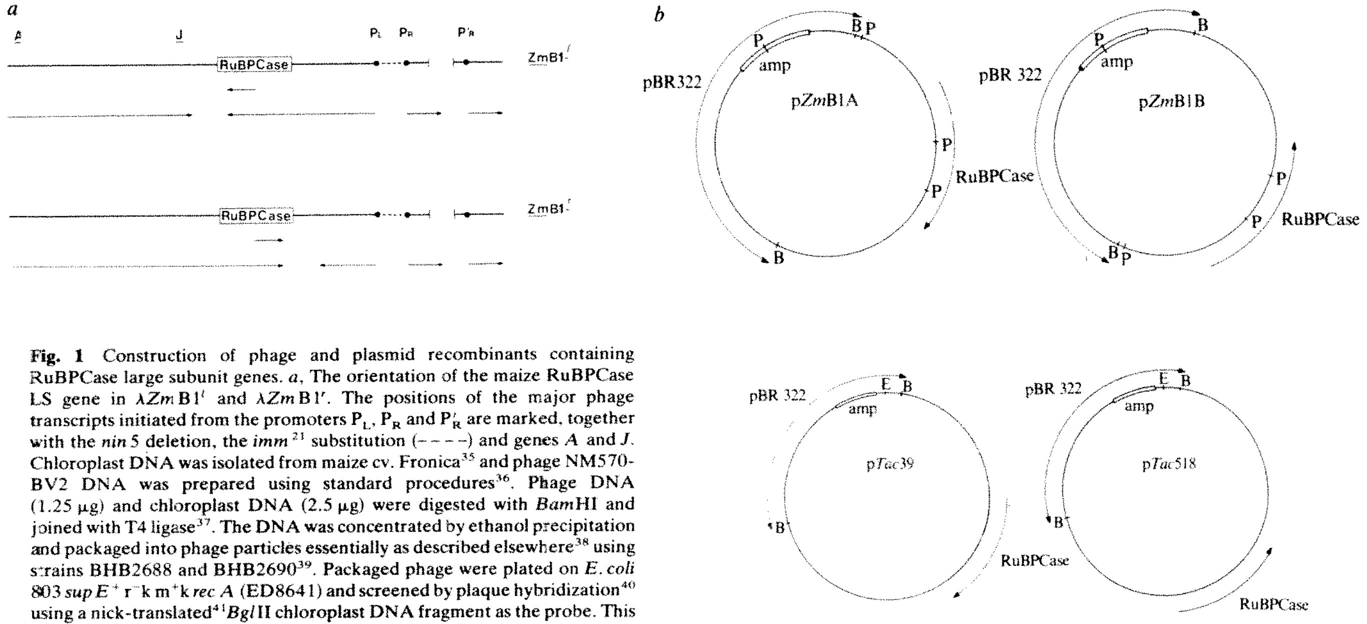

Fig. 1 Construction of phage and plasmid recombinants containing RuBPCase large subunit genes. *a*, The orientation of the maize RuBPCase LS gene in λ*Zm*B1^l and λ*Zm*B1^r. The positions of the major phage transcripts initiated from the promoters P_L, P_R and P'_R are marked, together with the *nin* 5 deletion, the *imm*[21] substitution (– – – –) and genes *A* and *J*. Chloroplast DNA was isolated from maize cv. Fronica[35] and phage NM570-BV2 DNA was prepared using standard procedures[36]. Phage DNA (1.25 μg) and chloroplast DNA (2.5 μg) were digested with *Bam*HI and joined with T4 ligase[37]. The DNA was concentrated by ethanol precipitation and packaged into phage particles essentially as described elsewhere[38] using strains BHB2688 and BHB2690[39]. Packaged phage were plated on *E. coli* 803 $supE^+\ r_k^-m_k^+\ recA$ (ED8641) and screened by plaque hybridization[40] using a nick-translated[41] *Bgl*II chloroplast DNA fragment as the probe. This fragment contains the complete RuBPCase LS gene sequence[21]. Positive clones were plaque purified and phage isolated from liquid lysates[36]. The orientation of the RuBPCase LS gene in the phage chromosome was deduced from the asymmetric distribution of *Eco*RI sites[21,22] and confirmed by transfer to nitrocellulose filters[42] and hybridization with the nick-translated *Bgl*II fragment. *b*, The orientation of the maize RuBPCase LS gene in plasmids p*Zm*B1A and p*Zm*B1B. The position of *Bam*HI (B) and *Pst*I (P) sites and the direction of transcription of the maize gene are indicated. λ*Zm*B1 DNA (2 μg) and pBR322 DNA (0.2 μg) were digested with *Bam*HI and joined with T4 ligase. The DNA was transformed into strain ED8641 and clones resistant to ampicillin and sensitive to tetracycline selected. Purified plasmids[43] with the RuBPCase LS gene in either of the two orientations were identified by the asymmetric distribution of *Pst*I sites[21,23] and confirmed by hybridization with the *Bgl*II fragment as described in *a*. *c*, The orientation of the wheat RuBPCase LS gene in plasmids p*Tac*39 and p*Tac*518. The position of *Bam*HI (B) sites and the direction of transcription of the wheat gene are indicated. The map of p*Tac*39 was produced from information provided by C. M. Bowman and T. A. Dyer. The wheat fragment was excised with *Bam*HI and re-joined with T4 ligase to obtain p*Tac*518 with the fragment in the opposite orientation.

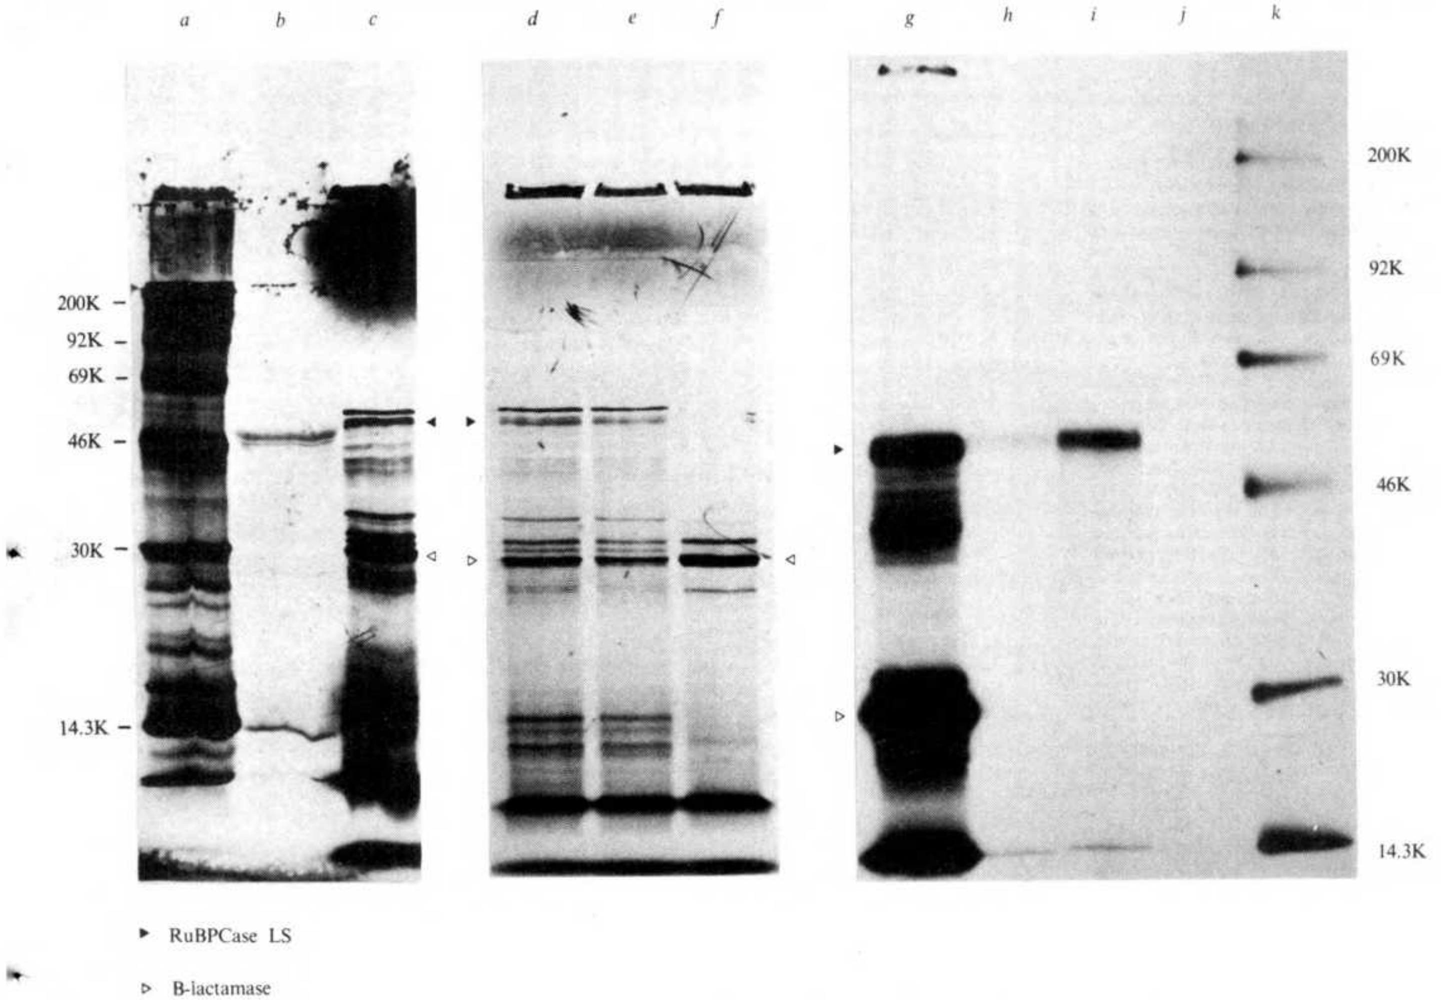

Fig. 2 Expression of RuBPCase LS in *E. coli* minicells. The plasmids pBR322, p*Tac* 39, p*Tac* 518, p*Zm* B1A and p*Zm* B1B were transformed into the minicell strain DS410[24]. Minicells were prepared from 200 ml of an overnight culture grown in brain heart infusion[24]. The minicells were preincubated for 30 min at 37 °C in minimal medium and then incubated for a further 60 min in the presence of 10–20 μCi L-[^{35}S] methionine (Amersham). Prewarmed L broth was added and after a further incubation for 15 min the minicells were collected by centrifugation and lysed by boiling in 100 μl of 2% (w/v) SDS for 2 min. The number of proteins synthesized was examined by SDS-polyacrylamide gel electrophoresis[44], followed by autoradiography of the dried gels. For immunoprecipitation the SDS minicell lysate was diluted with 1 ml of Triton buffer (50 mM Tris-HCl *p*H 7.8, 0.15 M NaCl, 2 mM EDTA, 1% (v/v) Triton X-100) and clarified at 20,000*g* for 10 min. To the supernatant was added 10 μl of either anti-RuBPCase serum or pre-immune serum. After incubation at 20 °C for 2 h the antigen–antibody complex was absorbed to protein A–Sepharose (equivalent to 5 mg dried Sepharose) by shaking gently for 1–2 h. The Sepharose was washed once with Triton buffer containing 1 M NaCl and three times with Triton buffer. The Sepharose pellet was resuspended in 20μl of SDS loading buffer and applied directly to a 10% polyacrylamide gel and electrophoresed in the presence of SDS[44]. The dried gels were examined by autoradiography or fluorography[29] at −80 °C. Wheat and maize RuBPCase were purified for immunization, and as standards, by chromatography on Sephadex G-75, Ultrogel AcA22 and DEAE-Sephadex A50[45] followed by sucrose gradient centrifugation[46]. Gels were calibrated with a ^{14}C-methylated protein mixture (Amersham, CFA.626). The molecular weight markers were lysozyme (14,300), carbonic anhydrase (30,000), ovalbumin (46,000), bovine serum albumin (69,000), phosphorylase *b* (92,000) and myosin (200,000). *a*, Molecular weight markers (long exposure); *b*, p*Tac* 39 incubated with anti-RuBPCase serum and protein A–Sepharose; *c*, total p*Tac* 39; *d*, total p*Tac* 39; *e*, total p*Tac* 518; *f*, total pBR322; *g*, total p*Zm* BlA; *h*, p*Zm* BlA incubated with a RuBPCase immunoabsorbent and eluted with 8 M urea[45]; *i*, p*Zm* BlA incubated with anti-RuBPCase serum and protein A–Sepharose; *j*, p*Zm* BlA incubated with pre-immune serum and protein A–Sepharose; *k*, molecular weight markers (short exposure).

In vivo expression of RuBPCase large subunit gene on plasmids

Plasmids with both orientations of the RuBPCase LS gene from maize (p*Zm* BlA and p*Zm* B1B) and wheat (p*Tac* 39 and p*Tac* 518) were transformed into the minicell-producing strain DS410[24]. Minicells containing each of the four plasmids and a pBR322 control were prepared and incubated in the presence of L-[^{35}S] methionine to label specifically proteins synthesized from the plasmids[24]. Autoradiography of extracts separated on SDS-polyacrylamide gels demonstrated that several additional polypeptides were synthesized when the recombinant plasmids were present in the minicells, compared with the pBR322 control (Fig. 2). One of these additional polypeptides had a MW of 52–53,000 and a similar mobility to the purified RuBPCase large subunit isolated from leaves (data not shown). The identity of this polypeptide was confirmed by incubating the *in vivo* labelled minicell extracts with anti-RuBPCase serum and recovering the antigen–antibody complex by absorption to protein A–Sepharose. Radioactive polypeptides eluted from the protein A–Sepharose were resolved by SDS-polyacrylamide gel electrophoresis mainly as a major band of MW 52–53,000, although traces of other polypeptides could be detected after prolonged fluorography (Fig. 2). The RuBPCase LS polypeptide was not recovered if pre-immune serum was incubated with the minicell extracts. The slight difference in mobility between the immunoabsorbed wheat polypeptide and the corresponding polypeptide in the total minicell extract (Fig. 2, tracks *b*, *c*) is probably due to distortion in the gel by an unlabelled polypeptide present in large amounts in this part of the gel, which we suspect to be the heavy chain of IgG that is absorbed to the protein A–Sepharose.

The number and relative amounts of polypeptides synthesized from the RuBPCase LS plasmids were independent of the orientation of the chloroplast fragments in pBR322. Tran-

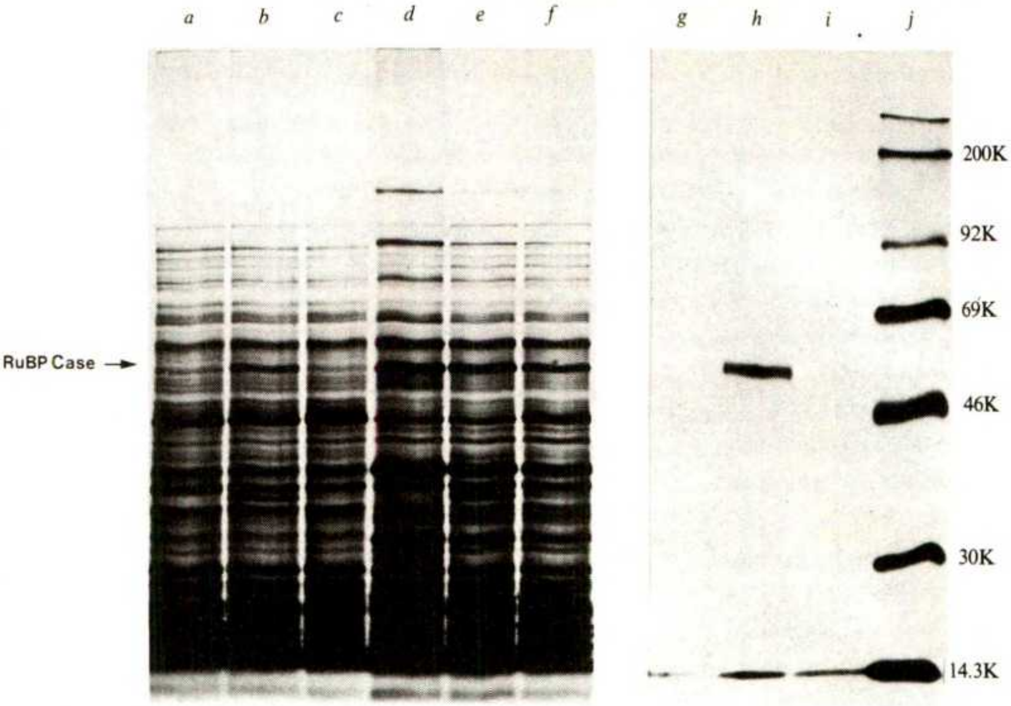

Fig. 3 Expression of maize RuBPCase LS during lytic infection with phage recombinants. *E. coli S*159 was grown in minimal medium with maltose and UV light-irradiated essentially as described by Jaskunas *et al.*[25]. 50 µl (5×10^7 bacteria) were mixed on ice with 5 µl (1×10^8 plaque-forming units) of phage suspension. For cells labelled early during infection the samples were incubated at 37 °C for 3 min and then diluted with 200 µl of prewarmed M9 salts, 1 mM $MgSO_4$, 0.3% (w/v) maltose, 0.04 µg methionine per ml, containing 10 µCi of L-[^{35}S]methionine. After 10 min the cells were chased with 30 µl of 2 mg ml^{-1} methionine for 1 min. For cells labelled late during infection the samples were incubated at 37 °C for 12 min, diluted with the isotope solutions as above and incubated for 10 min, and finally chased as before. Protein synthesis was terminated by the addition of 1 ml of cold acetone at −20 °C for 30 min. Precipitated proteins were collected by centrifugation and dried. Total protein synthesis was examined by dissolving the pellet in SDS loading buffer, resolving the polypeptides by electrophoresis on 10% polyacrylamide gels[44] and autoradiography of the dried gels. For immunoabsorption the precipitated protein was boiled for 2 min in 100 µl of 2% (w/v) SDS, cooled to room temperature and diluted with 1 ml of Triton buffer (Fig. 2). Conditions for incubating with antiserum and protein A–Sepharose were identical to those for Fig. 2. The immunoabsorbed protein was detected by fluorography[28] at −80 °C. Early labelling with: *a*, λNM 570–BV2; *b*, $\lambda Zm\text{B}1^{l}$; *c*, $\lambda Zm\text{B}1^{r}$. Late labelling with: *d*, λNM 570–BV2; *e*, $\lambda Zm\text{B}1^{l}$; *f*, $\lambda Zm\text{B}1^{r}$. Immunoabsorbed polypeptides after early infection with: *g*, λNM 570–BV2; *h*, $\lambda Zm\text{B}1^{l}$; *i*, $\lambda Zm\text{B}1^{r}$. The MW markers (*j*) were identical to those of Fig. 2.

scription and translation from sites within the chloroplast fragments seems the most likely explanation of this expression, in view of the absence of an orientation effect on the synthesis of maize and wheat RuBPCase LS. What is known of pBR322 transcription suggests that the level of expression of a gene using external promoters would be very different if inserted in opposite orientations in the *Bam*HI site.

To estimate the proportion of RuBPCase LS synthesized compared with β-lactamase, which is encoded on the same plasmid, we used scanning densitometry of the autoradiographs. After adjustment for the methionine content of RuBPCase LS and β-lactamase, the amount of RuBPCase LS synthesized is equivalent to approximately a 1 : 3 molar ratio.

Lytic expression of maize RuBPCase LS

To increase the synthesis of the large subunit of maize RuBPCase in *E. coli* we used P_L-initiated transcription to drive expression of the chloroplast gene. Phage-directed protein synthesis was examined by infecting UV light-irradiated *S*159 cells in the presence of L-[^{35}S]methionine[25] and resolving the products by polyacrylamide gel electrophoresis (Fig. 3). Incubation of lysates with anti-RuBPCase serum and immunoabsorption to protein A–Sepharose were used to verify the identity of the large subunit (Fig. 3).

Lytic expression of maize RuBPCase LS is strongly dependent on the orientation of the gene in the phage chromosome and on transcription from λ promoters. The kinetics of synthesis of the polypeptide (Fig. 4) demonstrate that when the chloroplast gene is transcribed from the *l*-strand of λ, RuBPCase LS accumulates rapidly in the first 10 min post-infection and accounts for 0.5–1.0% of total protein synthesis at this stage; RuBPCase LS synthesis then decreases. This pattern of expression is entirely consistent with the synthesis of RuBPCase LS as an early protein by P_L-initiated transcription, followed by repression of P_L by the phage *cro* gene product[26]. When the

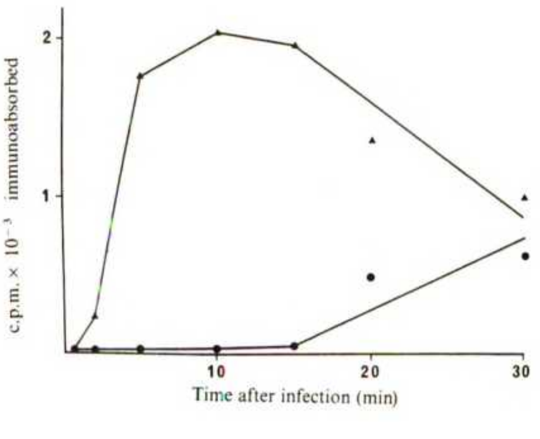

Fig. 4 Kinetics of expression of maize RuBPCase LS gene in *E. coli* cells infected with $\lambda \text{ZmB}1^{l}$(▲) or $\lambda Zm\text{B}1^{r}$(●). UV light-irradiated *S*159 cells were prepared[25]. 300 µl (3×10^8 bacteria) were mixed on ice with 30 µl (6×10^8 plaque-forming units) of phage suspension. After incubation at 37 °C for 3 min, 1.2 ml of prewarmed M9 salts, 1 mM $MgSO_4$, 0.3% (w/v) maltose, 0.05 µg L-methionine and 60 µCi L-[^{35}S]methionine were added. Duplicate 100-µl samples were withdrawn at the times indicated and added to 1 ml of cold acetone. After 30 min at −20 °C the proteins were collected by centrifugation, dried and boiled in 100 µl of 2% (w/v) SDS for 2 min. Triton buffer (1 ml) (Fig. 2) was added and after centrifuging at 20,000*g* for 10 min, an excess of anti-RuBPCase serum (20 µl) was added to the supernatant and incubated at 4 °C overnight. The antigen–antibody complex was absorbed to excess protein A–sepharaose (equivalent to 10 mg dried Sepharose) by shaking gently for 2 h at 20 °C. The Sepharose was washed three times with 1 – ml volumes of 1 M NaCl and once with 0.15 M NaCl, both in Triton buffer. The absorbed protein was eluted with four 250-µl aliquots of 50 mM Tris-HCl *p*H 8.0, 8 M urea, 0.2 M NaCl and 100 µg ml^{-1} bovine serum albumin. The four aliquots were combined and protein precipitated with an equal volume of cold 10% (w/v) trichloroacetic acid. The precipitates were collected on GF/C filters, washed three times with 5% (w/v) trichloroacetic acid, once with ethanol and dried. The filters were processed by liquid scintillation counting. The results were corrected for background by using *S*159 cells infected with the vector NM570-BV2 in the presence of L-[^{35}S]methionine and processed as above.

orientation of the chloroplast gene is reversed so that phage-initiated transcription is on the *r*-strand, the pattern of synthesis follows that expected of a late phage protein[27] and occurs after 15–20 min post-infection. The maize chloroplast fragment was cloned into the sites $sbam\lambda$-2 and $sbam\lambda$-3 (ref. 22), thus eliminating the phage *b* region and its transcription termination sites. This explains the observed transcription of the chloroplast gene from phage promoters regardless of the orientation of the gene.

To confirm the function of the phage promoters on the enhanced expression of the maize RuBPCase LS gene we infected a homoimmune λ lysogen, $S159(imm^{21})$, with $\lambda Zm\mathrm{B}1^{l}$ and $\lambda Zm\mathrm{B}1^{r}$. The lysogen synthesizes phage repressor to block the major leftward and rightward transcriptions[28] during infection with the λ recombinants, thus allowing the effect of phage transcription on synthesis of RuBPCase LS to be determined. The fact that we were unable to detect any synthesis of RuBPCase LS by fluorography[29] of immunoabsorbed extracts from the infected lysogens indicates that the enhanced expression of the chloroplast gene is dependent on λ transcription. Expression of the RuBPCase gene in infected lysogens using the endogenous chloroplast promoter was also not detectable, probably due to the low copy (two) of the template introduced during infection.

Discussion

We have demonstrated that the maize and wheat chloroplast genes for the large subunit of RuBPCase are expressed in *E. coli* to give a product of the correct size. This expression is apparently directed on plasmids by transcription initiated from chloroplast sequences that function as promoters. The maize RuBPCase LS gene and flanking regions have been sequenced and were reported to lack a 'classical' prokaryotic promoter sequence[19]. However, scrutiny of the published sequence[19] does reveal structural features similar to those observed in prokaryotic promoters. The sequences of special interest lie between −80 and −125 nucleotides before the start of the codon for the *N*-terminal methionine residue. The region includes the sequence TTGATA (base pairs −119 to −114) which has a high degree of homology with the conserved TTGACA sequence frequently found (around −35 base pairs) before the initiation point of mRNA transcription in prokaryotes[30]. Such a sequence is implicated in the initial recognition of the promoter site by *E. coli* RNA polymerase[30]. This sequence in maize is followed by the sequence TAGATT (base pairs −92 to −87) in a similar position and has significant homology to a Pribnow box[31]. Additional regions of less conserved homology are present on either side of the putative Pribnow box and the TTGATA sequence in maize when compared with a prototype prokaryotic promoter sequence[30]. A typical prokaryotic ribosome binding site GGAGG[9] is centred at −8 base pairs before the N-terminal methionine codon. Koller and Dyer (personal communication) have demonstrated by electron microscopy that *E. coli* RNA polymerase holoenzyme binds specifically to a region on the maize fragment similar to that possessing the sequences described above.

The maize chloroplast DNA sequence therefore possesses features that would lead one to suspect that expression of this plant gene in *E. coli* was possible and our results confirm this expectation. The amount of RuBPCase LS synthesized compared with β-lactamase indicates that expression of the chloroplast gene from a chloroplast promoter in *E. coli* is not insignificant. The ability of chloroplast sequences to initiate transcription has been investigated further by ligating *Sau*3A-generated chloroplast fragments from the wheat RuBPCase LS plasmid p*Tac*39 into the *Bam*HI site of the promoter-deleted β-galactosidase plasmid pMC489[32] and screening recombinants for the synthesis of the β-galactosidase fragment. Clones have been isolated that synthesize the β-galactodase fragment when chloroplast sequences are placed at the 5′ end of the *E. coli* gene, suggesting that initiation of transcription of β-galactosidase mRNA occurs from a chloroplast promoter sequence[33].

The expression of chloroplast genes in *E. coli*, if a general phenomenon, will be advantageous for several reasons. (1) The synthesis *in vivo* of chloroplast-encoded antigens in bacterial colonies or phage plaques will allow solid-phase radioimmunoassay[34] to be used for the rapid identification of clones of interest, avoiding the time-consuming method of *in vitro* coupled transcription–translation systems to identify clones[11]. (2) It should also make possible the identification of some chloroplast genes by complementation of *E. coli* mutants. (3) *In vitro* and *in vivo* mutagenesis and modification of cloned chloroplast genes can be accomplished and the results of such changes on the expression of the gene and the nature of the product can be monitored in bacterial cells. (4) The use of *E. coli* to synthesize chloroplast proteins will be of value for the purification of proteins present only in small amounts in the plant cell, and in the purification of the subunit components of oligomeric enzymes.

Our demonstration that the level of synthesis of RuBPCase large subunits can be increased by using phage promoters should facilitate examination of the assembly mechanism of the RuBPCase holoenzyme and the catalytic function of isolated large subunits that have not been denatured during preparation.

We thank R. B. Flavell for continual encouragment and interest, C. M. Bowman and T. A. Dyer for p*Tac*39, the maize *Bgl*II fragment and unpublished results, J. C. Gray for raising antiserum and K. and N. Murray for instruction in the use of λ and for providing most of the phage and bacterial strains used. Financial support was provided by the National Research Development Corporation.

Genetic analysis of K88-mediated adhesion of enterotoxigenic *Escherichia coli*

Michael Kehoe[*], Richard Sellwood[†], Patricia Shipley[‡] & Gordon Dougan[*]

[*] Department of Microbiology, Moyne Institute, Trinity College, Dublin 2, Ireland
[†] Institute for Research on Animal Diseases, Compton, Newbury, Berkshire, UK
[‡] Department of Microbiology, Virginia Commonwealth University, Richmond, Virginia 23298, USA

Four cistrons (adh) *involved in the expression of the K88 adhesion system have been identified and mapped. Three of these* (adh *A*, adh *B and* adh *C*) *are located in a single operon* (*I*) *whereas the fourth* (adh *D*) *is expressed from a separate promoter* (*operon II*). *The polypeptides encoded by these cistrons have been identified and their role in the formation and regulation of K88 fimbriae* (*pili*) *is discussed.*

THE ability to adhere specifically to mammalian epithelial cells is an important virulence characteristic of many pathogenic bacteria[1,2]. Adhesion to host tissues is often the first step in the establishment of an infection[3], thus elucidation of the mechanisms promoting adhesion could lead to the development of novel anti-adhesive drugs and improved vaccines. Many enterotoxigenic strains of *Escherichia coli* adhere specifically to the epithelial cells of the host's small intestine, where they secrete enterotoxins which are an important cause of diarrhoea in piglets, calves and human infants[4-7].

The adhesiveness of these *E. coli* strains is host specific and often associated with characteristic fimbrial proteinaceous antigens on the bacterial cell surface[8,9]: K88 and 987P in porcine strains[10,11], K99 in bovine strains[12], and the colonizing-factor antigens in human strains[13]. Each of these antigens is encoded by large (~70 kilobase pair) plasmids[7,13]. An 11.5-kilobase pair DNA fragment encoding the K88 serotype *ac* determinant has been cloned[14,15] into the multicopy vector plasmid pBR322 (ref. 16). The K88$^+$ hybrid plasmid was termed pPS002. To provide conclusive evidence for the role of the K88 antigen in adhesion and to determine the genetic basis of its expression, a number of deletion and transposon Tn*5* insertion mutants of pPS002 were isolated and analysed.

Deletion mutants of pPS002 generated *in vitro*

E. coli K12 strain C600 harbouring pPS002 readily agglutinates in anti-K88 sera (K88$^+$), causes mannose-resistant haemagglutination (MRHA$^+$) of guinea pig erythrocytes, carries K88 fimbriae on its surface and adheres strongly to isolated porcine brush border cells *in vitro* (Adh$^+$) (Table 1, Fig. 1). C600 has none of these properties. All the above tests are normally used to identify cells carrying wild-type K88*ac* plasmids.

The smallest deletion of pPS002 that was K88$^+$, MRHA$^+$, Adh$^+$ is pMK005 (Table 1, Fig. 2). This deletion mutant differs from pPS002 in that a 5.0-kilobase pair *Eco*RI fragment (E$_2$) is deleted. The remaining 6.5 kilobase pairs of cloned DNA sequence are sufficient to code for the K88$^+$, MRHA$^+$, Adh$^+$ phenotypes.

The deletion mutants pMK001, pMK002, and pMK006 are K88$^-$, MRHA$^-$ and Adh$^-$. Restriction endonuclease analysis of pMK001 DNA showed that this mutation resulted from a deletion extending from near the *Eco*RI site in pBR322 into the cloned DNA sequences and retains only ~1.6 kilobase pairs of the original cloned fragment (Fig. 2). Mutants pMK002 and pMK006 differ from pMK005 in that pMK002 has lost the 1.73-kilobase pair *Eco*RI fragment E$_3$ and pMK006 has lost an extensive part of it. Thus at least part of the sequences encoding the K88$^+$, MRHA$^+$, Adh$^+$ phenotypes are located within the 1.73-kilobase pair *Eco*RI fragment E$_3$.

To determine whether E$_3$ contains sufficient information to express the K88 antigen, the fragment was cloned separately into the single *Eco*RI site on the cloning vector pAC184 (ref. 17). The resulting hybrid plasmid, pMK007, was K88$^-$, MRHA$^-$ and Adh$^-$ (Table 1). These defects could not be

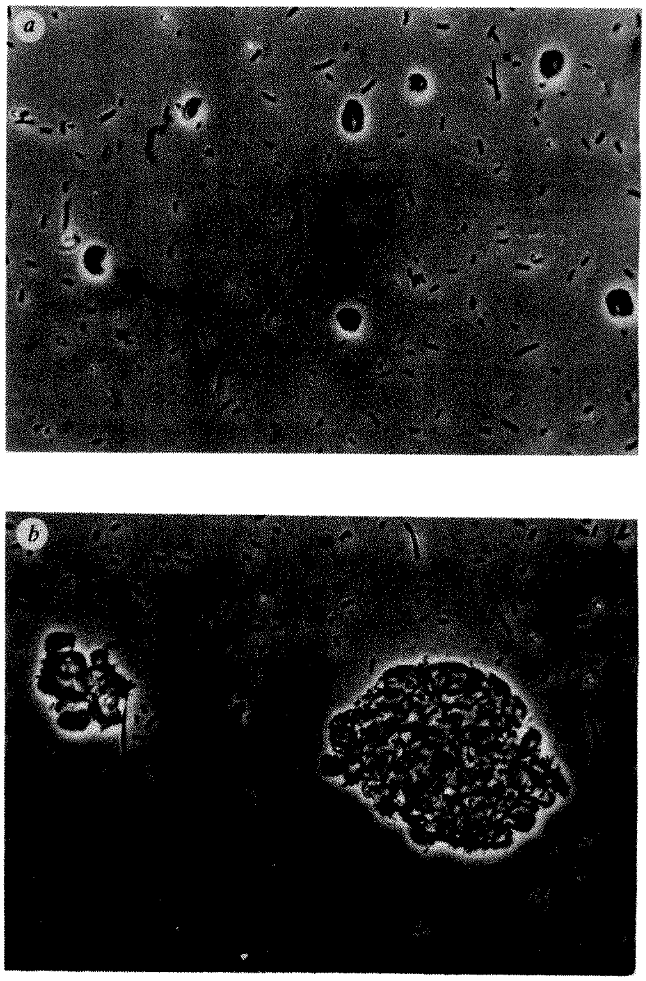

Fig. 1 Adhesion of K88$^+$ Adh$^+$ strains to porcine brush border cells. The adhesion tests were carried out in the presence of 0.5% (w/v) mannose, as described elsewhere[25]. Adhesion was scored from − to + + + +. *a*, Pig brush border cells (arrowed) plus the K88$^-$ Adh$^-$ host strain C600; *b*, pig brush border cells plus C600 harbouring the K88$^+$ Adh$^+$ plasmid, pPS002.

0028–0836/81/200122—05$01.00

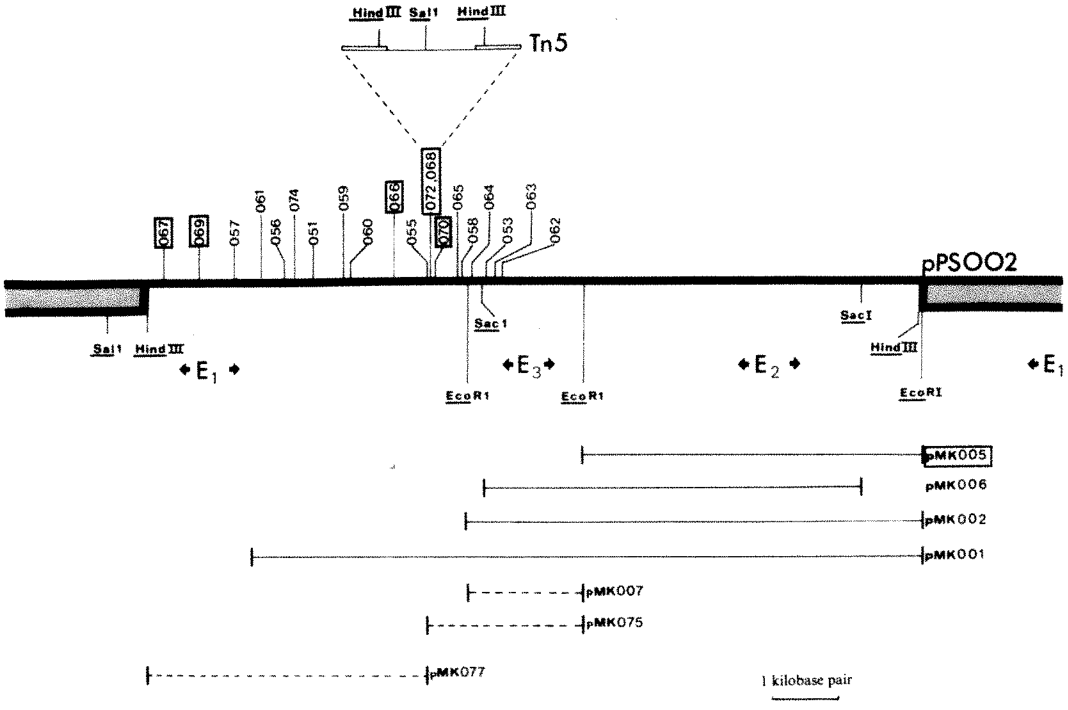

Fig. 2 Mutants of pPS002. The central solid line represents the cloned DNA sequences in pPS002; the wider shaded boxes at each end represent vector (pBR322) DNA sequences. The cleavage sites for several restriction endonucleases are indicated below the line. The three *Eco*RI fragments are indicated by the letters E_1, E_2 and E_3 in order of decreasing size. The lines beneath correspond to the DNA sequences which have been deleted in the mutants indicated; broken lines correspond to the DNA sequences which have been cloned separately into another vector to generate the hybrid plasmids indicated. The deletion mutant pMK001 was isolated after transforming C600 with linear pPS002 DNA generated by partial cleavage with *Eco*RI. The mutants pMK002, pMK005 and pMK006 were generated by deleting particular restriction enzyme fragments *in vitro*. The hybrid plasmid pMK007 was constructed by cloning *Eco*RI fragment E_3 into the vector pAC184. pMK075 was constructed by recircularizing the largest *Hin*dIII fragment of the pMK005::Tn*5* mutant, pMK070. Cloning of a different *Hin*dIII fragment from pMK070 into pAC184 generated the hybrid pMK077. In addition to the pPS002 DNA sequences indicated, the hybrid plasmids pMK075 and pMK077 contain 1.16 kilobase pairs of Tn*5* DNA sequences. The sites of the Tn*5* insertions are indicated by the perpendicular lines above pPS002. The structure of Tn*5* is shown above mutant pMK068[26]. The positions of the Tn*5* insertions were mapped by a series of *Sal*I and *Eco*RI, *Hin*dIII double digests. Mutants whose numbers are enclosed in boxes (for example pMK068) are K88$^+$Adh$^+$; the remaining mutants are K88$^-$Adh$^-$. Plasmid DNA was isolated as described elsewhere[27]. The conditions for restriction enzyme digests and the T_4 ligase reactions were as recommended by the manufacturers. Transformation of C600 was carried out as described elsewhere[28] and agarose gel electrophoresis as described in ref. 29. The Tn*5* insertions into pMK005 were isolated by infecting a Su$^-$ host harbouring pMK005 with the phage λ 467 b221 cI_{857} O_{29} P_{80} *rex*::Tn*5* at a multiplicity of ~0.5. This phage cannot lysogenize, nor can it replicate in a Su$^-$ host. Phage and host were mixed and incubated for 2–3 h at room temperature to allow transposition of Tn*5* and expression of the kanamycin resistance (Km^r) genes. Dilutions were plated onto nutrient agar containing kanamycin. The plasmid DNA from ~2,000 pooled Km^r colonies was used to transform C600, selecting for ampicillin resistance Km^r transformants. Only one pMK005::Tn*5* transformant from each infection experiment was used for further study.

complimented when pMK007 was introduced into C600 harbouring pMK002, indicating either that a gene or an operon involved in the expression of all three phenotypes spans the *Eco*RI site within the cloned DNA sequences in pMK005.

Tn*5* insertion mutants of pMK005

To map in more detail the DNA sequences encoding the K88$^+$, MRHA$^+$, Adh$^+$ phenotypes, a series of independent Tn*5* insertion mutants in plasmid pMK005 was isolated and mapped (Fig. 2). Twenty-three insertions within the cloned DNA sequences were chosen for further study (see Table 1); 19 of the pMK005::Tn*5* plasmids were phenotypically K88$^-$, MRHA$^-$ and Adh$^-$. These mutations spanned an extensive region (~5.5 kilobase pairs) of the cloned DNA sequences. Five of the Tn*5* insertions mapping within the cloned sequences were still K88$^+$, MRHA$^+$, Adh$^+$; two of these (pMK069 and pMK067) mapped close to one end of the sequence whereas three (pMK072, pMK070 and pMK068) were clustered in a small region in the centre. This cluster of K88$^+$, MRHA$^+$, Adh$^+$ Tn*5* insertions effectively divides pMK005 into two regions which accommodate K88$^-$, MRHA$^-$, Adh$^-$ Tn*5* insertion mutations (see Fig. 2). As insertion of Tn*5* into a proximal gene in an operon exerts a strong polar effect (~99%) on the expression of distal genes[18], this suggests that the genes involved in the expression of the K88 determinant are organized into at least two distinct operons.

Cells harbouring one of the insertion mutants, pMK066, were found to be K88$^+$ and Adh$^+$ but were MRHA$^-$. It has been assumed that the reactions involved in the adhesion of K88$^+$ enterotoxigenic *E. coli* strains to pig brush border cells and to guinea pig red blood cells are identical but the mutant pMK066 indicates that the situation may be a little more complex.

Polypeptides encoded by pMK005 and its deletion mutants in minicells

The two regions of pMK005 DNA which accommodate Tn*5* insertions altering the expression of the K88$^+$ Adh$^+$ MRHA$^+$ phenotypes are large enough to encode for polypeptides of molecular weight (MW) up to at least 138,000. The *E. coli* minicell system[19,20] was used to detect pMK005-encoded polypeptides (Table 1, Fig. 3). In addition to the vector (pBR322)-encoded β-lactamase polypeptides, the K88$^+$ Adh$^+$ MRHA$^+$ plasmid, pMK005, expressed at least four polypeptides of MWs 70,000, 29,000, 23,500 and 17,000 (Fig. 3*a*). Minicells harbouring the extensive deletion mutant, pMK001, failed to express any of these four polypeptides (Fig. 3*d*) indicating that they are encoded within the cloned DNA sequences of pMK005. The 23,500-MW polypeptide which has previously been shown to be the K88 antigen is expressed at a very high rate, forming up to 4% of the total cell protein[14].

The deletion mutants pMK002 and pMK006 expressed high levels of the 70,000, 29,000 and 17,000-MW polypeptides in minicells but failed to produce detectable quantities of the 23,500-MW K88 antigen (Fig. 3*b, c*). Thus, the cistrons encoding the former three polypeptides are located within the 4.8 kilobase pair cloned DNA sequences retained by pMK002 (Fig. 2) whereas at least part of the DNA sequences required for the expression of the K88 antigen are located within the

Table 1 Characteristics of pPS002, pMK005 and their mutant derivatives

Slide agglutination tests using anti-K88 serum were done. Serum was prepared by inoculating rabbits with K88 fimbrial subunit, purified as described by Mooi and de Graff[22]. The anti-K88 serum was dialysed and concentrated as described in ref. 23 and absorbed against C600 before use. Mannose-resistant haemagglutination (MRHA) of guinea pig erythrocytes was tested in the presence of 0.5% mannose as described in ref. 24. *In vitro* adhesion tests were carried out in the presence of 0.5% mannose as described elsewhere[25]. The degree of adhesion was scored from – to ++++. IG+ indicates that in these mutants low levels of the 23,500-MW K88 antigen could be detected by the immunoprecipitin gel overlay technique described in Fig. 4 legend.

1.7-kilobase pair *Eco*RI fragment, E_3. Minicells harbouring the pAC184–E_3 hybrid plasmid, pMK007, failed to express the K88 antigen (Fig. 3*e*).

Polypeptides expressed by pMK005::Tn*5* mutants in minicells

In addition to polypeptides expressed from pMK005 DNA sequences, all the pMK005::Tn*5* mutants expressed four polypeptides in minicells which are known to be encoded by the transposon[21]. The K88$^+$ Adh$^+$ MRHA$^+$ pMK005::Tn*5* mutants (pMK067, pMK068, pMK069, pMK070 and pMK072) expressed high levels of the 70,000, 29,000, 23,500 and 17,000-MW polypeptides described above in minicells (Fig. 3*s*). Six of the K88$^-$ Adh$^-$ MRHA$^-$ pMK005::Tn*5* mutants (pMK053, pMK058, pMK062, pMK064 and pMK065) expressed high levels of the 70,000, 29,000 and 17,000-MW polypeptides but failed to express detectable levels of the 23,500-MW K88 antigen (Fig. 3*g*–*i*, *k*). If the 23,500-MW polypeptide was being expressed in reduced quantities by these mutants it might not be distinguishable from the 24,000-MW Tn*5*-encoded neomycin phosphotransferase band on the fluorographs, nor would it be readily detected by Coomassie blue staining of SDS polyacrylamide gels of total cell protein. However, the immunoprecipitin gel overlay technique described in Fig. 4 legend also failed to detect any significant production of the K88 antigen by the six mutants (data not shown). The Tn*5* insertions in all six of these mutants map adjacent to each other within a ~650-base pair region which spans the *Eco*RI site separating *Eco*RI fragments E_1 and E_3 (Fig. 2). Thus the position of the cistron (*adh* D) encoding the 23,500-MW K88 antigen can be mapped (Fig. 5). The direction of transcription of this cistron is tentatively suggested by the observation that mutants pMK062 and

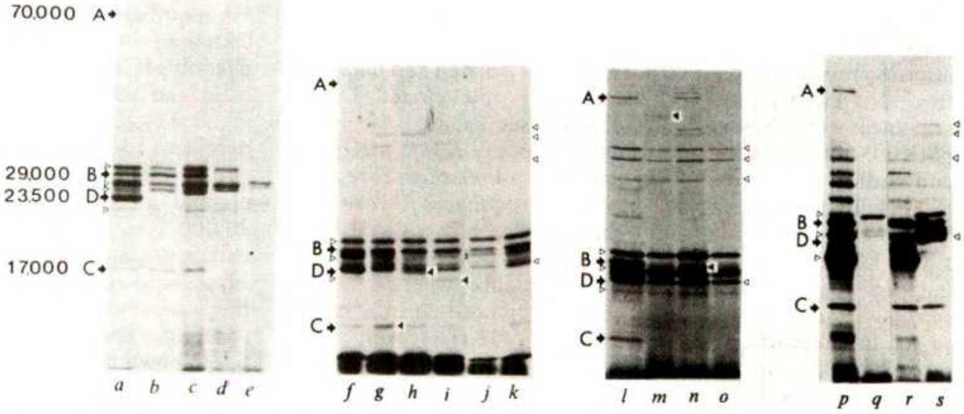

Fig. 3 Fluorographs of polypeptides expressed in minicells by pMK005 and its mutant derivatives. Where a number of different mutants produce the same pattern of polypeptides only representative mutants are shown. The pMK005-encoded polypeptides are indicated by solid black arrows at the side of the diagram; open arrows indicate vector-encoded polypeptides, that is, β-lactamase and its precursors in the case of pBR322-based hybrid plasmids (for example, *a*) or chloramphenicol acetyltransferase (CAT) in the case of pAC184-based hybrid plasmids (*r*). Note that in the case of the pAC184-based hybrid plasmid pMK007, the CAT determinant has been insertionally inactivated by the cloned DNA sequence (*e*). Fragments of polypeptides described in the text are labelled with small solid arrows within the diagram. Plasmid pMK005 and its mutant derivatives were transformed into the *E. coli* minicell strain DS410 (ref. 27). Plasmid-encoded polypeptides were detected by autoradiography and/or fluorography[30] of SDS-polyacrylamide gels of ^{35}S-methionine-labelled minicell preparations[19]. *a*, *f*, pMK005; *b*, pMK006; *c*, pMK002; *d*, pMK001; *e*, pMK007; *g*, pMK053; *h*, pMK062; *i*, pMK063; (*j*) pMK055; *k*, pMK064 (representative of pMK058 and pMK065); *l*, *s*, pMK070 (representatives of pMK067, pMK069, pMK072 and pMK068); *m*, pMK060 (representative of pMK059); *n*, pMK066; *o*, pMK051 (representative of pMK056; pMK057; pMK061 and pMK074); *p*, pMK075 and pMK077; *q*, pMK075; and *r*, pMK077.

pMK063 express additional polypeptides of MWs 21,000 and 19,000 respectively, which seem to be fragments of the K88 antigen resulting from termination of transcription or translation by a signal located within the Tn*5* insertion. In addition, the 17,000-MW band produced by mutant pMK053 is consistently very intense, suggesting that this is a doublet consisting of a ~17,000-MW fragment of the K88 antigen comigrating with the 17,000-MW polypeptide described above. The sizes of these fragments are consistent with the relative positions of the Tn*5* insertions in these mutants.

Mutant pMK055 expressed high levels of the 70,000 and 29,000-MW polypeptides in minicells but failed to produce detectable levels of the 23,500-MW K88 antigen or the 17,000-MW polypeptide (Fig. 3*j*). The Tn*5* insertion in this mutant seems to be located in a cistron (referred to as *adh* C) encoding the 17,000-MW polypeptide. The *adh* C cistron is separated from the *adh* D cistron by a site which accommodates a number of K88$^+$ Adh$^+$ MRHA$^+$ Tn*5* insertions (Fig. 2 and see below). Therefore the absence of the 23,500-MW polypeptide in mutant pMK055 cannot be explained by polarity. It is possible that the 17,000-MW *adh* C product is a positive regulator required for the expression of the *adh* D cistron.

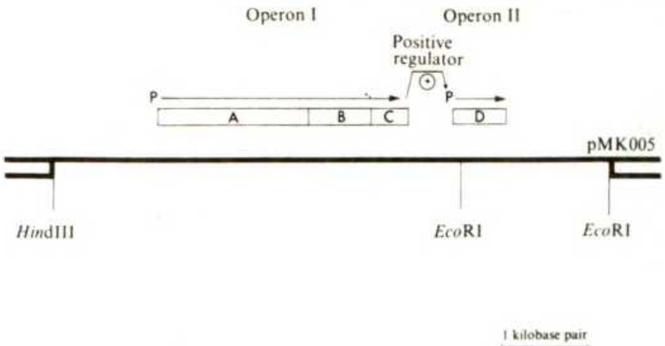

Fig. 5 Model of the genetic organization of the adhesion cistrons. The central solid line represents the cloned DNA sequences in the smallest Adh$^+$ K88$^+$ MRHA$^+$ plasmid, pMK005, the wider shaded boxes at each end represent vector (pBR322) DNA sequences. The boxes above the line represent the *adh* A, *adh* B, *adh* C and *adh* D cistrons; arrowed lines above these indicate the direction of transcription of operons I and II from their respective promoters (P). The 17,000-MW polypeptide product of *adh* C is thought to be a positive regulator required for the expression of operon II (see text).

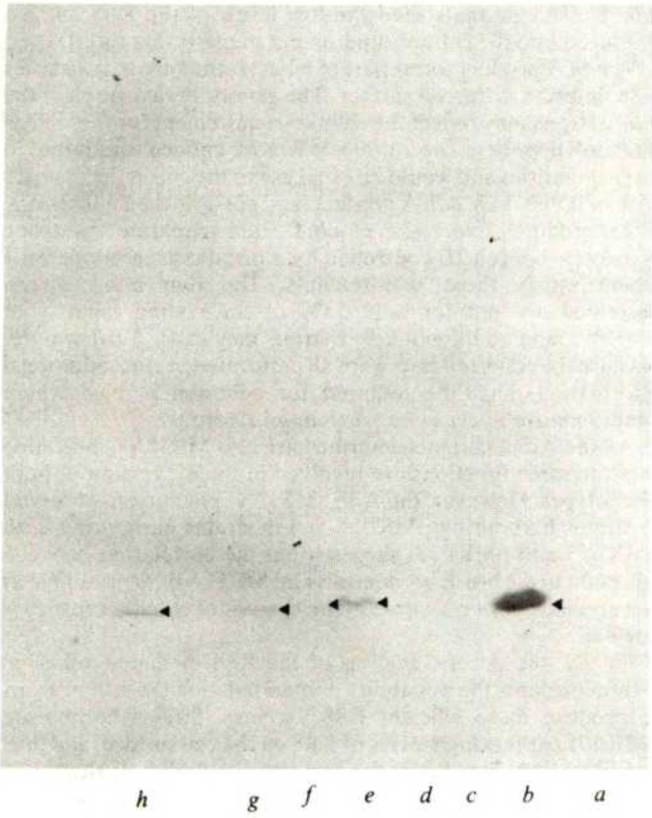

Fig. 4 Immunoprecipitin overlay gel: the method used was a modification of the technique of Broome and Gilbert[31] (B. Crowe, unpublished results). Whole cells harbouring the plasmid being tested were scraped from a nutrient agar plate and resuspended in SDS-polyacrylamide gel final sample buffer, boiled for 2 min and the polypeptides separated on a 12.5% SDS-polyacrylamide gel. When electrophoresis was complete the gel was washed twice (20 min) with gentle shaking in water and soaked for a further 20 min in 15 mM barbitol–HCl buffer, *p*H 8.6, containing 1% (v/v) Triton X-100. The gel was transferred to a glass plate and overlaid with a 1% (w/v) agarose gel in barbitol buffer, containing evenly dispersed anti-K88 antibodies. This was incubated overnight at room temperature in a moist box to allow diffusion of polypeptides from the polyacrylamide gel into the agarose anti-K88 overlay gel. Control experiments using the K88$^+$ Adh$^+$ MRHA$^+$ strain, pMK005, showed that the denatured 23,500-MW K88 polypeptide could be readily detected as a precipitin band in the agarose anti-K88 overlay gel. After incubation the immunoprecipitin agarose gel was washed in 0.1 M NaCl and pressed several times to remove excess antibodies and unprecipitated polypeptides. The immunoprecipitin agarose gel was finally dried in a warm air stream and stained with Coomassie blue. *a*, C600 host; other tracks, C600 harbouring the plasmids *b*, pMK005; *c*, pMK077; *d*, pMK075; *e*, pMK077 and pMK075; *f*, pMK057; *g*, pMK074; *h*, pMK066.

Plasmid pMK066 is the only K88$^+$ Adh$^+$ MRHA$^-$ Tn*5* insertion mutant. Minicells containing this plasmid expressed high levels of the 70,000-MW polypeptide but did not produce the other three polypeptides (Fig. 3*n*). However this mutant produces reduced quantities of the 23,500-MW K88 antigen which was detected by the immunoprecipitin gel overlay technique (Fig. 4*h*). In addition, pMK066 encodes high levels of a new polypeptide of MW 28,000 (Fig. 3*n*). We believe that this polypeptide is a fragment of the 29,000-MW polypeptide which is normally expressed from a cistron (termed *adh* B) whose distal end spans the Tn*5* insertion site in pMK066. This mutation maps adjacent to the left of *adh* C (Fig. 5). The absence of detectable quantities of the 17,000-MW *adh* C product in minicells harbouring pMK066 is explained by suggesting that *adh* B and *adh* C are located in the same operon (operon I, Fig. 5) and that the *adh* B::Tn*5* insertion exerts a strong polar effect on the expression of *adh* C. In the absence of normal levels of the *adh* C product, the level of expression of the *adh* D cistron is reduced. In addition to the 28,000-MW fragment of the *adh* B cistron, pMK066 produces a second new polypeptide of MW 31,000, which can sometimes be resolved from the 30,000 β-lactamase precursor on SDS polyacrylamide gels (data not shown). The origin of this polypeptide is not understood.

The Tn*5* insertions in the remaining K88$^-$ Adh$^-$ MRHA$^-$ pMK005::Tn*5* mutants are located adjacent to each other within a 1.7-kilobase pair region of pMK005 (Fig. 2)—this region is large enough to encode polypeptides totalling a MW of at least 68,000. All these mutants failed to express detectable levels of the four polypeptides in minicells (Fig. 3*m*, *o*). Two mutants (pMK059 and pMK060) which map very close together express a new polypeptide of MW 65,000 which could be a fragment of the 70,000-MW polypeptide. The Tn*5* insertions in all these mutants seem to be located in a cistron (termed *adh* A) which encodes the 70,000-MW polypeptide. The absence of the 29,000 and 17,000-MW polypeptides is explained by suggesting that the *adh* A cistron is located in the promoter proximal part of operon I (Fig. 5) and *adh* A::Tn*5* mutants exert a strong polar effect on the expression of the *adh* B and *adh* C cistrons. The polar effects of *adh* A::Tn*5* mutants and the *adh* B::Tn*5* mutant indicate that operon I is transcribed from left to right as described in Fig. 5. The coding capacity of the 2.8 kilobase pairs of DNA extending from the promoter-proximal *adh*A::Tn*5* insertion, pMK057, to the promoter-distal *adh*C::Tn*5* insertion, pMK055, can be completely accounted for by the *adh*A, *adh*B and *adh*C products (Figs 2, 5).

As the *adh*B::Tn*5* mutant, pMK066, expressed low levels of the 23,000-MW K88 antigen in the absence of normal levels of the *adh*C product the *adh*A::Tn*5* mutants should also express reduced levels of the *adh*D cistron. Representative *adh*A::Tn*5* mutants were analysed by the immunoprecipitin gel overlay technique and were shown to express reduced levels of the K88 antigen (Fig. 4*f*, *g*). However, unlike pMK066, these mutants were Adh$^-$ and were not readily agglutinated by anti-K88 serum in slide agglutination tests (Table 1). Radial immunodiffusion of concentrated cell-free supernatants of these mutants showed that the K88 antigen was present in the culture supernatants (data not shown). These results suggest that in the absence of the 70,000-MW *adh*A product the K88 antigen is shed into the supernatant rather than being assembled into normal K88 fimbriae.

Cloning operons I and II on different compatible plasmids

If the genetic organization of the *adh* cistrons proposed in Fig. 5 is correct it should be possible to obtain high-level expression of the K88 antigen when operons I and II are present in the same host cell but on different compatible plasmids. Furthermore, the 23,500-MW *adh*D product should only be expressed at high levels when complemented in *trans* by operon I, whereas the *adh*A, *adh*B and *adh*C products should be expressed at high levels even when operon I is present alone in the cell. This hypothesis was tested as follows.

The compatible hybrid plasmids pMK075 (pBR322–operon II) and pMK077 (pAC184–operon I) were produced by cloning *Hin*dIII fragments from the pMK005::Tn*5* mutant, pMK070 (Fig. 2). As expected, cells harbouring either pMK075 or pMK077 alone were K88$^-$, Adh$^-$ and MRHA$^-$ (Table 1) and minicells harbouring pMK075 alone did not produce detectable levels of any of the four polypeptides, whereas minicells harbouring pMK077 alone expressed high levels of the 70,000, 29,000 and 17,000-MW polypeptides only (Fig. 3*q*, *r*).

E. coli C600 harbouring both pMK075 and pMK077 expressed reasonably high levels of the K88 antigen (Fig. 4*e*) and were K88$^+$ Adh$^+$ but surprisingly MRHA$^-$ (Table 1). Minicells harbouring both pMK075 and pMK077 expressed high levels of the 70,000, 29,000 and17,000-MW polypeptides but low levels of the 23,500-MW K88 antigen and other pMK075-encoded polypeptides (for example, β-lactamase and its precursors; Fig. 3*p*). It seems that pMK077 and pMK075 do not segregate equally into minicells. However, experiments with whole cells harbouring both of these plasmids (see above) clearly show that pMK075 can express high levels of the 23,500-MW K88 antigen when complemented in *trans* by pMK077. These results support the genetic organization and control of the *adh* cistrons outlined in Fig. 5. However, the MRHA$^-$ phenotype of whole cells harbouring both pMK075 and pMK077 is difficult to understand (see below).

Discussion

Four cistrons, for which we suggested the terms *adh*A, *adh*B, *adh*C and *adh*D, involved in K88-mediated adhesion of enterotoxigenic *E. coli* strains have been identified and mapped (Fig. 5) and their polypeptide products identified in minicells. The 23,500-MW *adh*D product is clearly the K88 fimbrial subunit. The results tentatively suggest the functions of two of the other polypeptides. The 17,000-MW *adh*C product seems to be a positive regulator which controls the expression of *adh*D. However, an alternative explanation to account for the reduction in K88 expression in *adh*C-defective mutants cannot be ruled out. It is possible that in these mutants the *adh*D product has been produced in a precursor form which was not identified by the methods used and that the defect is one of polypeptide processing rather than genetic regulation. The observation that *adh*A::Tn*5* mutants shed the low levels of the K88 antigen produced into the culture supernatant suggests that the 70,000-MW *adh*A product forms part of a basal structure that attaches K88 fimbriae to the cell surface. The genetic organization of the *adh* cistrons may reflect the cellular requirement for the individual polypeptides. The 23,000-MW K88 antigen is required in large quantities and would be of no use to the cell in the absence of the 70,000-MW *adh*A product (and possibly the 29,000-MW *adh*B product). Expression of *adh*D from a separate and strong promoter (operon II) controlled by a distal cistron of operon I would satisfy these requirements. The four *adh* cistrons described account for only 54% of the coding capacity of pMK005 and additional *adh* cistrons may exist. Furthermore, because the adhesion tests were all performed *in vitro*, additional information might be required for adhesion *in vivo* where conditions are likely to be much more rigorous.

All the Adh$^-$ mutants described are also MRHA$^-$, indicating that the same functions are involved in the expression of both phenotypes. However, the Adh$^+$ MRHA$^-$ phenotype, observed in strains harbouring pMK066 and in strains harbouring both pMK075 and pMK077, suggests that the correlation between adhesion to pig brush border cells and MRHA is not as simple as has previously been assumed. The reason for this discrepancy is unclear.

Finally, the genetic analysis of the K88-mediated adhesion system presents the possibility of manipulating the *adh* cistrons to produce more efficient K88 vaccines. Strains harbouring pMK005 express high levels of K88 on the cell surface, and thus would be ideal candidates for oral vaccine studies. It should be possible to construct non-polar *adh*A$^-$ mutants that secrete high levels of the K88 antigen into the culture supernatant and thus facilitate purification of the K88 antigen.

Using a synthetic oligonucleotide primer, cloned DNA fragments, each containing the entire coding sequence of rat relaxin, have been isolated from a clone 'bank' of ovarian mRNA sequences. The nucleotide sequence of these clones demonstrates that relaxin is synthesized as a preprorelaxin molecule with an unexpectedly large connecting peptide of 105 amino acid residues.

THE peptide hormone relaxin is produced by the corpora lutea of ovaries during pregnancy in many mammalian species, including pigs[1], rats[2] and humans[3], but also surprisingly in a number of non-mammalian groups (notably the shark)[4]. The secretion of the hormone into the blood stream just before parturition results in a marked softening and lengthening of the pubic symphysis and a softening of the cervix which facilitates the birth process. Relaxin also inhibits uterine contractions and may influence the timing of parturition[5].

The primary structure of porcine relaxin[4,6,7] consists of two peptide chains of 22 and 31 residues, covalently linked by one intra- and two inter-chain disulphide bonds. The locations of the disulphide bonds are homologous to the structures of insulin and insulin-like growth factors (IGFs)[8], for which reason it was anticipated that relaxin is also synthesized as a single-chain precursor polypeptide with a connecting peptide linking the A and B chains. Furthermore, by analogy with the structure of proinsulin[9], it has been suggested that the B chain is at the NH_2-terminus of the precursor molecule.

Nevertheless, porcine relaxin appears to have a precursor of molecular weight (MW) at least 22,000 (22 K) as determined by *in vitro* translation[10], which is much larger than the 11K precursor of insulin, implying either that the connecting peptide of relaxin is far longer than that of insulin (about 30 amino acids) or that there is a peptide extension of the A or B chains which is removed during the processing of the precursor molecule. The recently determined primary structure of rat relaxin[11] has, like porcine relaxin, a limited structural homology with insulin, with an identical disposition of half-cystine residues; the A chain has 24 amino acids, the B chain 35 amino acids.

We report here the *in vitro* synthesis and cloning of cDNA transcribed from total mRNA isolated from pregnant rat ovaries into the bacterial plasmid pBR322. Clones containing the coding sequence for relaxin were detected using a relaxin-specific cDNA probe obtained with the aid of a synthetic oligonucleotide primer. Nucleotide sequence analysis elucidated the entire coding sequence for rat relaxin together with the structure of the 3′-untranslated region, and most of the 5′-untranslated region.

Isolation of cDNA clones

The proportions of relaxin-specific mRNA produced by the corpora lutea of ovaries in pregnant rats are not sufficiently high for the convenient detection and isolation of hormone-specific clones (as with insulin mRNA in the islets of Langerhans[12] and growth hormone in the pituitary[13]). Accordingly, we chose first to generate a cloned cDNA 'bank' from total ovarian mRNA and then sought to detect cDNA clones containing the relaxin-coding sequence using an oligonucleotide primer based on the known amino acid sequence of rat relaxin[11]. (A similar method has been used successfully to detect low levels (0.6%) of gastrin cDNA in a total cDNA population from antral mucosa[14].)

Although the choice of the oligonucleotide primer must be determined from the amino acid sequence of the protein, the degeneracy of the genetic code entails ambiguity at some positions. However, it has been shown[15] that the effects of possible mismatches are minimized by selecting G wherever there is a choice between A and G in the oligonucleotide primer and by selecting T where there is a choice between C and T; the result will either be the correct base pairing or a G–T mismatch. A suitable primer for rat relaxin was chosen by searching through the amino acid sequence[11] to find the region (amino acids 6–9 in the B chain, Trp-Met-Asp-Gln, Fig. 1) for which the nucleotide sequence of the mRNA had the minimum number of ambiguities. We obtained the synthetic primer 5′-TGGTCCATCCA-3′ containing only one possible mismatch within the first 11 nucleotides of this portion of the coding sequence. This primer, being complementary to the mRNA, was used to generate relaxin-specific cDNA from the priming site on the mRNA template (Fig. 2).

mRNA was prepared from 40 ovaries of rats on days 18–20 of pregnancy (term is 21 days) when relaxin levels are highest[16]. Single-stranded cDNA was synthesized using oligo(dT) primer and reverse transcriptase[17] and, after removal of RNA by alkali digestion, converted into double-stranded cDNA by polymerase I (Klenow fragment). This generates a molecule with a hairpin structure on one end and a poly(dA-dT)tract at the other[12]. The hairpin structure was removed by S_1 nuclease and poly(dC) homopolymeric extensions were added onto the 3′ ends with terminal transferase[18].

A clone bank was obtained by inserting the total cDNA population into the *Pst*I endonuclease cleavage site of the bacterial plasmid pBR322[19], using specific hybridization between poly(dG) tails synthesized on the plasmid and poly(dC) tails on the cDNA. An *Escherichia coli* K12 strain (RR1) was transformed with the recombinant molecules (efficiency = 10^5 clones per μg plasmid) and colonies were selected by resistance to tetracycline. Individual colonies were screened on nitrocellulose filters[20] with a radioactive cDNA probe synthesized from the relaxin-specific primer as described above (Fig. 2).

From a total of ~5,000 recombinant clones, 20 colonies hybridized with the cDNA probe (Fig. 2, lane *e*) and also hybridized positively when rescreened with the specific 150-

0028-0836/81/200127—05$01.00

nucleotide fragment eluted from an 8% polyacrylamide gel. Plasmid DNA isolated from 10-ml cultures of each colony was found to contain cloned DNA fragments of 700–900 base pairs. This was not unexpected, because the use of what was essentially a 5′-specific relaxin probe results in the selection of clones carrying nearly full-length cDNA copies of relaxin mRNA.

Extraction of the cDNA insert by cleavage of recombinant plasmids at the *Pst*I sites revealed two types of clone. Sixteen recombinants (type I) contained an internal *Pst*I site in the cDNA insert, giving rise to a 600-base pair DNA fragment (subsequently shown to represent the 3′ portion of the mRNA) and a 150–300-base pair DNA fragment (from the 5′ region of the mRNA). The remaining four recombinants (type II) contained inserts of a similar size but without an internal *Pst*I site.

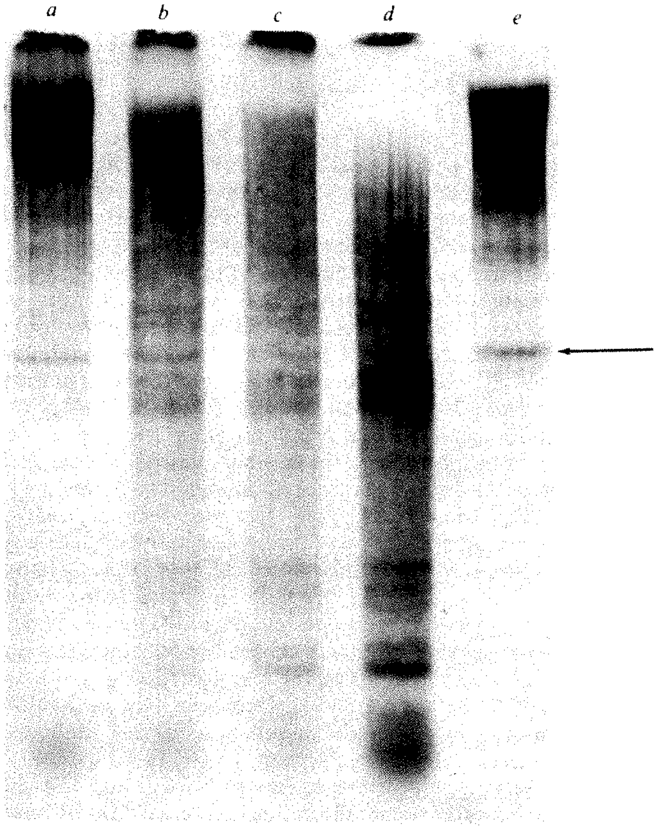

Fig. 2 Primed cDNA synthesis using rat ovarian mRNA and the synthetic undecamer 5′-TGGTCCATCCA-3′ (Collaborative Research Products). mRNA was prepared from rat ovaries, taken on days 18–20 of pregnancy, by extraction in 6 M guanidinium thiocyanate[46] and isolation of polyadenylated RNA on oligo(dT) cellulose[17]. Aliquots (200 ng) of mRNA were transcribed into cDNA in 10-μl reactions containing synthetic primer (1 ng), 50 mM Tris-HCl *p*H 8.0, 50 mM KCl, 7 mM $MgCl_2$, 1 mM 2-mercaptoethanol, 400 μM each of dGTP, dCTP, dTTP, 50 nM $[\alpha\text{-}^{32}P]$dATP (2,000 Ci $mmol^{-1}$), reverse transcriptase (7 units) and various concentrations of nonradioactive dATP (*a*, 1 μM; *b*, 200 nM; *c*, 50 nM; *d*, 0; *e*, 1 μM (preparative scale)) at 37 °C for 20 min. cDNA was denatured in 10 μl of 0.2 M NaOH and heated to 90 °C for 2 min before analysis on a 20 cm × 20 cm 8% polyacrylamide slab gel (150 V, 3 h). The autoradiograph of the dried gel is shown above (Dupont Cronex MRF-31). The predominant cDNA fragment of ~150 nucleotides length (arrowed) is absent in a primed synthesis of non-pregnant rat ovarian mRNA (data not shown) and therefore is probably transcribed from a pregnancy-specific mRNA expected to be rat relaxin. For use in colony hybridizations 10 μg of mRNA were transcribed with 5 ng of primer and a dATP concentration of 1 μM designed to give maximal specific activity in the predominant 150-base cDNA fragment (*e*, above). The reaction mixture was extracted with phenol–chloroform (1 : 1 v/v) in the presence of EDTA (10 mM). Unincorporated nucleotide triphosphates were removed in a column (1 cm × 5 cm) of Sephadex G-50 equilibrated with 0.15 M NaCl, 50 mM Tris-HCl *p*H 7.5 and 1 mM EDTA. cDNA was precipitated with EtOH; dissolved in 0.1 M NaOH and heated to 70 °C for 20 min to remove mRNA. The total cDNA preparation was neutralized and diluted in Denhardt's solution[47] before colony hybridization screens on nitrocellulose filters. Alternatively, the cDNA mixture was fractionated on a 8% polyacrylamide slab gel, the predominant 150-base fragment excised from the gel, electroeluted and precipitated for specific colony screens.

Primary structure of mRNA

The largest plasmid of each type was isolated from 2 l of cells yielding about 1 mg of DNA (pR-RLX1 from type I, pR-RLX2 from type II). The cDNA insert was recovered after *Pst*I digestion and subjected to nucleotide sequence analysis using both chemical and chain termination methods (Fig. 3). The primary structure of relaxin mRNA (Fig. 4) was deduced from the nucleotide sequence of the 840-base pair insert in pR-RLX1. The other type of insert (pR-RLX2) was also completely sequenced, and differed only in the deletion of one nucleotide triplet over the *Pst*I site (GCA or CAG deleted from positions 254–256 or 255–257). The insert within pR-RLX2 was prematurely terminated at nucleotide 77, but was otherwise identical to the structure shown in Fig. 4, thus confirming most of the coding sequence.

The sequence of the 5′-untranslated region does not represent the entire mRNA because the hairpin loop structure of the double-stranded cDNA was removed. However, the size of the specific cDNA synthesized with the relaxin primer (150 nucleotides) suggests that only about 14 nucleotides of the 5′-untranslated sequence are missing from the cloned sequence shown in Fig. 4. It was therefore not surprising to find the clones differing mainly in the size of the 5′ end. A repeat of nucleotides 5–18 over 18–31 may be significant in terms of a regulatory function, but sequences in this region of cloned cDNAs must be viewed cautiously due to the possibility of errors[21] unless confirmed by similar examination of other clones or by direct sequencing of cDNA transcribed from the mRNA[14].

The sequence AAUAAUA in the 3′-untranslated region starting at position 776, about 20 nucleotides from the poly(A) tract, is similar to sequences found in other eukaryotic mRNAs[22,23] and is probably involved in the addition of the 3′-poly(A) sequences after transcription.

The coding sequence of 560 nucleotides (44–604) contains a nonrandom distribution of codon choices, the significance of which is unknown[24].

Amino acid sequence

Figure 4 gives the amino acid sequence for the physiological precursor to rat relaxin (preprorelaxin). The regions corresponding to the known sequences of the A and B chains of rat relaxins are readily identified and the independently derived DNA and peptide sequences for these regions are in complete agreement. The signal peptide of 22 amino acids is followed in order by the B chain (35 residues), a connecting peptide region (105 residues) and the A chain (24 residues). A single stop codon (UGA) follows the cysteine codon for the C-terminal residue of the A chain.

The signal peptide of preprorelaxin contains 22 predominantly hydrophobic amino acids, starting at the initiator codon (AUG, Met) and terminating in Ala before the B chain. There is little homology with the signal peptides of other secreted hormones, apart from the typically high leucine content, which produces some random alignments. A cleavage, presumably by a membrane peptidase after a residue with a small side chain (Ala at position −1), is common of the processing in many signal peptides[25]. The resultant precursor secreted into the endoplasmic reticulum and eventually being packaged into vesicles at the Golgi apparatus is the 164-residue prorelaxin.

The size of the connecting (C) peptide of 105 residues is one of the surprising features of the prorelaxin structure. One of its functions is presumably to direct folding of the precursor so that the correct disulphide bonds are formed between the B and A chains. However, a connecting bridge of about 30 residues is sufficient to perform this function in proinsulin and even smaller bridges of 11 and 8 residues are found in IGF I and IGF II, respectively[26] (Fig. 5). Experiments involving artificial cross-

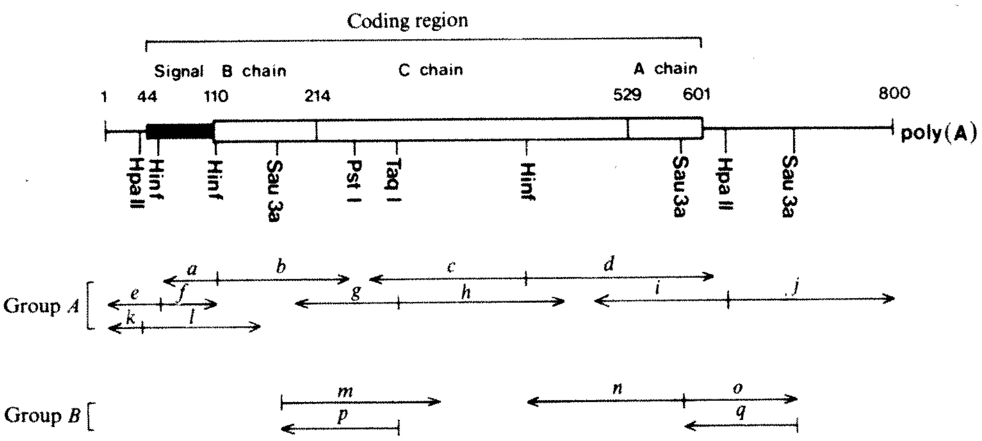

Fig. 3 Schematic diagram of the structural gene for rat relaxin. The nucleotide sequence of 800 base pairs was deduced from the largest recombinant plasmid isolated from the colony screen (pR-RX1, insert of about 900 base pairs into pBR322). Nucleotide residues are numbered in the direction 5′ to 3′ in the message strand, beginning with the first base in the 5′-untranslated region. The poly(dG)·poly(dC) homopolymeric extensions of about 20 nucleotides on each end of the insert are not depicted. The coding region for rat preprorelaxin has been divided into the 66-base coding region corresponding to the signal peptide, the 105-base B chain, 315-base connecting or C peptide and 72-base A chain. The poly(A) extension corresponding to the 3′-terminal sequence of the mRNA structure was found to be about 40 nucleotides long. The insert contained an internal *Pst*I recognition site. Thus, cleavage of plasmid pR-RLX1 with *Pst*I generated a 300-base fragment (containing the 5′-untranslated region) and a 600-base fragment (containing the 3′-untranslated region and poly(A) tract.) The nucleotide sequence of the cloned DNA plasmid was determined using both the method of Maxam and Gilbert[29] and that of Sanger *et al.*[30]. The plasmid was digested with a selection of restriction enzymes which each form 5′-overhanging ends (*Taq*I, *Hin*f, *Hpa*II or *Sau*3a as shown). DNA fragments were end-labelled for the Maxam and Gilbert procedure (group *A*) by incorporating appropriate radionucleotides with reverse transcriptase. Reaction conditions were 50 mM Tris-HCl *p*H 8.0, 50 mM KCl, 7 mM $MgCl_2$, 1 mM 2-mercaptoethanol, [α-^{32}P]dNTP (50 μCi, 2,000 Ci mmol^{-1}) and reverse transcriptase (2 units) in a 20-μl mixture containing the DNA fragment (about 1 μg) at 37 °C for 20 min. After strand separation in alkali, or digestion with a different enzyme, the unique end-labelled fragments were separated on a polyacrylamide slab gel, then detected by autoradiography or by ethidium staining, and electroeluted. The nucleotide sequence was determined by chemical degradation[29] followed by separation of fragments into a sequence ladder on thin 40 cm × 40 cm polyacrylamide slab gels[48]. Fragments sequenced by this procedure are as follows (the letters in italics refer to the horizontal arrows and the labelled ends of the restriction fragments are designated by an asterisk). *a*, *Hin*f–*Hin*f*; *b*, **Hin*f–*Pst*I; *c*, *Pst*I–*Hin*f*; *d*, **Hin*f–*Hpa*II; *e*, *Pst*I–*Hin*f*; *f*, **Hin*f–*Hin*f; *g*, *Sau*3a–*Taq*I*; *h*, **Taq*I–*Sau*3a; *i*, *Hin*f–*Hpa*II*; *j*, **Hpa*II–*Pst*I; *k*, *Pst*I–*Hpa*II*; *l*, **Hpa*II–*Pst*I. Alternatively (group *B*), fragments generated by digestion with *Sau*3a or *Taq*I were subcloned (by ligation to the corresponding complementary ends) into the *Bam*HI or *Acc*I site of bacteriophage M13mp7 and grown after transformation of permissive hosts (*E. coli* strain JMB101). The sequence of these subcloned fragments (*m*–*q*) was determined by primed DNA synthesis using a synthetic primer complementary to the codons for amino acids 13–17 in the β-galactosidase gene. Dideoxynucleotides (P-L Biochemicals) were incorporated using polymerase I (Klenow fragment) in conditions described by Sanger *et al.*[30].

links between insulin A and B chains indicate that a bridge equivalent in length to only one or two amino acids is adequate to direct the correct refolding of previously reduced chains[27]. Thus, the C peptide of prorelaxin vastly exceeds in length the probable minimum requirements for correct alignment of the A and B chains. Although there is no sequence homology between relaxin and insulin C bridges, there is a similar region:

Glu-Asp-Gly-Gly-Pro-Pro-Glu rat relaxin
Glu-Leu-Gly-Gly-Gly-Pro-Glu rat insulin I

with five out of seven identical residues. (Vicinal glycine residues are found in most known insulin C peptides.)

Processing of rat preprorelaxin

As groups of two or more lysine and/or arginine residues are commonly found at sequence regions where processing of peptide hormone precursors occurs[25] and are presumed to act as recognition signals for intracellular proteases, it is surprising that there is no cluster of basic residues immediately adjacent to the C-terminal end of the B chain of relaxin. Not all basic clusters, however, are sites for proteolytic cleavage. For example, the rat relaxin A chain contains the sequence Arg-Arg internally and parathyroid hormone contains two internal basic clusters which are not cleaved in the conversion of proparathyroid hormone to parathyroid hormone[28]. In preprorelaxin there is a cluster of four basic amino acids adjacent to the N-terminus of the A chain (Arg-Lys-Lys-Arg). However, the C-terminal residue of the B chain is leucine 35, and it is followed by the sequence

Ser-Gln-Glu-Glu(AGC CAG GAG GAG)

An examination of the nucleotide sequence in this region (Fig. 4) reveals that a deletion of a single base in the codon for the serine would result in the in-phase sequence AGG AGG, which codes for Arg-Arg. Hence, we examined very carefully the possibility of a sequencing error in this region. However, sequencing experiments using both Maxam-Gilbert[29] and Sanger[30] procedures carried out on both strands of several fragments derived from this region gave unequivocal results in favour of the Ser-Gln-Glu-Glu formulation for the amino acid sequence (see Fig. 3). Furthermore, it can be seen that such a deletion of a nucleotide in this region would lead to a reading frame in which a stop codon appears within 15 nucleotides at position 237–239. A further possibility we considered was an error in the copying of the mRNA sequence by reverse transcriptase. However, this explanation was ruled out because the identical sequence was obtained for this region from another rat relaxin clone (pR-RLX2) (see Fig. 4). This also removes the possibility of a mutation during the cloning procedure itself. A further possibility must be considered, that the processing point is in fact at the next pair of basic residues carboxyl terminal to the present putative cleavage point. This would occur at the Arg-Lys sequence at positions 77–78 of the prorelaxin sequence. In this case, rat relaxin would have a B chain of ~76 residues, and the form which has been isolated from pregnant ovaries and sequenced[11] (which has a B chain of 35 residues) would have to be generated from the larger form by further proteolytic cleavage. We believe this is unlikely because the 6,000-MW (6K) form of relaxin was isolated from ovaries frozen at once in liquid nitrogen and stored at −70 °C until workup by a procedure designed to minimize proteolysis[31]. Further, the 6K form of rat relaxin as isolated by two groups[31,32] is biologically active both in the mouse pubic symphysis bioassay and the rat uterus bioassay. This does not preclude the possibility that there are several forms of rat relaxin generated by variable processing of its precursor. Several high-molecular-weight forms of porcine relaxin have been identified in extracts of pregnant sow ovaries[33]. If the precursor to porcine relaxin is similar to rat preprorelaxin in having a large C-peptide bridge, as seems probable from its molecular weight in *in vitro* translation systems[10], these high-molecular-weight forms of immunologically active relaxin could represent the basic 6K form with variable extensions to A and/or B chains resulting from incomplete removal of the C peptide. Such molecules might represent intermediates in the generation of the biologically active relaxin. However, they might also have a different spectrum of biological properties from the 6K relaxin.

Another possible functional role for the large C peptide may be that it contains peptide sequences with other hormonal activities. This would make prorelaxin analogous to the 31K precursor to ACTH and β-endorphin[34] in containing more than

Fig. 4 Primary structure of rat preprorelaxin mRNA. The nucleotide sequence of the mRNA was deduced from that of the 900-base pair cDNA insert in pR-RLX1 (compiled in Fig. 3). Nucleotides are numbered sequentially from the 5′ end, being adjacent to the poly(dG) tail in the cDNA. The 5′-terminal sequence is derived solely from one cDNA clone and certainly does not represent the entire sequence of the intact cellular mRNA. However, the 3′ end contains a poly(A) tract of about 40 nucleotides and probably represents the exact mRNA structure. The predicted amino acid sequence shown above is numbered sequentially from the amino terminus of the relaxin B-chain sequence through the 164-residue prorelaxin structure to the termination codon. Therefore, the signal sequence has been numbered from methionine (−22) at the first initiation codon to be found from the 5′ end. The nucleotide sequence of a second clone (pR-RLX2) beginning at position 77 was identical over the coding region to pR-RLX1 with the exception of a deletion of alanine 49 (marked by an asterisk). This could represent the deletion of either nucleotides GCA (254–256) or CAG (255–257).

one hormone within its coding sequence. The presence of two groups of dibasic residues at positions 77–78 and 109–110 of prorelaxin could represent processing points for generation of such putative hormones. At present this suggestion is purely speculative, and based only on the conservation during evolution in at least one and possibly two species of relaxin of what seems to be an unnecessarily large C peptide. There is no information on the fate of the C peptide. However, it should be possible to develop radioimmunoassays using synthetic peptide fragments based on the C-peptide sequence proposed here. Such studies should define whether the C peptide is stored and secreted along with the 6K form of relaxin.

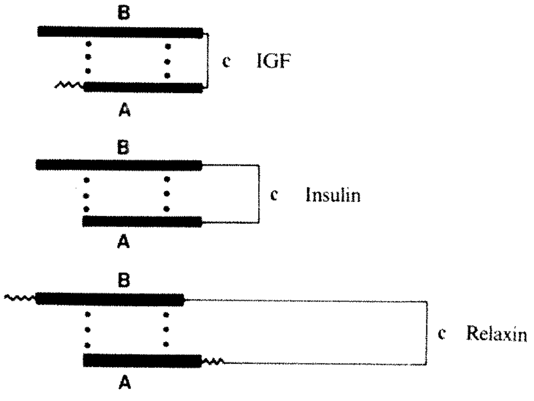

Fig. 5 Schematic comparison of the prohormone structures for insulin-like growth factors[40], insulin[40] and relaxin. These structures represent the precursor form of the hormones after the signal peptide has been removed and before subsequent enzymatic cleavage. The precursor molecules all have structures designated from the amino terminus as B chain: connecting (C) peptide: A chain, with the relative size of the C peptides drawn approximately to scale. The wavy lines represent relaxin and IGF A- and B-chain regions which are nonhomologous to insulin.

The genes for rat preprorelaxin

The finding of two clones encoding slightly different preprorelaxin molecules was fortuitous and resulted from the fact that the single difference (deletion of a base triplet) removed a *Pst*I cleavage site. It seems unlikely that the difference occurred during cDNA synthesis or cloning, as several examples of each type of clone were found. It is more likely that they represent different preprorelaxin mRNAs, whose translation products would differ only by the presence or absence of alanine at position 49 (within the C-peptide region).

There are several possible explanations for the finding of two preprorelaxin mRNAs. As the mRNA was extracted from pooled ovaries from at least 20 pregnant rats from standard laboratory strains not specially selected for genetic uniformity, allelic variation may account for the two mRNAs. Alternatively

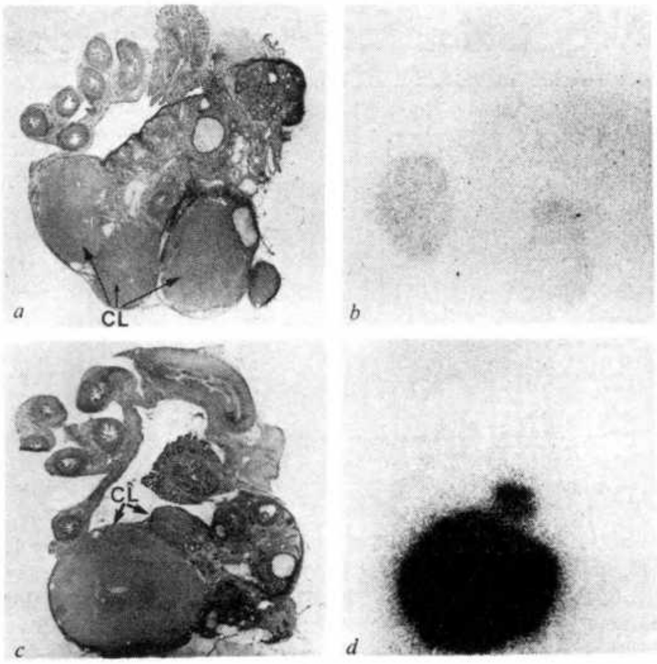

Fig. 6 Hybridization histochemistry[43] used to detect the site of hormone synthesis at the mRNA level in rat ovaries. A relaxin-specific radiolabelled cDNA probe was synthesized from 200 ng of the *Hpa*II fragment of pR-RLX1 (nucleotides 40–628). This represents the entire coding region of rat preprorelaxin with only a small portion of the untranslated regions. The synthesis of the radioactive probe followed the procedure of Taylor *et al.*[49] incorporating [α-^{32}P]dATP with polymerase I (Klenow fragment) and random primers. Tissue sections (6 μm) were cut on a cryostat, fixed and hybridized according to a previous method published from this laboratory[43]. *a*, A non-pregnant rat ovary with corpora lutea marked CL (arrowed) and adjacent stroma, follicles and uterine tube; *b*, autoradiograph of *a* showing background labelling; *c*, a late pregnant rat ovary (18th day) with corpora lutea, adjacent follicles and uterine tube; *d*, autoradiograph of *c* showing heavy labelling of corpora lutea as the site of highest mRNA concentration in the ovary. ×10.

there may be two non-allelic genes for relaxin, as there are for rat insulin[35]. It may be relevant that the deletion found in type II clones is almost exactly in the position of the intervening sequence within the C-peptide regions of human and chicken insulins[36,37] and rat insulin II. This raises a further possibility, that the deletion is the result of a minor variation in excision of an intervening sequence. Such a mechanism has been suggested as a possible source of the 20K version of human growth hormone which differs from the usual 22K form by the deletion of residues 32–46 (refs 38, 39).

Whatever the origin of the two relaxin mRNA species, it seems plausible to suggest that an intron may interrupt the coding sequence for the relaxin C peptide in the genomic DNA. It has previously been proposed that the intervening sequence in the insulin C peptide may account for its being the most highly variable part of the proinsulin molecule, with additions and deletions as well as sequence changes[40]. The striking variability in the size of the C peptide between insulin, relaxin and IGF (Fig. 5) could reflect variations in the relative extent of removal of a common 'genomic C bridge' by successive processing of pre-mRNA and prohormone molecules. These hypotheses can be tested by examining relaxin-encoding clones obtained from cDNA and genomic DNA from individual rats.

Site of hormone biosynthesis in rat ovaries

Immunohistochemical studies have detected relaxin in the corpora lutea of rat ovaries during pregnancy[41] and in cytoplasmic vesicles in pig corpora lutea[42]. These studies support the belief that relaxin is synthesized on ribosomes of the rough endoplasmic reticulum and stored in vesicles of the granulosa lutein cells. We have used an alternative approach, termed hybridization histochemistry[43], which has the advantage of being able to detect in specially prepared whole sections of tissue those areas which contain specific mRNA populations. Using a ^{32}P-labelled cloned cDNA probe corresponding to the coding region of rat preprorelaxin we have identified the major site of mRNA synthesis in ovaries of pregnant rats (Fig. 6). The specificity for the corpora lutea compared with background labelling on adjacent areas of tissue indicates the presence of high levels of relaxin mRNA within the corpora lutea. There was a low level of labelling of the corpora lutea of ovaries from non-pregnant rats due to either nonspecific adsorption or the presence of small amounts of relaxin-specific mRNA in the non-pregnant state. It should be possible to demonstrate the period during which the relaxin gene(s) are expressed by studying the hybridization of the probe to tissue sections taken at various stages throughout pregnancy. Furthermore, when probes corresponding to relaxin mRNA are available from other species such as the human and guinea pig, the technique could be used to examine questions which have been raised[44,45] concerning the site of relaxin synthesis in tissues other than the ovaries.

We thank Jennifer Penschow for preparation of sections for hybridization histochemistry, Dr D. Kemp for terminal transferase and Dr J. Messing for M13mp7. AMV reverse transcriptase was provided by Dr J. Beard through The Office of Program Sources and Logistics, Viral Cancer Program, NCI. This work was supported by grants from the National Health and Medical Research Council of Australia, the Myer Family Trusts, the Ian Potter Foundation, the Howard Florey Biomedical Foundation (USA) and by grant no. HD 11908 (to H.D.N.) from the NIH.

Optical spectrum of the unusual supernova remnant G109.1−1.0

William P. Blair & Robert P. Kirshner

Department of Astronomy, University of Michigan, Ann Arbor, Michigan 48109, USA

The new supernova remnant G109.1−1.0 has important X-ray and radio parallels to the SS433–W50 pair. We have obtained a spectrum of the faint optical filaments associated with the large shell-like radio source. The spectrum shows strong [S II] λλ 6,717, 6,731 emission relative to Hα, which is characteristic of shock-heated gas and which confirms that the filaments are part of the supernova remnant, and is generally similar to spectra of the Cygnus Loop. By assuming pressure equilibrium between the optical filaments and the interior of the remnant, we find an initial energy of 3×10^{51} erg, which is higher than that found from X-ray measurements. When compared with W50, the G109.1−1.0 remnant has filaments of higher density, and weaker [N II] emission.

G109.1−1.0 is a newly discovered galactic supernova remnant (SNR) which has been found to be a source of both X-ray[1] and non thermal radio radiation[2]. The X-ray image obtained with the Einstein Observatory shows an incomplete shell of emission with a diameter of ~36 arc min. A strong, compact X-ray source with no known optical counterpart appears at the centre of the X-ray shell. The radio observations show a smaller but complete shell with a spectral index $\alpha\approx-0.5$ ($S_\nu \propto \nu^\alpha$), which is typical for SNRs. These observations also show enhancements in the radio shell along a NE–SW line which approximately line up with a jet-like feature seen both in radio and X ray. This morphology has strong parallels with the association[3–5] between the SNR W50 and the bizarre object SS433.

The distance of G109.9−1.0 has been estimated from its radio surface brightness, Σ, assuming a relationship between Σ and the diameter (D). However, because the angular size of the SNR is different in X-ray and radio maps, and because of differences in the various Σ–D relations, the distance is only roughly known, with estimates ranging from 3.6 to 5.2 kpc. Using the X-ray angular diameter of ~36 arc min, and parameterizing to distance d = 4 kpc, we find the diameter of the SNR is

$$D = 41.9\left(\frac{d}{4\ \text{kpc}}\right)\ \text{pc}$$

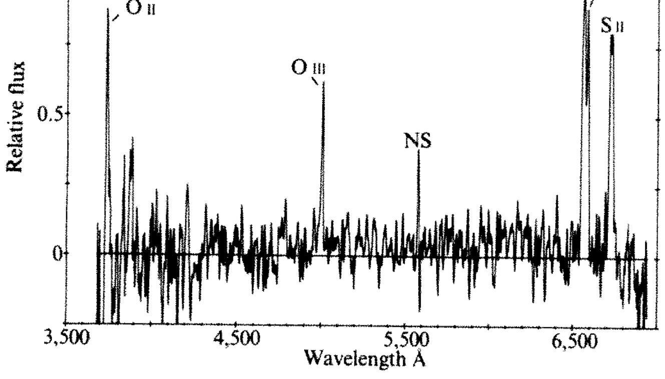

Fig. 1 The optical spectrum of G109.1−1.0 as observed at McGraw-Hill Observatory on 17 October 1980.

Table 1 Line strengths for G109.1−1.0

Line	λ	F(Hα = 100)	I(Hα = 100)†	Cygnus‡ Loop-Pos 2
[O II]	3,727	85	762	430
Hβ	4,861	<15	<48	34
[O III]	4,959	15	44	28
[O III]	5,007	52	151	85
[N II]	6,548	29*	29	29
Hα	6,563	100	100	100
[N II]	6,584	89	86	87
[S II]	6,717	73	66	72
[S II]	6,731	73	66	55

* Assumes [N II] λ 6,584/λ 6,548 = 3.0.
† Assumes $E(B-V)=1.1$.
‡ From ref. 8.

Near the regions of enhanced radio emission are several faint optical filaments visible on the Palomar Observatory Sky Survey (POSS) red plate and on deep Hα and [S II] Schmidt plates[2]. We obtained a spectrum of one of these filaments on 17 October 1980 with the intensified Reticon scanner on the 1.3-m telescope at McGraw-Hill Observatory. This filament is located in the southern portion of the remnant at (1950) α = 22 h 59 min 45 s, δ = 58° 25′ 05″; it runs in a nearly radial direction and is about 2 arc min in length. A 4 × 40 arc s slit was placed along the filament and alternate 10-min integrations were obtained on the object and on a sky position ~10 arc min to the south—well outside the observed emission region. This technique along with the extreme faintness of the filament caused inexact sky subtraction in the resulting spectrum, which is shown reduced to fluxes by standard methods[6] (Fig. 1). The total integration time on the object was 3,000 s.

The observed line fluxes, $F(\lambda)$, relative to $F(\text{H}\alpha)$ = 100 are shown in Table 1. We were not able to detect Hβ in our spectrum and hence cannot determine the reddening directly. However, the reddening has been estimated for two Sharpless HII regions[7] nearby which are thought to be at approximately the same distance as the remnant[1]. Using a median value of $E(B-V)=1.1$, we show these reddening corrected line intensities, $I(\lambda)$, in Table 1. The relative line strengths are accurate to 30% except for [O II] λ 3,727, which is worse because the detector sensitivity is poor and rapidly changing in this region.

We have also listed in Table 1 the relative line strengths[8] of Miller's position 2 in the Cygnus Loop SNR. Comparing these with our observations of G109.1−1.0, we see broad similarities in the relative line strengths. The main difference is that the lines of [O II] λ 3,727 and [O III] λλ 4,959, 5,007 are stronger in G109.1−1.0 although the estimates of these lines are particularly vulnerable to the uncertain reddening. The strong lines of [S II] λλ 6,717, 6,731 and [N II] λ 6,584 relative to Hα are the usual indicators of shock heating[9] and this confirms that we are seeing the optical filaments of a SNR.

Our spectrum is not good enough to warrant a detailed analysis and comparison with published shock models, but we can use the relative strengths of the [S II] λλ 6,717, 6,731 lines to estimate the electron density in the S^+ zone of the emitting region. Using updated collisional cross-sections for [S II][10] and a five-level atom calculation, we estimate N_e(S II) ≈700 cm^{-2}.

As the remnant is not bright optically, it is probably still in the adiabatic expansion phase. The optical filaments are probably dense clouds which have been overtaken by the blast wave from the supernova as it travels through the interstellar gas. Using the formulation of McKee and Cowie[11], we can estimate the initial energy of the supernova by assuming rough pressure equilibrium between the clouds and intercloud gas (now emitting X rays), given by

$$E_0 = 5.6\times10^{43}(\beta')^{-1}N_e(\text{S II})D(\text{pc})^3\ \text{erg}$$

0028-0836/81/200132—02$01.00

here β' is a factor of the order of unity which relates the pressure in the cloud and intercloud gas. Using values of N_e(S II) and D mentioned earler, we find

$$E_0 = 2.88\times 10^{51}\left(\frac{d}{4\ \mathrm{kpc}}\right)^3\ \mathrm{erg}$$

This is considerably greater than the value of $\sim 7\times 10^{50}$ erg which has been found for the Cygnus Loop (which is about the same diameter) using the same method[6]. More importantly, it is more than an order of magnitude greater than the initial energy calculated from the X-ray luminosity. Using the X-ray parameters derived by Gregory and Fahlman[1], we find

$$E_0(\mathrm{X\ ray}) = 1.84\times 10^{50}\left(\frac{d}{4\ \mathrm{kpc}}\right)^3\ \mathrm{erg}$$

This type of discrepancy for SNR has been noticed previously[12] and may indicate either that the magnetic pressure in the filaments is non-negligible or that there are beams from the central object, as in W50.

The presence of a central radio and X-ray source in G109.1−1.0 and a possible jet-like structure[1] indicate a striking similarity to W50. The emission-line object SS433, which is believed to be associated with W50, also shows a double jet structure in both X rays[3] and radio[13]. The axis of this jet seems to be aligned with the enhanced 'radio ear' structure of W50 and it is in this region where faint optical filaments are visible on the POSS red print. Spectra of some of these filaments[5,14,15] indicate a qualitative similarity to the position we have observed in G109.1−1.0, except that in W50 the [N II] and [S II] lines are much stronger relative to Hα and the density as measured from the [S II] lines is lower in W50.

Cosmological consequences of grand unified theories on density fluctuations

David Lindley

Astronomy Centre, University of Sussex, Falmer,
Brighton BN1 9QH, UK

Recent investigations into the cosmological consequences of grand unified theories (GUTs) of elementary particles have shown that the observed matter–antimatter asymmetry of the Universe can be explained without recourse to the hypothesis of specific initial conditions. It is shown here that the origin of inhomogeneities in the matter distribution, which are thought to be responsible for the later formation of galaxies, cannot be explained by a simple addition of density fluctuations to the standard model. The appearance of these fluctuations, after the epoch when baryon number is fixed, is almost purely adiabatic, any departure from adiabaticity falling off in inverse proportion to the mass of the perturbation.

Fry *et al.*[1] have calculated detailed models for the creation of baryon number in the early stages of the Universe. Their results are parametrized by a quantity $K = 2.9\times 10^{17}\alpha(m_X/\mathrm{GeV})^{-1}$, where $\alpha \simeq 10^{-2}$ is the GUT coupling constant, and m_X is the mass of the superheavy X-boson whose decay is responsible for the generation of baryon number. If $K \ll 1$, the X-bosons freeze out of thermal equilibrium while they still have relativistic energies, and their number density relative to other particles is independent of the freeze-out temperature and of K. If, on the other hand, $K > 1$, the freeze-out temperature is less than m_X, and the number of X-bosons is reduced by a Boltzmann factor. The resulting ratio B of baryon to photon number then decreases with increasing K.

In models of slightly inhomogeneous cosmologies, one conventionally imagines the Universe to consist of a patchwork of pieces, each larger than the horizon at any given time, and each evolving like a separate Friedmann model with a particular value of curvature[2]. In one of the perturbed regions, the expansion rate will be slightly altered by the curvature term, and this will mean that the freeze-out epoch t_f and temperature T_f will differ from the corresponding values in the unperturbed region (which is taken to have zero curvature). If $K < 1$, this variation in T_f will have no effect on the final value of B, but if $K > 1$, B depends on T_f through the Boltzmann factor. (Strictly speaking, the dependence of B on T_f only vanishes in the limit $T_f/m_X \to \infty$, but it falls off rapidly as the X-bosons become relativistic at freeze-out.) Consider a perturbed region just entering the horizon at t_f. If the density variation is $\delta\rho/\rho = \kappa$, the expansion rate[2] will be

$$(\dot{R}/R) = \left(\frac{8\pi G}{3}\rho\right)^{1/2}(1-\kappa)^{1/2} \simeq \left(\frac{8\pi G}{3}\rho\right)^{1/2}\left(1-\frac{\kappa}{2}\right) \qquad (1)$$

Fry *et al.*[1] give a simple analytic expression for B which applies in the limit $K \gg 1$. Using a variable $z = m_X/T$, then $B = \varepsilon/z_f K$, where ε is the baryon number produced in the decay of an $X\bar{X}$ pair; z_f denotes the freeze-out temperature, and is the larger of the two solutions of

$$Kz^{7/2}\,\mathrm{e}^{-z} = 1-\frac{\kappa}{2} \qquad (2)$$

This equation, although like that given by Fry *et al.*, incorporates the modified expansion rate of equation (1). Now, let z_f be the solution of equation (2) in the unperturbed ($\kappa = 0$) region, and let $z_f' = z_f + \mathrm{d}z_f$ be the solution for non-zero κ. It is easy to show that $\mathrm{d}z_f/z_f \simeq \kappa/(2z_f - 7)$. The bad behaviour at $z_f \simeq 7/2$ is because equation (2) is an approximation which fails for small z; we therefore require $z_f \gg 7/2$, and take $\mathrm{d}z_f/z_f \simeq \kappa/2z_f$. With the expression for B, then $\delta B/B = -\mathrm{d}z_f/z_f \simeq \kappa/2z_f$. The minus sign means that regions of higher density (positive κ) have smaller values of baryon-to-photon ratio, because freeze-out occurs later in the overdense regions, where the expansion rate is reduced. These conclusions were reached qualitatively by Turner and Schramm[3] and by Barrow[4].

It can be concluded that if K is small, density fluctuations do not alter B: that is, they are entirely adiabatic. If $K > 1$, then departures from adiabaticity can be achieved, but the effect decreases with increasing K (which implies increasing z_f). There must therefore be some pair of values of K and z_f (presumably near unity) for which the non-adiabaticity is maximized. The appearance of the fluctuations is, in a sense, the opposite of isothermal, because the variation in baryon density is smaller than that in radiation density. Note that these departures from adiabaticity have no dynamical significance at these early stages of cosmic evolution, because at these times baryon number is simply a quantum number attached to the various particles comprising the radiation gas. Variations in baryon density reflect variations in the locally averaged baryon number at different points. Only at a later stage ($t \simeq 10^{-4}$ s), when nucleons become massive (non-relativistic) particles carrying the baryon number, does the distinction between adiabatic and isothermal fluctuations have a dynamical role.

0028-0836/81/200133—02$01.00

The result derived above applies directly only to those fluctuations entering the horizon at t_f. A region much larger than the horizon at this time will have the same relation betwen κ, $\delta\rho/\rho$ and $\delta B/B$ at t_f, but its subsequent evolution must be taken into account. The growth law for large perturbations is $\delta\rho/\rho \propto t$. Bardeen[5] has shown that the time-dependence of perturbed quantities depends on their definition. The analysis here, using different Friedmann models for different regions, corresponds, in Bardeen's terminology, to a description based on co-moving spatial hypersurfaces, for which the quoted growth law applies in a radiation dominated universe. By the time a large perturbation comes within the horizon, at t_h, its density contrast will have been increased by the factor t_h/t_f. Meanwhile, however, the values of B in perturbed and unperturbed regions will have remained constant, because they are quantities purely local to each region, and so $\delta B/B$ will have also remained constant. Thus the departure from adiabaticity will be reduced by a factor t_h/t_f, and as the horizon mass is proportional to t, the non-adiabatic part of the perturbation falls off in inverse proportion to the mass of the inhomogeneity. Because $t_f \simeq 10^{-33}$ s, and t_h can be as large as 10^{12} s for a region entering the horizon at recombination, the character of perturbations large enough to be of interest for galaxy formation will be purely adiabatic to a very high degree.

Hogan[6] has recently shown that, in a hot big bang, cosmological fluctuations induced by a phase transition at a later stage of cosmic history than is considered here are inevitably insufficient in magnitude to account for galaxy formation. In a 'tepid' big bang, such spontaneous fluctuations may be strong enough, but this requires $B \geq 1$ in the early stages[6], which cannot be provided by GUTs[7]. I have shown here that density fluctuations built into the initial conditions of the Universe are also incapable of being directly responsible for large matter inhomogeneities. A possible solution to this dilemma may lie in the generation of inhomogeneities through some kind of non-linear phenomenon (such as the 'Purcell effect'[8], although this requires strong adiabatic fluctuations, $\delta\rho/\rho \simeq 10\%$), or perhaps through the use of evaporating primordial black holes as a source of baryons[3].

Barrow and Turner[9] have performed a similar calculation to that presented here, but suggest that anisotropic (shear) fluctuations could produce useful isothermal variations because they alter the expansion rate at early times, but, unlike the modes considered here, subsequently decay rather than grow. Although the assumed presence of shear inhomogeneities is reasonable, at the same time one must ensure that density fluctuations are absent, to better than ~1 part in 10^{40} of the anisotropic modes, otherwise they will eventually grow and dominate. It thus seems that rather special initial conditions would be needed to create significant isothermal fluctuations.

I thank Professor R. J. Tayler for advice on the presentation and the SRC for a research studentship. I also thank John Barrow for a preprint.

Meteoroid impact into short-period comet nuclei

Mark J. Cintala

Department of Geological Sciences, Brown University, Providence,
Rhode Island 02912, USA

After their introduction into the inner Solar System, most short-period comets spend the majority of each orbit within the asteroid belt. Provided that cometary material is similar to terrestrial snow in its shock behaviour, the nuclei would accumulate meteoroids as a consequence of collisions with asteroidal debris. Here the effects which extended meteoroid bombardment might have on short-period comet nuclei in ideal conditions are evaluated; the results are extrapolated to more probable situations, and their possible implications for asteroid and meteorite studies are considered. It is suggested that after devolatilization of the nucleus, the accumulated material might combine with primary cometary solids to produce environments conducive to the formation of polymict brecciated meteorites and to influence reflectance spectra of the 'asteroid'. In addition, such meteoroids removed from active nuclei during degassing could be placed in trajectories which might evolve into Earth-crossing orbits.

It is assumed here that comet nuclei are H_2O-rich bodies with weak, probably porous structures, containing a non-negligible fraction of non-volatile 'dust'[1]. Deduction of various physical properties suggests that the impact behaviour of nuclear material can be approximated by that of terrestrial snow (Table 1). Experimental studies reveal that a projectile impacting slightly packed snow will penetrate to many multiples of its own length[2]; its final location is generally at the apex of a conical 'crater'[2]; and the 'crater' is characterized by a large depth/diameter ratio, apparently due to a large amount of target compression[3]. A least-squares fit to data by Swinzow[2] for the penetration (L) of 0.55-cm metal cubes into snow (0.41–0.42 g cm^{-3}) yields

$$L = 0.2\, d\rho^{1.045} V_i^{0.349} \qquad (1)$$

where d, ρ and V_i are the projectile length, density and impact velocity, respectively (all variables in c.g.s. units). While some of the experiments used in deriving equation (1) involved impact velocities lower ($\leqslant 1.3$ km s^{-1}) than those considered to be ideal, many were conducted in conditions expected to apply for the cases treated below—within or near the snow–ice transition regime[4,5]. As spallation will remove mass from silicate projectiles during their penetration at high velocities, equation (1) should yield upper limits to penetration depths.

Assuming that a comet is perturbed into an orbit lying completely within the asteroid belt, then the total mass flux (ϕ) of particles impacting a non-gravitating surface of unit area can be written as

$$\phi = \frac{k\alpha}{\alpha + 1}\left(m_0^{\alpha+1} - M^{\alpha+1}\right) \qquad (2)$$

where k and α are constants, m_0 is the minimum particle mass

Table 1 Brief comparison of the physical properties of H_2O snow and those deduced for comet nuclei

Property	H_2O snow Value	Ref.	Comet nuclei Value	Ref.

0028-0836/81/200134—03$01.00

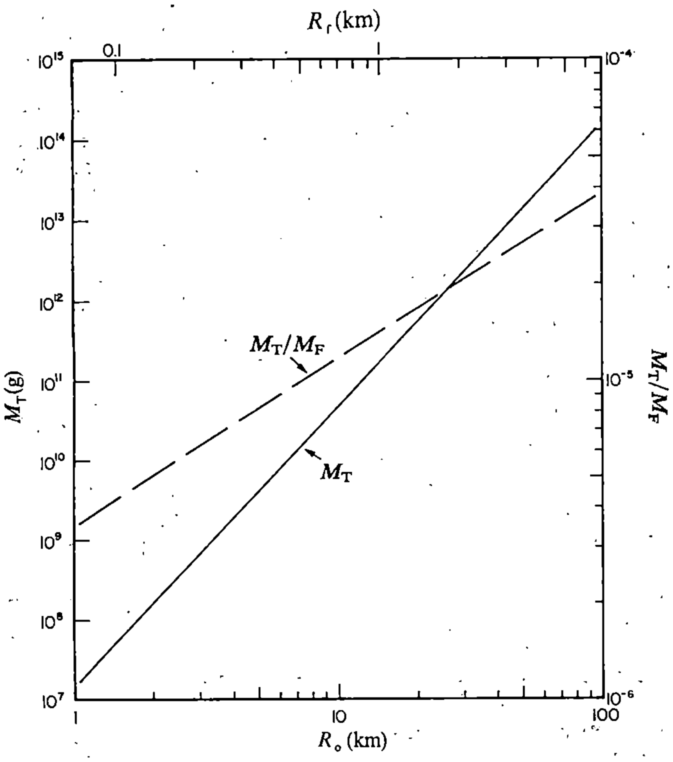

Fig. 1 Total mass of debris (M_T) accumulated by comet nuclei of various initial radii (R_0). M_F is the mass of the burned-out nucleus, exclusive of the accumulated debris, and R_f is the final radius of the devolatilized nucleus. For comparison, the lunar mare basalts comprise between 4×10^{-5} and 4×10^{-4} times the total lunar mass.

that can be retained against gas drag during the nucleus' devolatilization, and M is the largest mass which could be stopped within the average chord length of the (assumed spherical) nucleus. Projectiles with masses greater than M will either disrupt or completely penetrate the nucleus, the former of which would nullify the applicability of the following calculations. Using the equation derived by Whipple[1] to fix m_0 and equation (1) to establish M results in

$$\phi(t)=\frac{k\alpha}{\alpha+1}\left[\left(\frac{2.87\times10^{19}\rho}{nq^{27/4}R_c^3(t)}\right)^{\alpha+1} - (253.67R_c^3(t)\rho^{-2.135}V_i^{-1.047})^{\alpha+1}\right] \quad (3)$$

where $1/n$ is the fraction of incident solar radiation used in subliming ices and $R_c(t)$ is the time-dependent nuclear radius. The perihelion (q) is expressed in astronomical units. Taking the rate of change of the nuclear radius (λ) to be constant, its surface area at time t can be written as

$$A(t)=4\pi R_c^2(t)=4\pi(R_0-\lambda t)^2 \quad (4)$$

where R_0 is the initial radius. The total mass acquired by the nucleus from time 0 (introduction to the asteroid belt) to time T (total devolatilization) can be found from

$$M_T=\int_0^T \phi(t)A(t)\,dt \quad (5)$$

Only silicate projectiles will be treated here, making a chondritic density of 3.5 g cm^{-3} appropriate, and the average asteroidal encounter velocity of 5 km s^{-1} (ref. 6) will be used for this case. Conservative values of 2.0 AU and 1 will be assumed for q and n, respectively. Estimates made by Sekanina[7] yield a value of 2.84×10^{-6} cm s^{-1} for λ and a mean final radius (R_f) of $0.069\ R_0$. The impact flux in the asteroid belt suggested by Housen *et al.*[8] will be adopted, setting k and α at 4.74×10^{-17} and -0.833, respectively. Along with the fact that $R_f=R_0-\lambda T$, inserting these quantities in equation (5) yields

$$M_T=3.5\times10^{-10}(0.139R_0^{3.501}-1.204\times10^3R_0^{2.499})\ \text{g}. \quad (6)$$

The results of equation (6) for nuclei of various initial radii are shown in Fig. 1 which also includes the total accumulated masses normalized to the final nuclear mass (assuming $R_f=0.069\ R_0$ and a density of 3.0 g cm^{-3}).

It is anticipated that these former projectiles would, after devolatilization of the nucleus, be concentrated in the near-surface layers of the 'regolith'. The surface density of this 'foreign' debris (assuming an even distribution over the surface) can be found by dividing equation (6) by the final surface area of the nucleus ($A_f=4\pi R_f^2$)

$$\mu=5.85\times10^{-9}(0.139R_0^{1.501}-1.204\times10^3R_0^{0.499})\ \text{g cm}^{-2} \quad (7)$$

which, in turn, can be translated into an effective thickness (h) by

$$h(p)=\frac{\mu}{\rho(1-p)} \quad (8)$$

where p is the porosity of the surface layer. Values of $h(p)$ are plotted in Fig. 2 for various porosities and initial nuclear radii.

The orbit used in the calculations is not typical of most short-period comets[9], as most observed orbits are significantly more eccentric than that assumed here. Comets with highly inclined orbits are excluded from discussion, as they would spend negligible time in the plane of the asteroid belt. The more eccentric orbits will increase the average impact velocity of asteroid debris. Equation (3) shows, however, that the effects on $\phi(t)$ will be minor: a difference in V_i of a factor of ±5 will change $\phi(t)$ by a factor of only ∓0.3. The time spent outside the belt (hence, in a less frenzied impact environment) will also depend on the orbital eccentricity. Nonetheless, most short-period comets with aphelia inside the orbit of Jupiter spend a large fraction ($\geq75\%$) of each orbital period within the asteroid belt[10], thus placing minimal restrictions on the model results. Finally, the values of λ and $1/n$ used for the model orbit are almost certainly too high. At an orbital average distance of 2.8 AU, for example, water snow will sublime at $\sim9.2\times10^{-7}$ cm s^{-1} (ref. 11)—a rate lower than that used above by more than a factor of 3. Considering the fact that the average perihelion distance of the objects used in deriving λ is ~1.3 AU, the results given by equation (6) should be more appropriate for the

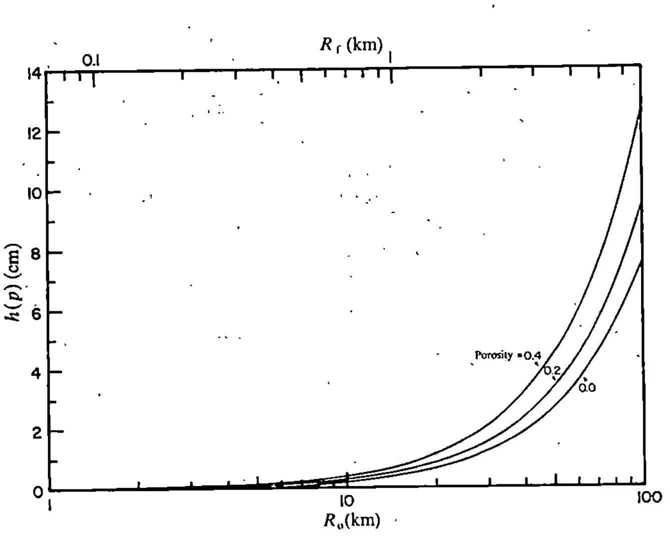

Fig. 2 Effective thickness of the accumulated debris layer as a function of porosity [$h(p)$] compared with the initial and final radii of the nucleus (R_0 and R_f, respectively). Most natural fragmental deposits have porosities of ~0.4. Projectile density: 3.5 g cm^{-3}.

Effective surface layer density (g cm^{-3}):	3.5	2.8	2.1
Porosity:	0	0.2	0.4

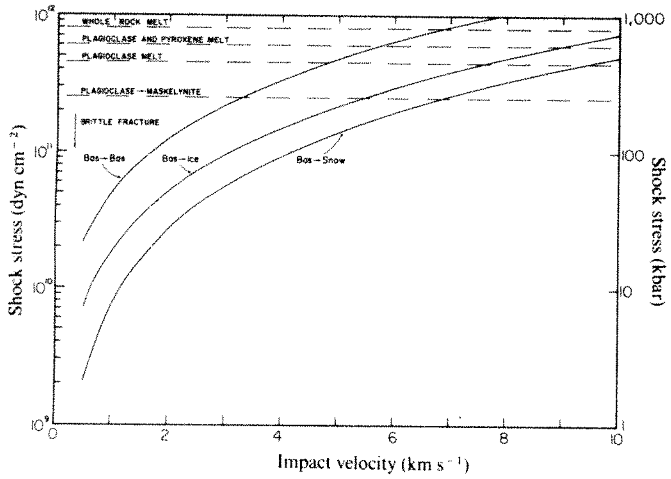

Fig. 3 One-dimensional shock stress as a function of impact velocity for basalt projectiles incident on basalt, H_2O ice, and Greenland snow. Dashed horizontal lines mark the stresses at which the indicated phase changes were observed to occur in experimentally shocked basalts[21].

average rate of radius decrease for more eccentric orbits. While ejection and vaporization of volatile and non-volatile material during impact events would also contribute to mass loss from the nucleus, its magnitude relative to the solar irradiation-induced component is unknown. The value of 1 used for $1/n$ implies that the albedo of the nucleus is effectively zero, thus yielding the unlikely condition that all incident radiation is absorbed and used in subliming the volatile ices. Clearly, this is not the case; a smaller average fraction of solar radiation will be partitioned into devolatilization of the nucleus. These values for λ and $1/n$ will yield a shorter lifetime for a given nucleus than would actually be the case. The calculated masses and effective thicknesses of debris should therefore be treated as conservative estimates *vis à vis* these parameters.

According to recent evidence[12], polymict brecciated meteorites might have been formed during low-velocity collisions between asteroids of dissimilar compositions. Another mechanism which could also account for some of these meteorite types might be the shock lithification of the variegated regolith of a burned-out short-period comet nucleus, such as that described above. Stresses sufficiently high to indurate particulate regoliths would be generated at the impact velocities expected to occur in the asteroid belt[10]. Thus, the generation of polymict breccias on such 'foster-parent' bodies would be directly analogous to the formation of their lunar counterparts. Insofar as the foreign fragments were, in all probability, originally components of asteroid regoliths[8,13], the observed abundance of implanted solar wind gases and solar flare/cosmic ray tracks should be consistent with this model.

Such a regolith would present a reflectance spectrum characteristic of the averaged behaviour of its component lithologies and/or mineralogies. While often considered to be carbonaceous, the composition of primary cometary debris is uncertain[13,14]. Thus, the spectral signature of a devolatilized nucleus cannot be predicted with confidence, suface exposures of foreign debris notwithstanding. For this reason, it would be a formidable task to select candidate objects on the basis of spectrophotometric grounds alone. Note that observations would be biased towards the larger objects, implying that the original (volatile-rich) nuclei would also have been large relative to most presently-active short-period comets[15]. This model predicts that more massive nuclei would have collected more debris, thus maximizing any spectral effects resulting from the overall process. 'Mixing models' similar to those applied by Chapman and Gaffey[16] might yield information relating to the efficiency of this mechanism. Orbital and dynamical studies of fireball and meteorite orbits present strong arguments in favour of some relationships between meteoroids and short-period comets[17,18]. Objections presented by petrologic and chemical arguments against cometary origins of non-carbonaceous meteorites[13,19] might be alleviated if the comets acquired the meteoroids during passage through the asteroid belt or at some earlier time in their histories. Figure 3 illustrates that no petrographically observable shock effects other than brittle fracture would occur in basalt-like assemblages as a result of collisions with comet nuclei at velocities lower than ~5–7 km s⁻¹. Comets in highly eccentric orbits (which characterize Earth-crossing comets, such as P/Encke) would encounter asteroidal debris at higher velocities (D. R. Davies and E. M. Shoemaker, personal communications), forcing the projectiles to incur greater shock damage. Fragments 'absorbed' by short-period comets in less elliptical orbits, however, would be subjected to relatively mild stress levels. Ejection of these meteoroids during periods of devolatilization would place them in orbits similar to that of the nucleus. If the nucleus' orbit were conducive to Jupiter-related perturbations[16], or if it had become Earth-crossing (for example, due to perturbations by Jupiter, or by nongravitational forces[20]), the ejected fragments would then be in orbits which could ultimately encounter the Earth. The total annual mass which might be delivered to the Earth by this mechanism is uncertain, but large fragments (of the order of 10^4–10^6 g, depending on the nuclear radius, perihelion, and so on[1]) can be removed from nuclei by gas drag. Because of the ease with which they lose solid debris, small nuclei should be more effective protagonists in this process.

Finally, a spacecraft with high-resolution (≤ 1 m) imaging, multispectral, and/or chemical mapping capability could survey the surface exposure of material on an active short-period comet nucleus. Such an investigation would provide important data regarding the composition, abundance and dispersal of debris in the regions of the asteroid belt traversed by the comet during its active lifetime.

This work was carried out under NASA grant NGR-40-002-088. Helpful reviews, comments and/or discussions were provided by A. Brown, J. Head, P. Mouginis-Mark, J. Whitford-Stark, L. Wilson, C. Chapman, D. Davis, F. Fanale, E. Shoemaker, J. Veverka, F. Whipple and B. Zellner. Many of the ideas presented here were conceived during conversations with members of the US Army Cold Regions Research and Engineering Laboratory in Hanover, NH. Coseismic changes in groundwater temperature of the Usu volcanic region

Hideki Shimamura & Hidefumi Watanabe

Geophysical Institute, Hokkaido University, Sapporo 060, Japan

Observations of groundwater temperature to an accuracy of 0.001 →C or better have been made at about 30 wells in various areas of impending earthquakes in Japan. The main aim of the observations was to monitor the crustal strain and/or the movement of groundwater which relate to earthquake occurrence. One thermometer was installed at a depth of 200 m in an active volcanic area, Usu, where an upward movement of the magma is occurring. We report here that there was a generally increasing temperature trend at this location: 0.3 →C in the half-year of observation. Decreases in the rate of increase preceded intense local earthquake activity. Temperature jumps were accompanied by large local earthquakes with magnitudes up to 4.2, and the polarity of the steps corresponded to the location of hypocentres. This is probably the first micro-temperature measurement made in the proximity of seismic activity.

Usu volcano, 70 km south-west of Sapporo, erupted on 7 August 1977, after lying dormant for ~30 yr. A series of eruptions followed the first one, continuing until October 1978. Many earthquakes have been observed in the area, beginning just before the first eruption and continuing to the present. The maximum magnitude of the earthquakes was 4.3. Although the earthquake activity has been gradually decreasing since the very first stage of Usu's eruption, it remains at a much higher level than that before the eruption. About two to four earthquakes of magnitude 4 are still occurring every month, so that a lot of small earthquakes are being observed by a local seismological network, consisting of 10 observation sites operated by the Usu volcanological observatory of Hokkaido University.

A precision quartz thermometer was placed in an observation well of depth 380 m, 2 km east of Usu volcano in October 1979. The quartz sensor was installed at a depth of 200 m (below this the well was too narrow). Our thermometer is accurate to 0.001 °C, has long-term stability, and is specially designed for geophysical field observations[1]. Our main aim was to monitor movements of groundwater which were probably related to changes in crustal stress and earthquake generation. Such observation is also interesting from the geothermal viewpoint, as an upward intrusion of magma beneath the volcano has been suggested[2]. Seismologically, this observation is a rare opportunity to observe many earthquakes with magnitude 4 at epicentral distances of less than several kilometres.

In general, the results show a nearly monotonic increase in the groundwater temperature (Fig. 1), which contrasts with observations in other regions; the increment being ~0.3 °C since the start of the observation. However the rate of increment has been slightly decreasing, which probably relates to the gradual decrease in volcanic activity such as crustal deformation or energy release. The thermometer has been tested for long-term stability and found to have a drift rate of less than 0.01 °C yr^{-1}, so that the observed increment cannot be due to instrumental error.

About 30 other thermometers have been installed since 1978 in various areas of impending earthquakes in Japan[1]. However, the Usu thermometer is the only one to have been deployed in an active volcanic area. Hence the general increase in recorded temperature is likely to be due to the upward movement of the magma that has been shown by various volcanological studies[2]. Other thermometers did not record such a large increment in the groundwater temperature, probably because there was no region in which a very shallow magma was rising. For the other wells the d.c.-shifts of the groundwater temperature are <0.03 °C; the present case is more than 10 times larger than those.

Fluctuations in the generally increasing rate are shown in Fig. 1. The decreases in the increasing rate precede high levels of earthquake activity. For example, they are obvious before 13 April, 30 April, and 12 May. Sometimes the ascending trend was even reversed just before intense activity. This applies to periods other than those illustrated in Fig. 1. The intense seismic activities are recurrent, but not periodic; hence we conclude that the 'predictions' of seismic activity by the change in the increasing rate of the observed temperature are caused by some physical mechanism.

It is also interesting that 'seismograms of temperature changes' are frequently recorded by the thermometer (Fig. 2). Almost all large earthquakes were recorded with sharp spikes, and most of them resulted in offsets of the temperature, as is seen in Fig. 2. The onsets of sharp spikes coincide with earthquakes within the accuracy of the sampling interval of the digital thermometer, 15 min; the peaks were reached rapidly, within the same sampling interval of the onset. On the other hand, the average time taken for the spikes to decay was a few tens of minutes. Sometimes the sampling interval was 1 h, as in Fig. 2, instead of 15 min. The amplitudes of the spikes are proportional to the local seismic intensity. The thermometer system was designed to be immune to strong accelerations in the near field of earthquakes and because it was developed to be installed in areas of impending earthquakes, there are no movable parts either in the sensing unit or in the recording unit. It was also tested for exposure to vibrations. We postulate therefore that the recorded spikes were due to frictional heat generated between the pressure case of the sensing unit and the surrounding water in the well as a result of the shaking caused by earthquakes.

Hence the spikes have little geophysical meaning except that we can estimate the thermal time constant with which the generated heat is diffused from the sensing element to the outer groundwater. In contrast, there are substantial offsets remaining

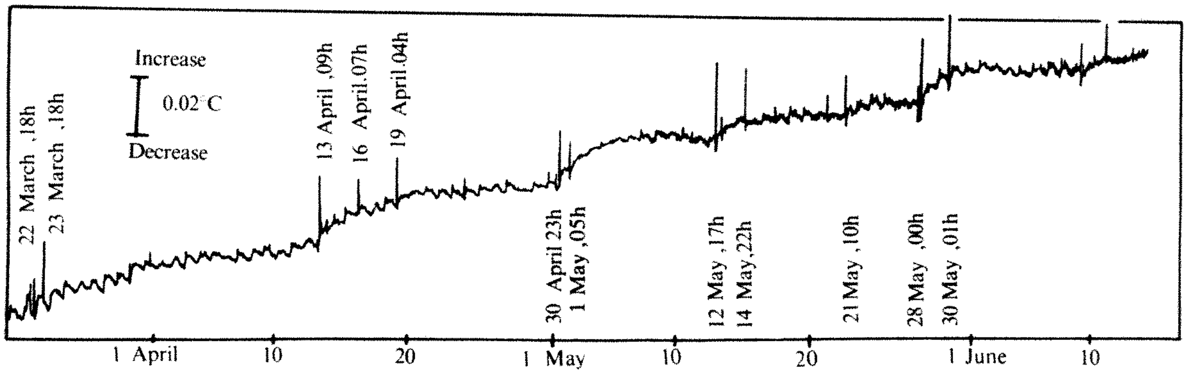

Fig. 1 Record of the groundwater temperature at Usu volcano, obtained by a precision quartz thermometer with an accuracy of 0.001 °C. Spikes correspond to large earthquakes, whose dates and times are indicated.

0028-0836/81/200137—02$01.00

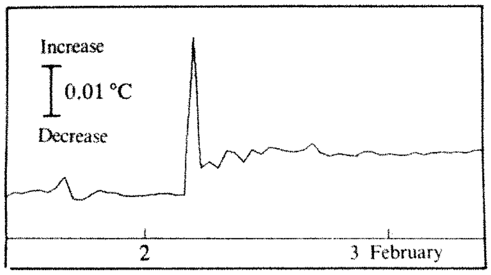

Fig. 2 A 'seismogram' recorded by the quartz thermometer. The record is characterized by a sharp spike which is accompanied by an offset of the groundwater temperature. This record was taken at the sampling interval of 1 h; the leading edges of the spikes actually have steeper onsets. Epicentre, Kita-byobu. Magnitude, 4.1.

Table 1 Magnitude and dates of earthquakes shown in Fig. 3

No.	Date (1980)	Mag	Temperature step (°C)
1	13 April	4.1	+0.0024
2	2 February	4.1	+0.0062
3	8 March	4.2	+0.01
4	23 March	4.1	+
5	23 January	4.2	+0.0063
6	23 March	3.9	−0.002
7	27 February	4.0	−0.0038
8	12 May	4.1	−0.003
9	30 April	3.9	−0.002
10	22 March	4.0	−0.0046
11	24 April	3.9	−0.001
12	14 May	3.9	−0.001

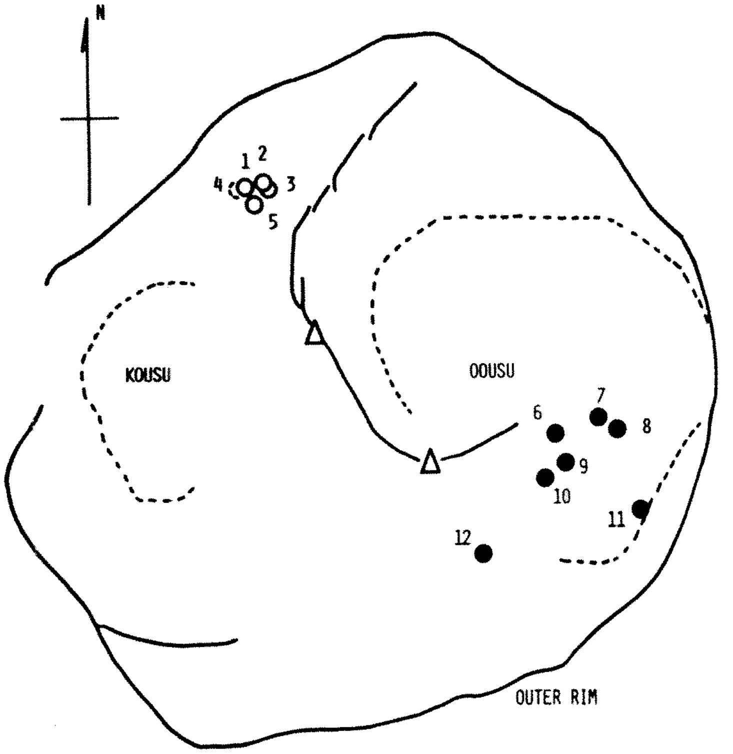

Fig. 3 The observation area, the earthquake epicentres and the location of the observation well. ●, Earthquakes with negative temperature offsets; ○, earthquakes with positive temperature offsets. The U-shaped solid line in the crater is a major surface fault zone. The earthquakes are listed in Table 1. Temperature offsets without a numeral indicate that the amount was too small to be reliably read, although polarity was positive. For magnitudes and dates of earthquakes see Table 1.

after the spikes: both positive and negative offsets were observed which indicates that the recorded offsets are not instrumentally caused by the strong vibration, because the local accelerations of the earthquakes were identical for the two groups which caused inverse polarities. We found that the polarity of the offsets are definitely determined by the locations of earthquake foci; the amounts of the offsets are closely related to earthquake magnitude (Fig. 3). However, we have not found a relationship between the amplitudes of the offsets and the focal depths that were distributed from the surface to 1.2 km.

The largest positive offset, +0.01 °C, was recorded during a magnitude 4.2 earthquake on 8 March 1980. All the group earthquakes (including the magnitude 4.2 earthquakes) that were associated with the positive offsets, occurred beneath the Kitabyobu region, which is the north-west part of the crater of the volcano. The group of earthquakes associated with negative offsets occurred, also without exception, beneath Oousu-minami, which is the south-east part of the crater. The mean epicentral distances of the two groups from the observation well were 2.7 and 1.5 km respectively.

These groups of earthquakes have their own focal mechanisms, which are almost identical within the groups: reverse fault for Kitabyobu, normal fault for Oousu-minami. Both mechanisms have fault planes which are steeply dipping. The fault mechanisms are consistent with a thrust movement, towards the north-east, of the U-shaped surface fault zone, which has been observed by geodetic measurements and geological observations.

At Usu volcano, large earthquakes occur only in these two regions. Smaller earthquakes are more diverse, covering almost all the crater region, and some occur beyond the outer rim, a few kilometres north-east. We did not observe offsets of the groundwater temperature for earthquakes whose magnitudes were <3.7, regardless of their focal locations, thus we do not know whether these small earthquakes generate smaller offsets beyond our detection capability, or whether they inherently do not generate offsets.

We do not have a definite physical explanation for the observed phenomena, the steep trend of the increase in groundwater temperature and the offsets of the temperature. However, the former is probably related to the upward movement of the magma, and the latter to a sudden release of the pore pressure when an earthquake occurs. If so, the monitoring of the pore pressure by the precise monitoring of the groundwater temperature is a promising technique for predicting earthquakes.

Recent glacier variations and volcanic eruptions

Stephen C. Porter

Quaternary Research Center, University of Washington, Seattle, Washington 98195, USA

The injection of volcanic dust and gases into the atmosphere during major eruptions has been advanced to explain short-term variations of climate[1–4]. A calculated global cooling of ~1 K during episodes of intense volcanic activity[3] could lead to a snowline depression sufficient to cause glacier advances equivalent to those of the last several centuries. The hypothesis would therefore be strengthened if a close relationship could be demonstrated between global volcanicity and the pattern of recent glacier variations. Glacier activity in the Northern Hemisphere during much of the past 100 yr shows a lack of synchrony with that in the Southern Hemisphere, but in each hemisphere the sequence of glacier variations matches the acidity record in polar ice cores and the frequency of volcanic eruptions in successive latitude belts. This suggests that glaciers fluctuate in response to atmospheric build-up of volcanic aerosols produced during large eruptions and that explosive volcanism may therefore be a major factor in modulating climate on the decadal scale.

Temperate mountain glaciers are an important source of proxy climatic data, for they respond rapidly to variations of climate by changing in size. A relationship between glacier fluctuations and volcanic episodes would imply a possible link between eruptive activity and climatic change. Fluctuations of many middle-latitude glaciers have been documented during the present century, and for certain glaciers discontinuous observations extend back into the nineteenth, eighteenth or even seventeenth centuries. For glaciers where such data do not exist or are incomplete, records of marginal variations during the past several hundred years often can be reconstructed and dated using geological and botanical methods[5].

Active volcanoes, defined as those which have erupted at least once since AD 1800, are concentrated disproportionately in the Northern Hemisphere; most lie between 60 °N and 10 °S latitude near the margins of converging lithospheric plates[6] (Fig. 1*a*). Few are found south of latitude 20 °S, and their number drops off sharply in both hemispheres polewards of 60°. This asymmetrical global distribution suggests that cumulative long-term loading of the atmosphere by volcanic aerosols may vary with latitude. This inference is supported by Lamb's plot showing the frequency of large dust-producing eruptions as a function of latitude which is dominated by eruptions in equatorial and northern middle latitudes (Fig. 1*b*). Dust entering the upper atmosphere at low latitudes is likely to disperse into both hemispheres, whereas dust injected at high latitudes may remain largely in one hemisphere[1,3]. Consequently, if large volcanic events do affect climate, then differing frequencies of major eruptions in successive latitude belts might produce contrasting climatic responses that could generate asynchronous patterns of glacier behaviour in the two hemispheres.

Most detailed records of glacier variations in the Northern Hemisphere come from mountainous areas lying between 40° and 70 °N latitude (especially Scandinavia, the Alps and northwestern North America) (Fig. 2); although the mountain ranges of central Asia contain many glaciers, sporadic observations, often separated by several decades[7], and the presence of surging glaciers make that region unsuitable for detailed analysis. Glacier advances during the past 100 yr culminated mainly between about 1880 and 1895 and between 1910 and 1925. An intermediate advance, climaxing between about 1900 and 1906, has been reported only south of latitude 62°. An episode of renewed advance began as early as the middle 1950s but increasingly was detected in the 1960s throughout northern middle latitudes. Widespread retreat of glaciers marked the interval between the middle 1920s and the early 1950s, with recession being most pronounced in the 1930s and 1940s[8–11]. Although there were a few reported advances during this interval, most involved surging glaciers. This period of marked retreat, one of the most striking features of the recent Northern Hemisphere glacial record, has attracted much attention, for not only did many glaciers experience considerable reduction in size, but some disappeared entirely.

The few mountain areas at low latitudes that support glaciers are poorly studied, but the limited data available suggest a pattern of fluctuations similar to that of northern middle latitudes.

Southern Hemisphere data come mainly from New Zealand and the Andes, although limited information is also available for certain sub-Antarctic islands. There are fewer recorded observations than for the Northern Hemisphere (Fig. 2) and conclusions based on them are, therefore, less reliable. Despite the large number of glaciers in the Andes, the record from South America is less well known than that from New Zealand and represents a smaller sample. Some of the best-documented advances in the southern Andes involve possible surging glaciers and were excluded from consideration. Glacier advances in the Southern Hemisphere culminated between the middle 1870s and the middle 1890s, between 1906 and 1910, in the first half of the 1930s and in the late 1940s. A recent renewed advance began in the late 1950s to early 1960s, slightly later than in the Northern Hemisphere.

In spite of the common view that glacier fluctuations have been in phase globally during the past 100 yr, in fact they were largely asynchronous between the Northern and Southern Hemispheres for much of this period (Fig. 2). Although a widespread re-advance of glaciers characterized the final decades of the nineteenth century in both hemispheres, a subsequent re-advance in northern middle latitudes that peaked between 1910 and 1925 preceded one in southern middle latitudes which culminated in the early to middle 1930s, a time when Northern Hemisphere glaciers were experiencing their most significant period of retreat. An advance of New Zealand

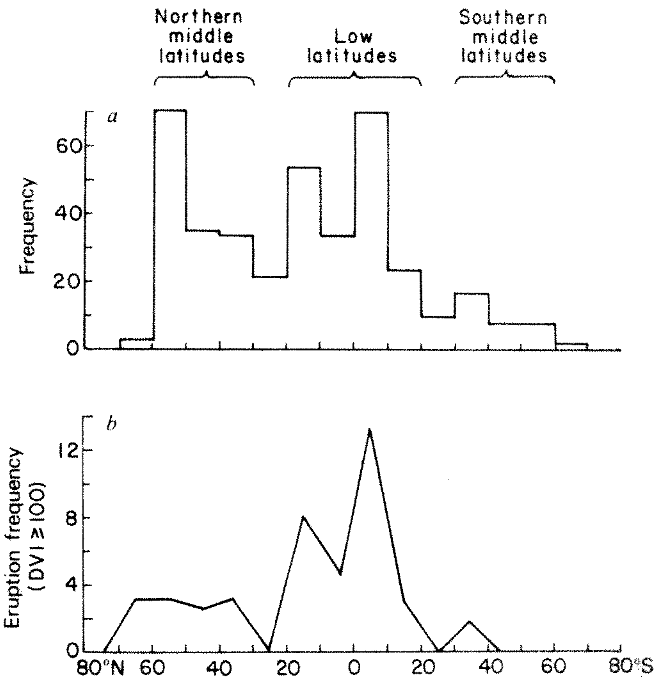

Fig. 1 *a*, Distribution of active volcanoes as a function of latitude. Data compiled from ref. 6. *b*, Number of eruptions per 10° latitude band producing a dust veil index (DVI) of ≥100 (excluding area south of 50 °S) for the period 1800–1964 (from ref. 1, Fig. 19a).

0028-0836/81/200139—04$01.00

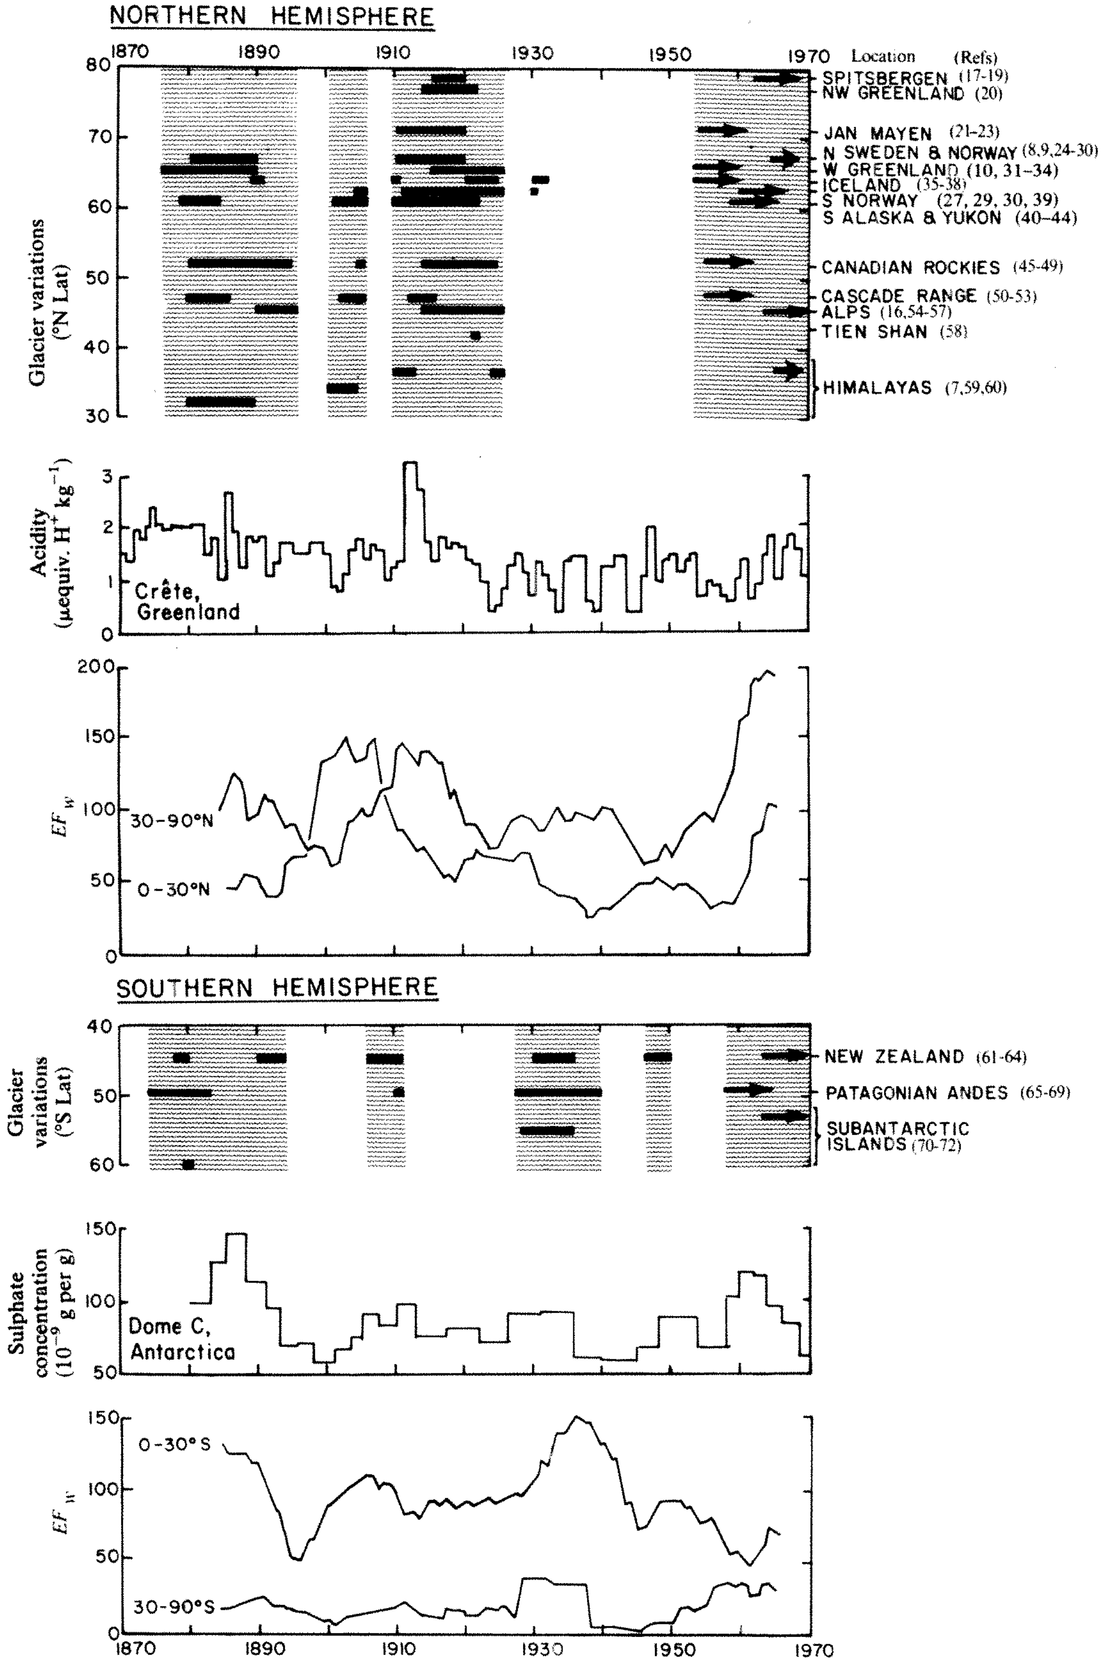

Fig. 2 Comparison of recent glacier variations in the Northern and Southern Hemispheres with acidity profiles from polar ice sheets and frequencies of recorded volcanic eruptions. Data sources for glacier variations given in parentheses. Bars represent intervals within which reported glacier advances culminated and are based mainly on direct observations; in a few cases they are based on ring counts of glacially tilted trees and by lichenometric dating where well-controlled lichen-growth curves have been constructed. Beginning of recent episodes of advance indicated by arrows. Data from known or suspected surging glaciers were excluded because marginal fluctuations of such glaciers may be anomalous and apparently unrelated to local or regional climate. Northern Hemisphere data set includes 115 culminations recorded for 76 glaciers, as well as 10 regional summaries, whereas Southern Hemisphere set represents 50 culminations for 30 glaciers. Spread of dates within each interval mainly reflects response lags of glaciers of different size or having different activity indices, or possible dating uncertainties. Vertically shaded zones show main groupings of data within each hemisphere. Acidity records from Crête (central Greenland) are from ref. 12, while Dome C (Antarctica) data are from ref. 13. Time series of weighted eruption frequencies (EF_w), based on compilation of Hirschboek[14], are 10-yr running totals.

glaciers that culminated in the late 1940s was not matched in northern latitudes where most glaciers continued to recede until the middle 1950s. This contrast in recent glacier fluctuations in the two hemispheres must be explained by any acceptable hypothesis of short-term climatic change.

A comparison of the hemispheric records of glacier fluctuations with variations in the concentration of volcanically-generated sulphate in polar ice sheet cores that has accumulated over the same time interval discloses some striking parallels. Volcanic acids deposited in snow layers shortly after a large eruption can be detected by measuring specific conductivity of meltwater samples or by electrical measurements of solid ice. An acidity profile along the well-dated Crête ice core from central Greenland[12] has strong peaks in the middle 1880s and about 1912–15. Sulphate concentration in snow layers from Dome C in East Antarctica[13] is high in the middle to late 1880s agnitude larger than moderate eruptions. Deca[redacted]ng tals for the period since 1880 are based on more 00 eat and moderate events. The time series show t te 880s and early 1890s were volcanically active in is- heres, but that during the twentieth century the N ern lemisphere experienced periods of high volcanic activity during e 1900s (especially at low latitudes), the 1910s (especially at iddle and high latitudes) and in the late 1950s and the 1960s. olcanoes in the Southern Hemisphere were active during the rst decade of this century at low latitudes, but the major period f eruptive activity in both latitude zones occurred between bout 1928 and 1940.

The two types of volcanic records each have shortcomings for nalysis of the spacial and temporal significance of aerosol-roducing eruptions. The existing ice-core records come from ne polar regions (71.6° N and 74.7 °S, respectively) and prob-bly emphasize eruptive events at middle to high latitudes although certain large low-latitude events like the 1883 erup-ion of Krakatoa (6 °S) are recognizable in both ice sheets; the ower magnitude 1963 Agung event (8.5 °S) is identified as a trong peak in the Antarctic core but is less pronounced in the reenland record). The acidity curves may de-emphasize large ow-latitude eruptions that generate little sulphate but eject fine sh in quantities sufficient to affect the climate for brief periods. The eruption frequency curves do not distinguish between sh-emitting eruptions and important sulphur-rich eruptions, he latter producing the most significant long-lasting atmos-heric effects. Furthermore, the frequency variations must artly reflect varying observational frequency rather than vary-ng volcanic activity. Nevertheless, the similar pattern in the two ypes of record over the past 100 yr suggests that they may rovide a reasonable picture of the temporal and spacial dis-ribution of major eruptions which have had the greatest impact n the atmosphere.

Episodes of glacier resurgence culminated during or shortly after intervals marked by high acidity levels in polar ice and increased frequency of volcanic eruptions in each hemisphere. The high eruption activity of northern middle- to high-latitude volcanoes in the 1910s and a corresponding acidity peak in Greenland ice, for example, coincided with widespread north-ern latitude glacier advances that culminated mainly between about 1912 and 1925, while high volcanic activity, a secondary acidity peak in Antarctic snow, and glacier re-advances marked the late 1920s and the 1930s in southern middle latitudes. The northern low-latitude peak in volcanic activity during the first decade of this century coincides with glacier advances in lower middle latitudes; such advances have not been reported from high latitudes. A similar pattern is seen in the Southern Hemisphere at the end of that decade. The resurgence of glacier activity in both hemispheres beginning in the middle to late 1950s parallels an increase in reported volcanic eruptions, as well as increases in acidity levels in the polar ice sheets.

The data base used in this analysis is of necessity restricted largely to middle latitudes. Moreover, the Southern Hemisphere data are less numerous than those from northern latitudes; this partly reflects the greater extent of land and of glaciated mountains in the Northern Hemisphere, but also a more thoroughly documented observational record. Further testing of the hypothesis, involving information from low-latitude glaciers, must await further data.

Extension of the analysis back in time is also desirable, but the number of carefully-documented glacier observations falls off rapidly in the decades before the middle nineteenth century, and the spacial distribution of data becomes much more restricted. middle latitudes that climaxed between about [illegible]25, and 1845–55[16] match rises in ice-core acidity levels and in the frequency of great ash eruptions[12,14]. These relationships, like those documented above, support the view that volcanic aerosols produced during episodes of large-scale eruptions are a major factor in modulating climate on the decadal scale.

This paper, an outgrowth of research supported by the NSF under grants EAR76-05704 and EAR78-23416, was written while I was a visiting scholar at Scott Polar Research Institute and a visiting fellow in Clare Hall at the University of Cambridge. I thank R. S. J. Sparks and G. de Q. Robin for critical reviews.

Glaciation, erosion and uplift over part of East Antarctica

Peter Wellman & R. J. Tingey

Bureau of Mineral Resources, PO Box 378, Canberra,
Australia 2601

Isostatic rebound effects after the removal of large glacial loads are well known from several parts of the world, but isostatic uplift during glaciation and caused by glacial erosion is less well documented. This is because preglacial landscapes, which provide a datum against which glacial erosion and related uplift is measured, are generally either destroyed by glaciation or not recognized. Remnants of such a preglacial land surface are exposed in the Prince Charles Mountains of East Antarctica. We now report that the amount of glacial erosion here is 1.5 km, measured by the difference in level between the preglacial land surface and the present mean (mostly subglacial) rock surface. The isostatic uplift caused by this erosion is ~0.8 km. Both amounts are thought to be well above average for East Antarctica and glaciated areas in general because the region is traversed by East Antarctica's largest outlet glacier system, parts of which are believed to surge periodically.

The Prince Charles Mountains (72° S, 72° E) are composed of complexly deformed Archaean and Proterozoic igneous, sedimentary and metamorphic rocks which are intruded by Cambrian granites and locally overlain by small intermontane enclaves of Permian sedimentary strata[1]. Near the main glaciers of the Lambert Glacier system the rocks are exposed in large mountains and massifs with broad, roughly concordant, summit plateaus; away from the glaciers there are long low ridges or small nunataks with spiky summits at the same or a lower level[2].

Topographical data[3] and field and airphoto studies have shown that summit altitudes range systematically from 1.25 km in the centre of the area—where summit plateaus are very flat and have 0.2 km of relief—to 2.60 km at the margins where summits, though roughly concordant, are of less uniform altitude (Fig. 1; Fig. 2 curve a). This has led to the interpretation, at first based mainly on morphological grounds, that the summits are relics of a preglacial erosion surface of generally low relief and locally nearly planar. A surface along the flanks of the Amery Ice Shelf with a present altitude of 0.2 km (Fig. 1 stippling) may be a downfaulted continuation of the erosion surface exposed further south. Remnants of nearly planar erosion surfaces of pre-breakup age are widespread in various Gondwanaland fragments[4-6] and we believe that the erosion surface exposed in the Prince Charles Mountains is of the same origin and age.

The summit plateaus in the Prince Charles Mountains, although regarded as the relics of a preglacial erosion surface have, nonetheless, been glaciated and have local mantles of exotic glacial debris and striated pavements. At one locality, however, (Fig. 1D) an erosion surface on banded gneisses is unconformably overlain by a partly vesicular olivine leucitite flows that gives a K–Ar whole-rock age of 50.4 ± 2.0 Myr (ref. 7). The 3 × 1 km flow remnant has vertical sides standing up to 10 m above the adjacent erosion surface. From the existence of this Eocene flow we infer that the underlying erosion is of pre-Eocene and therefore of preglaciation age, and that the

ııo [redacted] kness surveys[illegible] show that the present rock surface
has of up to 4 km. They are used together with the
alti exposed rock masses in estimation of the present
me rface level for 50 × 50 km areas. These in turn were
use alculate a running mean of rock altitudes over 100 × 100 km areas (Fig. 1; Fig. 2, curve e). This mean rock surface (curve e) ranges from −0.5 km along the axis of the lower Lambert Glacier to +0.5 km at the margin of the area studied The difference in level between it and the mean preglaciation surface (Fig. 2, curve a′) ranges from 1.3 to 2.0 km with a mean near 1.5 km; it is a measure of the regional glacial erosion.

Erosion of this order is likely to have caused vertical movement of the crust in the Prince Charles Mountains area although this will have been counteracted by the effect of the present glacial load. The low relief of the preglaciation land surface is interpreted as evidence that the area was stable in relative altitude and hence likely to have been in isostatic equilibrium before glaciation. We concluded[12] that the area is now in

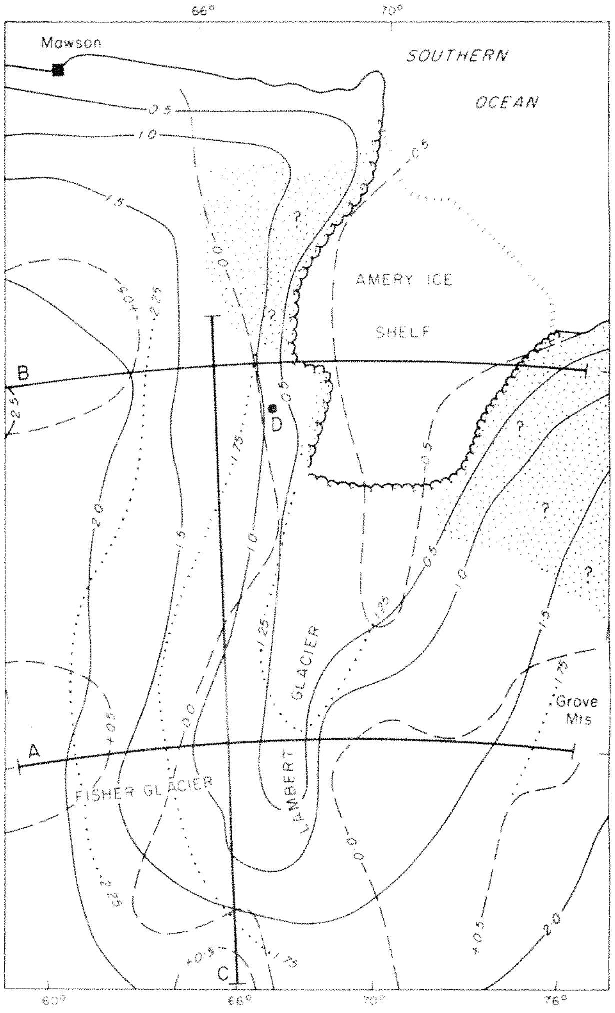

Fig. 1 Map of the Prince Charles Mountains area showing the present-day altitudes in kilometres of the high points of the summit plateau surface (dotted lines), the mean rock surface (dashed lines) and the ice surface (solid lines). Thick lines show the location of Fig. 2 cross-sections. D is the location of the Eocene lava flow discussed in the text. The stippled area is a possible downfaulted portion of the summit plateau surface, now at 0.2-km altitude.

0028–0836/81/200142—03$01.00

isostatic equilibrium from a previous analysis of mean rock altitudes, ice thicknesses for 100 × 100 km areas, and gravity data. If crustal structure does not change, then the removal by erosion of rock masses from a crust in isostatic equilibrium results in an uplift of the crust to maintain this equilibrium. The magnitude of this uplift depends on the density contrast between the crustal rocks and the underlying upper mantle[13]; it is likely to be between 0.80 and 0.87% of the thickness of rock removed. If there were no present-day ice load the original level of the preglaciation peneplain surface could be calculated to have been above the level of the present regional mean rock surface by 0.13–0.20 times the thickness (1.3–2.0 km) of rock removed by glacial erosion, or 0.17–0.40 km.

However, the present mean rock surface (Fig. 2, curve e) is depressed by ice loading, the effect of this loading being the same as that of a rock layer with the same mass per unit area as ice, that is 0.27–0.29 times the ice thickness (Fig. 2, curve b minus curve e) or between 0.3 and 0.5 km. On deglaciation the mean rock surface would be at the level of curve d of Fig. 2. The original level of the preglaciation peneplain would therefore have been 0.17–0.40 km above the level of curve d, at the level of curve c. It would have ranged up to ~1 km altitude near the edge of the region studied. The amount of isostatic uplift that has already occurred as a consequence of glacial erosion is given by the difference between the present level of the mean preglaciation surface (Fig. 2, curve a′) and its original level (curve c). It is between 0.7 and 1.5 km with a mean of 0.8 km.

This uplift and both the rate and amount of glacial erosion that caused it are thought to be above average for East Antarctica and glaciated areas in general because:

(1) The area is traversed by the largest ice stream in the world—there is a large ice flux from a large catchment.

(2) Glacier velocities are high because the area is near the maximum slope of the Antarctic ice cap and the lower sections of the glaciers have basal melting.

(3) At least part of the glacier system may be subject to periodic surging, with consequent short-lived episodes of very vigorous erosion.

However, the relative size of the present-day and past erosion rates is unknown. Modern evidence for near-surface glacial erosion in the Prince Charles Mountains is not abundant and consists of local undercutting of steep cliffs by locally steep, heavily crevassed glaciers. The major ice streams that traverse the Prince Charles Mountains have a base at or near pressure melting point[14], so significant subglacial erosion may be occurring[8,9]. However, it is possible that the valleys are now sufficiently deep that there is no significant erosion at the present flow rate. It seems unlikely that much of the erosion took place during the alpine glaciation that preceded the continental glaciation in the Miocene, because we believe that at this time relief and altitude were low in the Prince Charles Mountains area. It is more likely that erosion along the ice streams has continued during the whole period of continental glaciation but, except initially, has been intermittent and largely related to periodic surging of the glaciers. Such surging is suggested by glaciological studies[14,15], and also from an interpretation of moraines between 0 and 200 m above the present ice level of the Fisher and lower Lambert Glaciers[16]. Normal movement of large glaciers at rates between 50 and 200 m yr^{-1} is achieved by ice shear and recrystallization within the ice mass. During short-lived periodic surges the glacier movement and erosion are several orders of magnitude greater, the fast movement being by the ice moving on a basal water layer.

Evidence for high erosion uplift rates is likely to be found elsewhere in East Antarctica where major glaciers such as the Jutulstraumen traverse mountainous areas near the maximum slope of the ice cap. In mountainous areas of Greenland and north Canada, on the other hand, erosion and erosion-induced uplift are probably occurring more slowly because the glaciers are smaller and zones of high glacier slope are narrower. Nonetheless, the glacial landscapes of the mountains of Greenland and north Canada[8,9] are strikingly similar to those found in the Prince Charles Mountains and are classified as landscapes of selective linear erosion.

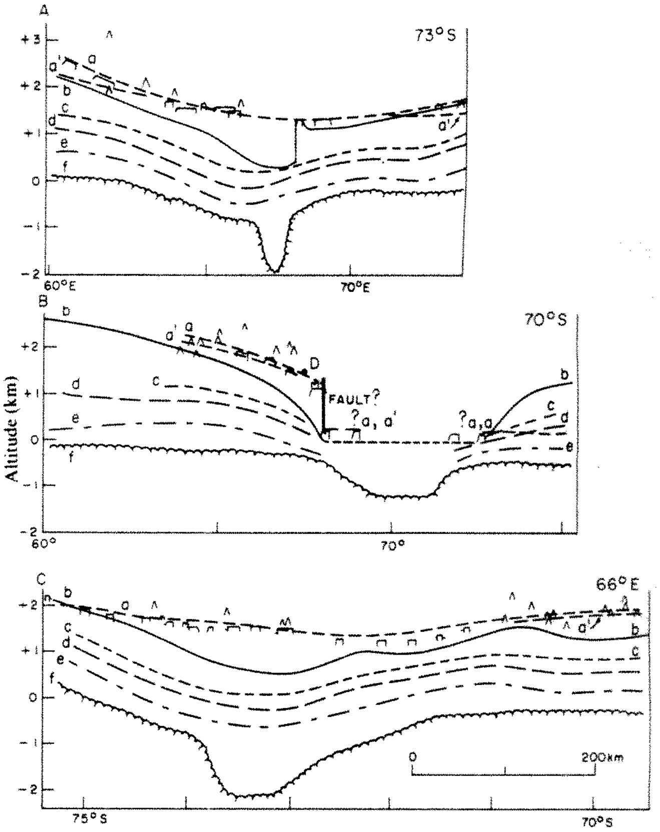

Fig. 2 Sections showing: projected high points of summit plateau and spiky summits, and their mean level (curve a); the present level of the mean preglacial surface (curve a′); the present ice surface (curve b); the original level of the preglaciation surface (curve c); predicted mean level of the present rock surface after deglaciation (curve d); present mean rock surface (curve e); and present lowest rock surface within 100 km of the section line (curve f). Fig. 1 shows the location of these sections.

Erosion rates beneath the main East Antarctic ice cap are probably much lower than those found in the Prince Charles Mountains because of the much lower ice velocity, much less widespread basal melting and lower rock relief. The subglacial landscape in these areas is likely to be one of areal scouring similar to that found in areas of Canada, Greenland and Fennoscandia which are thought to have been once covered by major ice caps[17]. The Fennoscandian and Canadian shields are thought to have been glacially eroded by only a few tens of metres[18].

The average rate of erosion inferred for the Prince Charles Mountains region since the onset of glaciation in the Oligocene[19] is 1.5 km during 30 Myr or 0.05 km Myr^{-1}. This is lower than reported rates[20] for very active orogenic areas: 0.21 km Myr^{-1} for the Himalayas during the past 40 Myr and 0.12 km Myr^{-1} for the Rocky Mountains in the late Cretaceous. It is similar to erosion rates for slightly orogenic areas such as the Appalachians or the Mississippi Basin. Our observations in the Prince Charles Mountains region thus apparently confirm that continental glaciation is not an especially vigorous erosional agent. Furthermore, although the Antarctic continent is widely regarded as being depressed by the ice load there are areas where glacial erosion has induced a net local uplift.

Short-term fluctuations in heavy metal concentrations in Antarctic snow

Michael P. Landy* & David A. Peel

British Antarctic Survey, Natural Environment Research Council,
Madingley Road, Cambridge CB3 0ET, UK

Heavy metal variations in polar ice cores may reflect changes in global airborne pollution[1]. Reported profiles from Antarctica[1–3] and Greenland[4], where sampling resolution was normally larger than a year, have shown a much greater variability than can be reasonably accounted for by variations in the annually smoothed emissions of anthropogenic sources and most natural sources. Volcanism has been invoked[4] to account for major features. We now report data from a finely resolved sample sequence from a remote plateau region of the Antarctic Peninsula. Variations of similar magnitude to those reported for longer time series occur also on the scale of seasonal changes and even of single snowfalls; these must be controlled by meteorological processes. We conclude that changes in large-scale transport processes and depositional mechanisms on longer time scales may have as important a role as emission rates in generating the concentration profiles observed in deeper ice cores.

Snow samples were collected in January 1977 from a remote site on the Antarctic Peninsula plateau (70°53′S, 64°57′W; altitude 1,860 m), 170 km from the Weddell Sea to the east and 200 km from the Bellingshausen Sea to the north-west. The plateau at these latitudes is 60–90 km wide and bordered east and west by mountain ranges, though neither was closer than 40 km. The prevailing northerly winds came from an area generally free from exposed rock.

Samples for heavy metal analysis were collected from a clean zone 150 m upwind of a vehicle-free camp site. All sampling tools and containers had been given three lengthy washes in 1 : 6 HNO_3 (Analar) followed by two thorough rinses with ultrapure water in the laboratory before transportation to the sampling site in sealed polythene bags. Two investigators, wearing full clean room garb, dug a 2-m-deep pit with steel shovels and then trimmed 10 cm from the rear wall using a polyethylene scraper.

Triplicated pit-face samples and duplicated 2-m cores (9-cm diameter) recovered directly behind the face with an aluminium hand auger were subdivided with a PTFE saw and stored in 1-l polyethylene containers. Relatively large and erratic metal concentrations subsequently measured in these samples suggested that contamination had occurred, probably from the PTFE saw. However, a 3.4-m core in ~20-cm lengths inside 60-cm acrylic tubes with polyethylene caps gave consistent data with no evidence of contamination; these values are presented here. For the marine ion and microparticle analyses, a 6.5-m core was sealed into polyethylene sleeving and placed inside 100-cm cardboard tubes. The cores were all collected within an area 30-cm square and stored at temperatures below −10 °C before analysis.

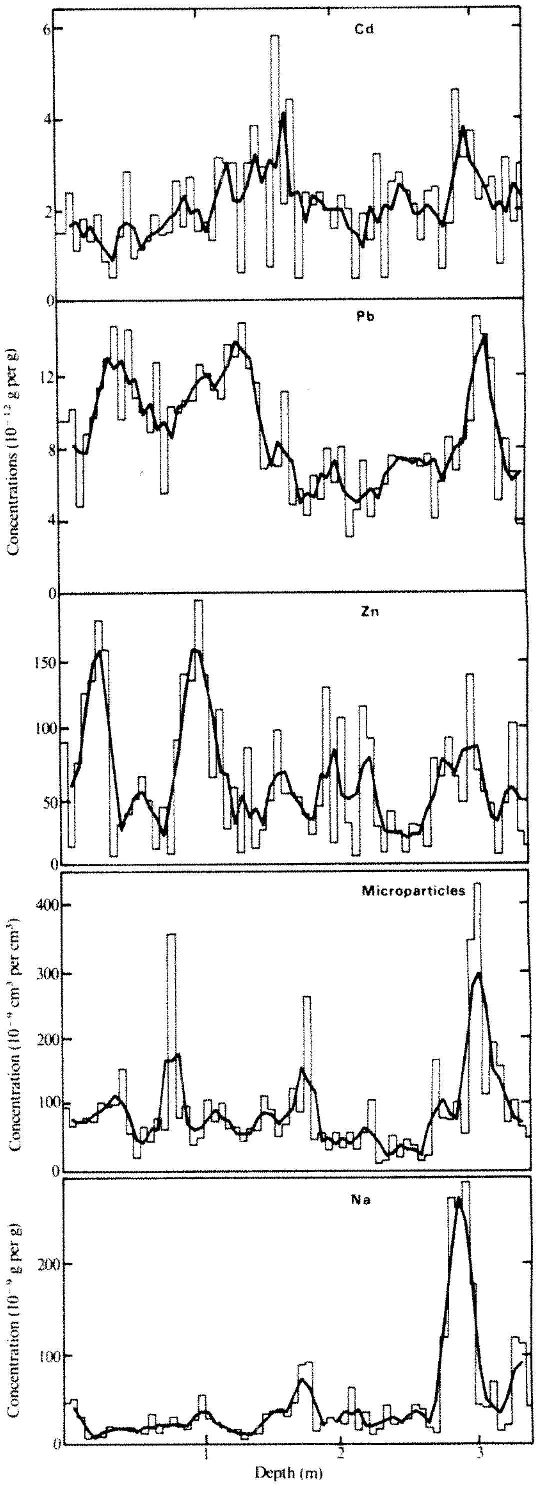

Fig. 1 Concentration profiles for Cd, Pb, Zn, microparticles (0.5–1.8 μm) and Na in the upper 350 cm of snow (May 1973–January 1977). The bold lines are running averages of three data points.

Analyses for Cd, Pb and Zn were performed on snowmelt in a Class-100 laminar flow work station by differential pulse anodic

0028–0836/81/200144—03$01.00

stripping voltammetry (DPASV) at a rotating glassy carbon electrode with *in situ* mercury plating[5]. The segments of the core stored in acrylic tubes were carefully transferred as required into a precleaned polyethylene container kept at −2 °C. The core was briefly removed from its container with insulated PVC clean room gloves. Using a polyethylene scoop, snow was excavated 5 cm into the core, leaving a cylinder of at least 1 cm thickness around the exterior to exclude any superficial contamination. Approximately 30 g of the snow was transferred to a glass voltammetry cell, 50 μl of a mercuric nitrate in 5% HNO_3 plating solution was added (giving 2×10^{-5} M Hg^{2+} at *p*H 2.9) and the sample was melted immediately before analysis. The quantity required for DPASV allowed almost continual analysis every 5-cm down the core, sufficient resolution to permit the study of short-term variations in concentration.

Three DPASV runs were performed on each sample, the final one with a standard addition of 1.5 ng Cd, Pb; 3.0 ng Zn, Cu (15 μl of 10^{-7} g per g Cd, Pb; 2×10^{-7} g per g Zn, Cu in 1% HNO_3). The exact volume of the sample was measured after analysis. Due to the difficulty both of obtaining ultrapure water with heavy metal concentrations consistently smaller than the cleanest snowmelt analysed and of using this to simulate a snow analysis, the concentrations presented here are not corrected for a procedural blank, and as such represent upper limit values. As one core only was available for heavy-metal analysis it was not possible to make a comparison with duplicated samples treated by more complete acid digestion. In a related study at Antarctic sites much closer to exposed rock, we have found[5] that digestion at *p*H 2.9 for 4 h at 110 °C causes no perceptible increase in the observed heavy-metal concentrations except for samples taken very close to and down-wind from rock exposures. Sodium was measured in snowmelt at *p*H 1.5 by flame emission spectrometry, and the microparticle distribution above 0.5 μm was measured in a clean air laboratory using a Coulter counter.

Table 1 Correlation factor matrix, calculated from 3-point running averages

	Cd	Pb	Zn	D*	Na
Cd	1.0				
Pb	−0.03	1.0			
Zn	−0.10	0.29	1.0		
D*	0.19	0.32	0.12	1.0	
Na	0.45	−0.18	0.06	0.32	1.0

*Microparticles in the range 0.5–1.8 μm.

Table 2 Crustal heavy metal enrichment factors calculated from the 3-point running averages in comparison with averages for east Antarctic snow deposited since 1968[1,2]

	Average	Minimum	Maximum	Comparative values for east Antarctic snow
Crustal				
Cd	52.6	14.2	131.5	4,400
Pb	3.5	0.9	7.6	160
Zn	4.0	0.7	12.8	40

The data from the top 3.4 m of snow (66 samples) are summarized in Fig. 1. The overall precision estimated from standards is 20% at the 95% confidence level. Superimposed on the data is a running average of three consecutive values, which reduces any systematic error introduced by comparing data from two different cores where identical snow layers may suffer a relative vertical displacement of up to 10 cm. The annual snow accumulation estimated from both stratigraphic observations and the oxygen isotope ratio profile of a 7-m core taken 100 m from the sampling site was 1.1 m (48 g cm^{-2} yr^{-1}). Support for the stratigraphy is obtained from spectral analysis of the marineion and dust concentration profiles (Fig. 1) which show strong peaks in auto-covariance and cross-covariance with lags of 115 cm. A seasonal periodicity for these species has been reported in other parts of Antarctica[6,7].

The average heavy metal concentrations over the 3-yr sequence are $(Cd = 2.1\pm1.0, Pb = 8.8\pm3.1 \text{ and } Zn = 63\pm47)\times10^{-12}$ g per g. Cu concentrations were usually near or below the detection limit; however, an upper limit of 20×10^{-12} g per g was obtained as an average over 35 samples. These values are similar in magnitude to those published for much more remote sites in Antarctica (Dome C[1] and South Pole[2]), and an order of magnitude smaller than concentrations measured by DPASV on the less remote Adelaide Island (Antarctic Peninsula)[5]. Low concentrations could be the result of a much larger snow accumulation rate at this site compared with the remote sites in East Antarctica, although there is evidence that trace element concentrations in snow are independent of the snow accumulation rate[8].

Previous studies have used more complete digestion of samples before analysis by flameless AAS and therefore these data may contain an additional proportion of metal species not included in our analysis. Our data refer to metal available to DPASV at *p*H 3: free metal ion, labile complexes, metal dissociated at the electrode surface from complexes and colloids, and species adsorbed on mineral matter. From the scant evidence available on the nature and reactivity of heavy metal particulates in the atmosphere, it seems likely that our analysis includes aerosols from the major pollutant sources which include mining, base-metal smelting and refining, and automobile exhausts; these are predominantly oxides, carbonates,

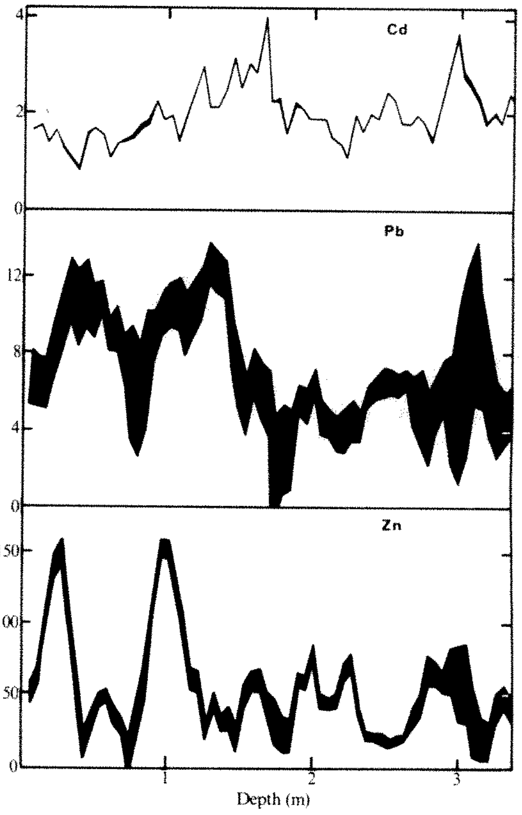

Fig. 2 Microparticle contribution to the heavy metal concentration profiles. The shaded area represents the proportion of metal attributable to microparticles, calculated using average crustal abundances[12].

sulphides, halids and elemental[9]. Emissions of elements and simple compounds by volcanic activity, postulated as a significant source of globally circulating heavy metals[1,3], would also be analysed, along with products of biological processes such as methylation which have been proposed as important natural sources of trace metals in the atmosphere[10,11]. Such emissions would be degraded by photochemical activity during long range atmospheric transport, and probably converted into oxide. Our analysis excludes the contribution from wind-blown dust where heavy metal has replaced other elements in a silicate lattice. Thus we would expect to exclude much of the heavy metal associated with mineral particles derived from aeolian action on the exposed volcanic rocks of the Antarctic Peninsula, which are likely to dominate the mineral content of our samples. The mean dust volume (m^3 per m^3 snowmelt) concentration at our sampling site is 110 p.p.b. (parts per 10^9) which can be compared with a concentration of 24 p.p.b. in the same size range reported[12] for the mean of snowfall at the South Pole deposited immediately before the recent increase in dust concentration at this site due to local human activity[13].

This value may be considered the upper limit to the concentration of microparticles transported to the Antarctic continent from neighbouring continents. On this basis, we estimate that ~80% of the microparticles in our samples are of local origin. If these make a significant contribution to the heavy-metal concentrations observed, then some correlation between the depth profiles for the heavy metals and the microparticle concentrations might be expected. The correlation matrix in Table 1 shows that, with the exception of a weak correlation (significant at the 5% level) between Pb and microparticles which arises from the coincidence of a single major peak at about a depth of 3 m, there was no correlation between the profiles despite the relatively large mineral content.

We can estimate the form of the maximum possible contribution by local dust to the input of heavy metals by assuming that these are of mean crustal composition and that all the heavy metal is available at pH 3. In estimating the mass flux we consider particles in the size range 0.5–1.8 μm. This upper limit prevents a bias in the data due to the influence of a relatively small number of larger particles which are least likely to be available for DPASV analysis. On the average, this size range represents ~53% of the total particle flux between 0.5 and 6 μm diameter. Figure 2 shows how the concentration profiles are modified when allowance is made for the contribution from local dust. The procedure seems to overestimate the contribution because for certain discrete events the estimate of the local heavy metal component is slightly greater than the total amount analysed. Except for occasional periods where trace element concentrations are low and may be almost completely of local origin a maximum average of only 2% of Cd, 29% Pb and 25% of Zn could be attributed to local dust. The residual heavy metal which we interpret as a long-range input to the Antarctic environment, shows enhanced short-period variations.

We have calculated crustal enrichment factors for the heavy metals (Table 2) assuming that the microparticles are of mean crustal composition[14]

$$EF_{\text{crust}} = \frac{\text{[metal] snow/[microparticles] snow}}{\text{proportion metal in average crustal material}}$$

These values represent upper limits as our estimate of microparticle concentration is based on a restricted size range, yet they are between 10 and 80 times lower than enrichment factors calculated for snow in east Antarctica[1,2]. These previous studies have calculated enrichment factors using Al as a crustal reference element, Al being measured[15] in samples of snow melt before digestion for heavy metal analysis. Comparison of the two methods is possible at the South Pole, where Hamilton and O'Kelly[12] measured microparticle size distributions using a Coulter counter in a continuous sequence of samples from a shallow pit covering the period 1956–64. From these data, the authors estimated a mean total dust volume concentration of 24 p.p.b. (72 p.p.b. by weight). This probably underestimates microparticle concentration as particles smaller than 0.5 μm are excluded. If the dust had contained a normal crustal abundance of Al then Al concentrations should have averaged 5.9 p.p.b. For samples covering the same period Boutron *et al.*[2] report direct measurements of 1.5 p.p.b. Al. Therefore, either previous reports represent samples in which Al may have been incompletely analysed due to partial sedimentation of mineral microparticles whilst the samples were melted, or there is considerable error in assuming that the average composition of microparticles penetrating the Antarctic environment is mean crustal in the major elements. This discrepancy could account for a reduction of our EF_{crust} values by a factor of 4, and a further factor of 5 could be due to the previously mentioned dilution effect of local dusts.

Although some of the noise in our concentration profiles may represent variations occurring during individual snowfall events due to progressive scavenging of impurities from the atmosphere, the depth range occupied by some of the major peaks is large compared with the likely precipitation in a single event. Moreover, there is a substantial difference, most noticeable for Zn and Pb, between the mean concentration in the upper 1.5 m and that in the lower 1.5 m on the time scale of seasonal and year-by-year changes. These variations, which range over an order of magnitude for Zn to a minimum factor of 2 for Cd, are much larger than can reasonably be accounted for by variations in global emission to the atmosphere. Sharp variations of similar magnitude, although with a much coarser resolution in longer time scales, have been reported in sample sequences from both the Antarctic and Greenland ice sheets. Several processes, including volcanism[1,3,4,9] have been invoked as possible causes of sporadic variations in global emission rates into the atmosphere.

In support of this idea a 100-yr old sample sequence from central east Antarctica has shown[3] a close parallel between major peaks in the stratospheric burden of volcanic aerosols and the measured concentrations of Zn and Pb. However, a similar mechanism cannot be invoked to account for the shorter term variations observed in our samples which are evidently linked to meteorological transport and depositional processes. As these seem to be capable of generating features in the concentration profiles preserved in snow layers in the short term which are of comparable magnitude to the variations observed in the longer records, we conclude that longer term changes in related meteorological processes may play a significant part in shaping the corresponding record in snow which need not necessarily reflect changes in global emission rates. Until the mechanisms responsible are more fully investigated caution must be exercised in interpreting variations in the concentrations of trace elements in ice cores in terms of varying global emission rates.

We thank J. Mumford for undertaking the analysis of Na and microparticle size distribution in our core samples.

Age of mineral equilibria in granulite facies nodules from kimberlites

Ben Harte & Peter M. Jackson

Among the nodular xenoliths erupted with kimberlites and alkali basalts some plagioclase-bearing and other granulite-facies nodules with metamorphic textures may represent rock samples plucked directly form the Earth's lower crust and Moho region. In studying these xenoliths it is tempting, as in the case of deeper mantle *xenoliths*[1], to use temperature–pressure estimates from mineral compositions to reconstruct petrological–depth relationships and geotherms for the time of eruption.[2–4] In such reconstructions it has been stressed[5–9] that possible modification of the xenolith mineral equilibria during the processes of eruption must be considered; but we emphasize here that the reconstructions may also be invalid because mineral equilibria had become inert or frozen long before eruption. We pay particular attention to nodules from kimberlites in Lesotho, and present some new age data. We argue further that medium- and coarse-grained rocks lacking a fluid phase in stable tectonic regions are unlikely to maintain local equilibrium at ambient geotherm conditions until depths well within the upper mantle are reached.

Granulite-facies xenoliths are relatively abundant in post-Karroo kimberlites occurring close to the supposed position of the southern margin of the Kaapvaal craton in South Africa and Lesotho[4]. Clinopyroxene, garnet and plagioclase are the common major minerals of the xenoliths, with orthopyroxene less common, and amphibole, biotite and scapolite relatively scarce. The nodules often show granuloblastic textures. Rogers and Du Toit[10] noted that the rocks of the nodules were probably related to Proterozoic granulites (of the Namaqua–Natal belt) exposed near the margin of the Kaapvaal craton. Griffin *et al.*[4] partly endorse such a relationship, but they relate the granuloblastic textures to annealing caused by heating during the Karroo episode, and consider the mineral equilibration temperatures to represent deep crustal temperatures at the time of kimberlite eruption. Betton and Cox (see refs 11, 12) suggest that the rocks represented by the nodules were initially formed adjacent to the crust–mantle boundary by crystallization of Karroo magmas and that they reequilibrated in deep crustal conditions before kimberlite eruption.

Recent work[3,4,13–15] has provided a relatively large amount of mineralogical data for estimating temperature–pressure conditions of formation for the granulite-facies nodules from northern Lesotho. For the plagioclase-bearing assemblages: Griffin *et al.*[4] estimate temperatures predominantly between 550 and 770 °C with pressures spreading largely from 4.5 to 15.5 kbar; Jackson[15] estimates temperatues and pressures in the ranges 600–800 °C and 15–20 kbar. These temperatue–pressure estimates yield unexpected results when used to reconstruct the thermal and petrological characteristics of the crust–mantle section underlying Lesotho at the time of kimberlite eruption. The temperatures, except in combination with the highest-pressure estimates, are distinctly higher than those expected by comparisons with normal geotherms for Precambrian shields and platforms and present data for southern Africa[16,17]. Also the higher pressure estimates[15] clearly place plagioclase-bearing rocks within the present day mantle as defined by available seismic data[18] on the depth of the Moho in South Africa.

Assuming that the nodules reflect ambient crustal temperature–pressure conditions at the time (Cretaceous) of kimberlite eruption, Griffin *et al.*[4] attribute the high temperatures estimated to the slow decay of the thermal effects of the earlier Karroo volcanism, and postulate a Cretaceous geotherm with several inflections. We suggest that the possibility must be considered that rocks in the lower crust contain frozen mineral equilibria, which, in this case, may be relics of Proterozoic orogenesis or of high geothermal gradients at the actual time of Karroo magmatism. Although the temperatures of 550–800 °C estimated from the granulite-facies nodules are high for stable continental crust they are by no means high compared with those indicated by amphibolite- and granulite-facies rocks in exposed orogenic belts. Traditionally, rocks collected at the Earth's surface from exhumed orogenic belts are assumed to contain frozen mineral equilibria predominantly reflecting the highest temperatures (or highest entropy states[19]) reached by the rocks. This assumption, which is applied to both volatile-bearing and volatile-free assemblages, is essentially the opposite of that of presumed approximate continual equilibration at depth adopted for the granulite facies nodules in the reconstruction of geotherms for the time of eruption.

The relatively dry nature of the nodule mineral assemblages from Lesotho as shown by the restricted occurrence of primary hydrous minerals (amphibole and biotite)[4,14,15], together with their estimated temperatures of formation, must indicate metamorphism in conditions of highly restricted water content[20]. Where such 'dry' rocks are subjected to metamorphism involving little deformation in the temperature range indicated for the nodules then the products usually fail to approach general textural and mineralogical equilibrium on the scale of a thin section—typically original textures and compositions are partly preserved whilst minerals are clouded and show partial replacement and corona textures[21–24]. Such features contrast with the general appearance of textural and mineralogical equilibrium seen in the Lesothon granulites[4,13–15], and cast doubt on them having equilibrated to ambient geotherm conditions since their initial formation.

We have endeavoured to obtain direct evidence on the age of the mineral equilibria in the nodules by radiometric dating. Two ^{206}Pb–^{238}U ages previously obtained[25] for zircons from the Lesothon granulite xenoliths yielded Proterozoic ages of 1,500 and 1,050 Myr. However, the refractory nature of zircon makes it unlikely that it reflects the time of recent equilibrium in most minerals. Biotite and amphibole are present in some of the nodules and the relatively low blocking or closure temperatures for Ar accumulation imply that the ^{40}K–^{40}Ar method on these minerals provides a means of assessing the minimum age of the mineral compositions yielding the temperature–pressure estimates. We have found only two nodules with sufficient fresh and texturally primary amphibole or biotite for separation and analysis. The K–Ar analytical results for the minerals from these nodules are given in Table 1: the mica yields an apparent age of ~1,000 Myr and the amphibole 714 Myr.

These Proterozoic ages clearly far exceed the < 100 Myr ages measured for emplacement of southern African kimberlites[25]. The two ages may relate to different geological events, but it would have been more reassuring had they been consistent. Furthermore the incorporation of extraneous ^{40}Ar which leads to erroneously old ages is well documented in some metamorphic micas[26] including, in particular, those from granulite facies rocks[27]. However a K–Ar whole-rock age of 90 Myr for the Monastery kimberlite[28] agrees with the Rb–Sr and U–Pb ages[25,29] and therefore does not suggest the presence of any extraneous Ar in the kimberlite. Also the 1,000 Myr biotite age agrees well with the 1,050 Myr obtained for one of the zircons

§ Mineral assemblage: garnet–orthopyroxene–amphibole–biotite.

extracted from the nodules[25], and is further supported by the extensive occurrence of ~1,000 Myr ages in the Namaqua-Natal Mobile Belt[30-32] on the borders of the Kaapvaal Craton. However, an Rb–Sr measurement on biotite LBM70 (Table 1) yielded ages ($\lambda_{Rb} = 1.42 \times 10^{-11}$ yr^{-1}) of 178 and 200 Myr with assumed initial ^{87}Sr/^{86}Sr ratios of 0.710 and 0.704 respectively.

Amphibole has recently been used quite satisfactorily to date granulite facies metamorphism[33] and extraneous Ar is relatively unknown in this mineral; so, although the 715 Myr age measured on LBM43 is younger than those normally reported for the Namaqua-Natal belt, it could, nevertheless, reflect a Proterozoic event. It is similar to a zircon age of 650 Myr reported from an inclusion in kimberlite from further north-west in Swaziland[25] and to a K–Ar age of 728 Myr measured on primary mica from a peridotite nodule in the Monastery Pipe (R. M. Macintyre and J. B. Dawson, unpublished data). Further data are obviously desirable, but the available radiometric ages clearly suggest that the mineral compositions of Lesothon granulite-facies nodules are more likely to relate to Proterozoic events than the ambient temperature–pressure conditions just before kimberlite eruption.

Considering a section of lithosphere, which is not undergoing significant deformation, magmatic or hydrothermal fluid transport events, the question arises of at what temperature and depth along the geotherm are minerals capable of maintaining chemical equilibrium within reasonably short geological time periods (~10 Myr). More information concerning the time taken for minerals to equilibrate at particular temperatures and other conditions (for example, volatile abundances, amounts of strain) has long been considered desirable. In the present instance, with predominantly anhydrous and unstrained minerals of medium-coarse grain size, equilibration must involve volume diffusion and be relatively sluggish. The general petrologic evidence noted above clearly indicates that the temperature required to produce compositional and textural equilibration in such assemblages must be >700 °C. On the basis of petrological data, Yardley[34] suggests that the diffusion of divalent cations in garnet becomes relatively rapid at ~700 °C; but the common occurrence of Al and Cr inhomogeneities in garnets in garnet–peridotite nodules indicates that general equilibrium requires higher temperatures. Other evidence, associated with exsolution in coarse mineral grains, also indicates the probability of long-term disequilibrium in mantle nodules[35,36]. Using approximate calculations[37] for diffusion distances and rates, the recent experimental data on Ca diffusion in clinopyroxene[38] indicates that temperatures >850 °C are required to equilibrate spherical grains of 5 mm diameter in 10 Myr. Hofmann and Hart[39] note the difficulty of achieving local equilibrium in crystalline peridotite lacking a melt phase at 1,000–1,200 °C; whilst comparisons[8,40] of cation distributions and geothermometers for minerals from peridotite nodules may indicate significant limits to attainment of overall equilibrium by diffusion as temperatures drop to 1,100 °C.

With geotherm temperatures higher than 800 °C and possibly in excess of 1,000 °C necessary for equilibration of essentially volatile-free, magma-free and unstrained mineral assemblages in a tectonically stable lithosphere section, there is a need to reconsider several aspects of the interpretation of upper mantle lithology and their bearing on magma genesis[39]. Using a temperature of 900 °C as a minimum for equilibration by volume diffusion, the geotherms of Clark and Ringwood[41] indicate the persistence of frozen mineral assemblages to lithosphere depths of 60 km beneath ocean basins and 105 km beneath continental shields. It follows that the 'dry' mineral assemblages adjacent to the Moho both in the lower crust and in large tracts of the upper part of the upper mantle cannot be predicted as usually assumed (see ref. 42) by a knowledge of phase equilibria, bulk composition and stable geotherm temperature–pressure estimates. Instead the mineral assemblages will be largely a reflection of past events, presumably dating from when the lithosphere section considered was located at a plate margin or otherwise involved in extensive major deformation and/or heating. The presence of old mantle lithosphere with largely frozen mineral equilibria will add to and emphasize the compositional heterogeneities within the upper mantle and provide an extensive source of material for contamination of magmas. The apparent absence[43] in kimberlites of ulramafic nodules representing the upper part of the upper mantle (at ambient geotherm temperatures <900–1,000 °C) could simply be the result of sampling only frozen mineral equilibria at these depths; with the corollary that ultramafic nodules indicating temperatures of mineral formation around 1,000 °C (±100 °C?) could be derived from the extensive depth range of mantle lithosphere lying at lower geotherm temperatures. Given the existence of such thicknesses of frozen lithosphere the similarities between nodules from Precambrian and Cretaceous African kimberlites[44] become less unexpected.

Mutualism in which ants must be present before plants produce food bodies

Stephen J. Risch

Section of Ecology and Systematics, Division of Biological Sciences,
Cornell University, Ithaca, New York 14850, USA

Fred R. Rickson

Botany Department, Oregon State University, Corvallis,
Oregon 97331, USA

Certain interactions between ants and plants can be classified as mutualisms[1–3], with benefit accruing to both members. The plant provides a source of energy, either as solid food or as nectar, and sometimes a domicile such as a hollow stem (or a stem capable of being made hollow by the ants) or hollow stipular thorns. The ants provide the plant with defence against herbivory and/or vine overgrowth. Whether the plant relies entirely or only in part on the ants for its defence, in relationships studied so far it always produces a source of food irrespective of the ants' presence. However, we report here that in the mutualistic relationship between the plant *Piper cenocladum* and the ant *Pheidole bicornis*, the production of food bodies is closely tied to the presence of the ants, so that when they are removed, production of food bodies nearly ceases and when ants reinvade the plant, production begins again. This is the first description of such a relationship in which the food tissue of the plant is induced by the insect.

Risch *et al.*[2,4] have shown that three Costa Rican species of *Piper* share a mutualistic relationship with *Pheidole bicornis* ants. These *Piper* species are slender, shrub-like plants that commonly grow to a height of several metres. They occur in the understory of mature, wet evergreen forests but are most common in more exposed areas such as light gaps caused by fallen trees or along creeks or paths. The plants provide a domicile within a cavity formed by the appressed, curled margins of the petiole (Fig. 1*a*), and the ants obtain additional living space by hollowing out the stem. Apparently the growth of the plants is not affected and no important structural damage is done. In return for the domicile and food tissue, the ants seem to help keep the plant free of invading vines, and remove small herbivorous insects and their eggs.

On the recurved adaxial surface of the petiole margins of *P. cenocladum*, single-celled food bodies are produced. They are collected and consumed by the ants. When a food body forms, the nucleus of an epidermal cell enlarges to seven to eight times its normal diameter and the external cell wall extends outwards (Fig. 1*b*, *c*). The nucleus then moves into the newly formed region of the cell and continues to enlarge together with the rest of the cell. The mature food cell (300–500 μm in diameter; Fig. 2) has a dense cytoplasm rich in protein and is filled with lipid droplets. (Chemical analysis by dry weight shows that food cells contain 10.7% protein, 2.1% carbohydrate and 22.2% lipid.)

Our initial observation was made on living plants of *P. cenocladum*, possessing a weak colony of *P. bicornis* ants, which had been established in a greenhouse at Oregon State University. When, after a short period, the colony died, newly produced leaves developed only a few food cells. This condition persisted in all leaves subsequently produced, although the plants thrived in greenhouse conditions. Because there was no precedent for the necessity of ants to be present for food cells to develop, we investigated the relationship between the insect and the plant in experiments conducted in Costa Rica.

First, we counted the average number of food cells in a *P. cenocladum* petiole tube by dissecting nine petioles from seven plants under a dissecting microscope. The average was 1,500 food cells for a 'typical' petiole. This became the standard against which to compare the results of the ant exclusion experiments described below.

In our first experiment, a 12% aqueous solution of benzene hexachloride (HCH, an insecticide) was injected into the petiole tube of the youngest four leaves of each of nine *P. cenocladum* plants growing at the La Selva Field Station, in the Atlantic lowlands of Costa Rica. After injection, the hole through which ants normally pass from the petioles to the stems was plugged with a sticky resin (Tanglefoot) and the base of the petioles was entirely covered with Tanglefoot to keep ants or other arthropods out of the petioles. After 47 days, all plants were in excellent condition, showing no apparent effects of the HCH. Each treated petiole contained less than 25 healthy food cells, significantly fewer than the number in plants occupied by ants (Wilcoxon signed rank test, $P < 0.01$). There were several large and almost totally decayed food bodies in each of these petioles but virtually no new food bodies were being produced.

In three of the nine plants, active ant colonies were found in petioles below the poisoned area. In those petioles with active ant colonies, the inside of the petiolar sheath was covered with a dense growth of food bodies, similar to that seen in plants not injected. In the remaining six plants, there were no living ants. Although only the top four petioles had received HCH, some of it had probably leaked into the hollow stem and killed the rest of the ant colonies. In these plants, even the petioles below the top four poisoned petioles contained no healthy food bodies.

In our second experiment, ants were added in the field to uncolonized plants of *P. cenocladum* in an isolated population near Turrialba, Costa Rica. By gently prying open the petiolar sheaths, we could see that there were fewer than 50 food bodies in each petiole: we did not actually count them, for that would have destroyed the petioles. *P. bicornis* ant colonies were transplanted to 18 of these plants by attaching an uprooted *P. cenocladum* plant containing an ant colony to each unoccupied plant. (Previous experiments had shown that in these conditions, the colony would usually leave the original plant

Fig. 1 *a*, Basal portion of a *Piper cenocladum* petiole showing the tube formed by the petiole margins. ×2. *b*, Early stage in food cell development. Note the expanding outer wall, enlarged nucleus and dense cytoplasm. ×820. *c*, Mid-stage in food cell development. ×820.

when it started to wilt and colonize the nearest unoccupied plant.)

After 40 days, 14 of the previously unoccupied plants possessed ant colonies in about one-third of their petioles. Comparison between plants showed that occupied petioles possessed significantly more food cells per petiole ($\bar{x} = 1,020$) than unoccupied petioles ($\bar{x} = 120$) (*t*-test, $P < 0.01$). In other unoccupied plants of the original population, the average was 19 food bodies per petiole, significantly less than either occupied or unoccupied petioles (*t*-test, $P < 0.05$).

In our third experiment, occupied *P. cenocladum* plants were transplanted into containers and moved into a greenhouse at Turrialba, Costa Rica. Nine of them wilted and died back, and their ant colonies departed. After a short period, the plants resumed vigorous growth, but produced no food bodies within the petiole tubes. Of those plants which resumed growth, five were given a new *P. bicornis* ant colony, and four were left unoccupied. After 40 days, nondestructive estimation of the petioles showed that the five with ants were producing a full complement of food cells (>1,000 per petiole), whereas the four without ants had almost no food tissues.

In our final experiment, 12 of the potted *P. cenocladum* plants which had retained their ant colony after transplantation were treated with hydrogen cyanide (HCN) gas. This killed the ant colony in 10 plants: 5 were retained in a greenhouse while the other 5 were further isolated in an indoor laboratory. After 53 days, all 10 plants had virtually no food bodies. Four plants were dissected and examined microscopically. Their petioles contained an average of 15 (1–20) food cells (significantly less than 1,500, Wilcoxon signed rank test, $P < 0.01$). No living arthropods, such as mites, were found in any of these dissected plants. Of the six remaining HCN-treated plants, four received transplanted ant colonies and two were set aside as final controls. After 51 days, all remaining plants were dissected. Those possessing an ant colony contained significantly more food cells per petiole ($\bar{x} = 1,811$ per petiole) than the two control plants ($\bar{x} = 22$ per petiole) (*t*-test, $P < 0.01$).

Each of our four experiments had the same end result: petioles occupied by a colony of *P. bicornis* produced a large complement of food cells (~1,500) while the ant-less petioles possessed a food cell population of 5–50. In addition to stimulating food body production, the ants apparently keep their food source free of fungus. No fungal hyphae were ever observed on food bodies in plants with ants. However, in plants without ants (either found naturally in the field or produced by killing off the ant colonies experimentally), the medium- and large-sized food bodies were nearly always covered with fungal hyphae.

It has been assumed that the plants in these relationships derive maximum benefit in immediately being able to support colonization by the protective ants. Therefore, some energy must always be wasted by the plant in the form of food tissue produced before a colony is established. Such food tissue is either eaten by other animals or falls to the ground. In *P. cenocladum*, however, photosynthate is not used for food tissue before ants arrive. Any energy saved could be put into, for example, the establishment of seedlings or growth. Such energy savings might be especially important to *P. cenocladum* as it grows in the low-light understory of wet, evergreen forests. Three other plants that harbour ants, *Cecropia*, *Acacia* and *Macaranga*, which produce food tissues even in the absence of ants, occur in well lit, disturbed habitats where presumably the amount of photosynthate is not limiting. We have occasionally collected *P. cenocladum* plants containing colonies of *Pheidole* other than *P. bicornis*. There has never been any trace of food bodies in their petioles. Yet in several cases in which *P. bicornis* was found in other petioles of the same plant, those petioles always contained many food bodies. Could it be that the species of *Pheidole* normally occupying *P. cenocladum* is uniquely able to stimulate the production of food bodies in its host?

Voice pitch as an aid to lipreading

Stuart Michael Rosen*, A. J. Fourcin*

The totally deafened adult, unable to make use of a hearing aid, has no alternative to lipreading for everyday communication. Lipreading, however, is no substitute for hearing speech. Many lipreaders have great difficulty in ideal conditions and even the best lipreaders find the task demanding and tiring. Prosthetic attempts to substitute for lost hearing have centred on three distinct types of intervention, visual[1,2], tactile[3–6] and electrocochlear[7–13]. As none of these is likely to yield a good understanding of speech independent of lipreading in the near future, we have attempted to isolate relatively simple patterns of stimulation that, although not intelligible in themselves, will aid lipreading. From this point of view, the fundamental frequency or 'pitch' of the voice is the most important pattern element because it provides both segmental and suprasegmental information and is practically invisible. It thus complements the visual information already available on the face. As we show here, with the voice pitch presented acoustically, normal listeners can lipread a speaker reading a continuous text at up to two and a half times the rate possible on the basis of lipreading alone. The pitch signal by itself, of course, is completely unintelligible. Although our work is primarily concerned with methods of electrical stimulation of the cochlea[10], it has implications for other sensory substitution techniques, the design of special purpose hearing aids and current theories of speech perception.

Understanding speech solely by vision is difficult for many reasons[14]. On the segmental level (pertaining to individual sounds), some articulatory positions are difficult or impossible to see, for example, g and k. Even for those sounds that are visible, few have unique visual cues. So, 'bet' and 'pet' look alike, as do 'vat' and 'fat'. The most important cause of such confusions is that vocal fold activity, although essential for signalling such contrasts, is invisible. The only difference between 'vat' and 'fat'

0028–0836/81/200150—03$01.00

is that the vocal folds vibrate throughout the v and not the f. In 'bet' and 'pet', the relevant cue is in the timing of the onset of vocal fold activity relative to the opening of the lips. Not only the presence or absence but also the rate of vocal fold vibration, the pitch contour, is important. This information is spread over two or more segments and is thus said to be suprasegmental. Also invisible, the pitch contour can signal among other things, aspects of syntactic structure, whether a question is being asked or a statement made, and which words are stressed in an utterance. Furthermore, voice pitch is the first component of speech mastered by the developing child[15] and is a major indicator of emotional attitude. Although vocal fold activity is not the only information missing in visible facial gestures, it is probably the major one. We should expect provision of it greatly to improve lipreading ability in those who have acquired an auditory knowledge of speech before becoming deaf.

To compare the relative contribution of various types of extra information to lipreading ability, we have made extensive use of a testing technique known as connected discourse tracking (CDT)[3]. In CDT, one person, designated the receiver, must repeat back verbatim what another person, the talker, has said. Every word must be correctly repeated; none may be skipped over. The talker decides on the length of segment to speak at one time although the receiver may interrupt. This length varies both between talker–receiver pairs and within pairs since the length of segments increases as the team become more skilful. When the receiver makes an error, the talker has two basic strategies available. First, and most common, he repeats the bit of text that was received in error. Second, he may comment about the error in any number of ways, for example, give a synonym or paraphrase the meaning. Unlike 'shadowing' tasks, never are the talker and receiver speaking at the same time.

Acoustic (but not visual) isolation between talker and receiver is achieved by placing them in two structurally separate adjoining soundproof rooms with thick viewing windows between and masking noise introduced into the receiver's room. This makes the speech of the talker completely inaudible to the receiver. The talker hears the receiver as normal from a microphone mounted on a set of headphones the receiver wears, routed to an amplifier and loudspeaker in the talker's room. As connected speech, rather than isolated segments, is used, the situation faced by the receiver seems close to that faced by the totally deaf in everyday life. This is important, as some aids, although helpful for isolated segments, show no gain for connected speech[6]. To quantify the task, the talker reads from a novel and performance is measured by calculating the average speed of transmission in words per min over the 5-min testing session.

Using this task we have compared lipreading alone with lipreading plus auditory pitch for five different receivers. Under the lipreading alone (LA) condition, receivers heard nothing through the headphones they were wearing and had to rely solely on visual cues. In the voice pitch (VP) condition, they heard the pitch contour of the talker, after suitable processing in order to make the frequency discrimination capabilities of the normal listeners match those shown by electrically stimulated deaf patients. The pitch of the talker was derived through use of a laryngograph which, by measuring impedance changes, senses vocal fold closure using external electrodes on either side of the speaker's neck[16]. Each receiver had the same talker for all 24 sessions, making a total of 2 hours per condition per talker–receiver pair. Results as a function of session number are shown in Fig. 1, and the mean rates, averaged over all sessions, are given in Table 1. All receivers are considerably faster with the pitch, although the extent of improvement varies. On the whole, the better lipreaders are helped more by the provision of voice fundamental frequency.

For convenience, we have used the laryngograph for the extraction of voice fundamental frequency, but a practical system must work from the acoustic waveform. Preliminary results of ours show that at least one method of acoustic extraction[17], although not nearly as accurate as a laryngographic technique, gives gains in lipreading ability as large as those

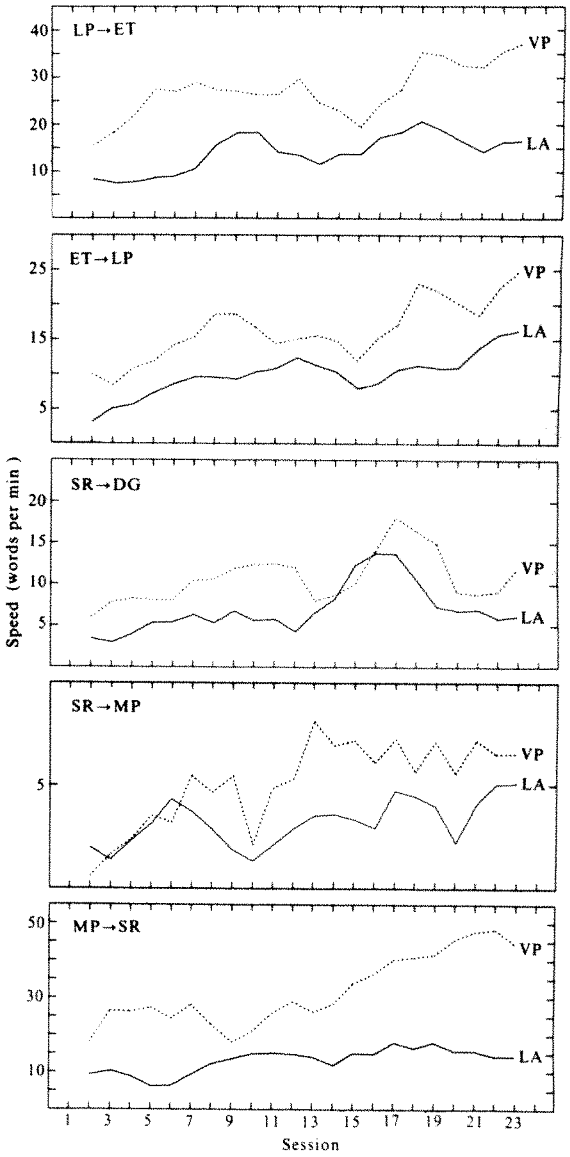

Fig. 1 Speed in words per min as a function of session number for five talker–receiver pairs in a connected discourse tracking task in two conditions. Sessions were 5 min long, making a total of 2 h per condition per talker–receiver pair. These curves result from three-point smoothing of the original data. Note the different scales for the different talker–receiver pairs. In condition LA (lipreading alone), receivers got no auditory information and had to rely totally on lipreading. In condition VP (voice pitch), receivers heard the voice pitch of the talker which was extracted using a laryngograph which senses vocal fold closures by means of a pair of electrodes on either side of the talker's neck. These closures triggered constant-amplitude 20-μs rectangular pulses. Further processing of this pitch information was necessary as electrically stimulated patients show, on the whole, less acute frequency discrimination capabilities than normal listeners. Although the data are sparse and variable on this issue, the most extensive work[21] shows that the median percentage differences in frequency needed for discrimination (the so-called difference limens or DLs) are 4, 7.6 and 6.5% at 125, 250 and 500 Hz, respectively. Patients can achieve values as low as 1–4% over this range[12,21]. We made the normal listening subjects functionally like the deaf by filtering the pulses triggered by the larynograph low-pass at 20 kHz (12 dB per octave) and high-pass at 4 kHz (48 dB per octave) before presenting them to the receiver through headphones (real ear probe frequency response flat within ±5 dB from 300 Hz to 8 kHz) at a peak level of 72 dBA (measured on a flat plate coupler). The receiver still hears the pitch contour of the talker, but in a reduced form. DLs measured for such stimuli on nine young and 'intelligent' but naive subjects were 6.8, 4.4 and 2.1% at 75, 150 and 300 Hz. Our simulation is thus quite good at the low frequencies and still reasonable over the range of frequencies adult males and females (the talkers in the study) typically use (70–350 Hz).

Table 1 Results from a connected discourse tracking task for five talker–receiver pairs averaged over 24 5-min sessions

Talker	Receiver	Speed (words per min) LA	Speed (words per min) VP	% Gain	Absolute gain (words per min)
LP	ET	14.0	27.1	94	13.1
ET	LP	10.0	16.6	66	6.6
SR	DG	6.9	10.7	55	3.8
SR	MP	3.2	5.0	56	1.8
MP	SR	12.9	31.7	146	18.8

Per cent gain is measured by the formula: $100 \times (\mathrm{VP} - \mathrm{LA})/\mathrm{LA}$ where LA and VP are the speeds attained in each condition.

reported above. Other methods of extraction will certainly prove as adequate.

Given that our simulation is a reasonable approximation to the situation experienced by an electrically stimulated deaf patient, these results augur well for single-channel electrocochlear stimulation based on the provision of voice pitch[10]. Comparisons among different methods, electro-auditory and otherwise, will be difficult until all have been tested by similar means. CDT has been used, however, in testing two tactile aids[3,6], giving a percentage gain of the aided over the lipreading alone condition of, at best, 30%. Comparison of such gains with those of Table 1 should give pause to those who maintain that the use of any prosthesis necessitating surgery is premature.

Because pitch, at least when it is presented auditorily, can be of such enormous help in lipreading, it may be fruitful to explore its provision by tactile and visual aids. Initial trials with a single vibrator transmitting pitch information using a temporal code have been disappointing[5], but better results may be obtained when pitch changes are signalled by changes in the place of stimulation[18,19]. Also, there are some patients with residual hearing at usable levels who have such severe recruitment (limited dynamic range) that they are unable to use hearing aids. As intensity changes are not necessary for the use of pitch information, such patients may gain much through use of a hearing aid that extracts and presents the pitch alone at the proper intensity.

Finally, these results contribute more generally to our understanding of speech perception. We have isolated one particular speech feature, presented it to subjects in a totally unnatural way, in a frequency region which, in fact, contains little energy during normally-voiced speech. The subjects have, however, been able to analyse this unfamiliar auditory input with reference to their existing knowledge of speech patterns and combine it effectively with visual information. The possibility that a single pattern feature can be used in this way is a necessary consequence of the point of view that speech perception depends primarily on separable auditory features which are extracted by the listener from the complex acoustic speech stream[20].

This work is done in conjunction with E. E. Douek and G. P. Clarke of Guy's Hospital and J. R. Walliker of University College London and is supported by the MRC, the Sir Halley Stewart Trust and the Royal National Institute for the Deaf. We thank our subjects, David Galbraith, Elisabeth Tunbridge, Lorna Pengelly and Mary Ann Peake; also, the Government Communication Headquarters for the loan of a real-time voice fundamental frequency extractor.

Magnetic sense of direction in woodmice for route-based navigation

Janice G. Mather & R. Robin Baker

Department of Zoology, University of Manchester,
Manchester M13 9PL, UK

Orientation to the Earth's magnetic field has been shown for bacteria, planarians, molluscs, insects, elasmobranch fish, salamanders and birds[1,2]. Recent work indicates that humans may also have a magnetic sense of direction[3,4]. We present here the first evidence for such a sense in a mammal other than man, the European woodmouse. In addition, by manipulation of the magnetic information available during the outward journey (an approach used previously with pigeons[5,6]), we present the first clear evidence that both route-based and location-based mechanisms can be involved in goal orientation following displacement.

All experiments were conducted on the European woodmouse, *Apodemus sylvaticus*, between 10.00 and 18.00 GMT from 23 June to 23 July 1980, at Woodchester Park Field Centre, Gloucestershire, UK. After capture in a Longworth trap, each individually fur-clipped mouse was allowed to enter an adjustable translucent plastic scroll which was then placed inside a transportation cage (Fig. 1). This cage was air tight and light proof, and supported two lateral coils of copper wire which could be activated to manipulate the ambient magnetic field. After a 2-min adaptation period, the cage plus animal was carried in a straight line roughly 40 m due north to a test site, the animals spending approximately 4 min inside the transportation cage. At this site the induced field was deactivated before the transportation cage was uncovered, taking care to ensure that the position of the Sun could not be detected by the mouse during the period from activation to deactivation of the artificial magnetic field. At the test site, the tube containing the animal was removed from the transportation cage and the mouse allowed to enter an orientation cage, which was housed inside a large cardboard box (70 cm diameter and 60 cm high). This box restricted both visual and olfactory cues, the latter being reduced further by the addition of Perspex doors to the orientation cage. The cage was positioned so that its four arms were directed towards magnetic north, south, east, and west. Four guy ropes anchored the cardboard screen firmly to the ground. The method was as described by Mather and Baker[7]. The cardboard box lid was folded over to create a 25-cm diameter window above the orientation cage. Consequently, only the sky directly overhead could be seen by the mouse from within the cage, any features on the horizon being screened by the box. During roughly half of the tests the sun shone into the box, though the Sun's disk could rarely be seen directly by the mouse in the cage.

Testing consisted of recording the time spent in each of the four arms of the orientation cage during a 4-min test period, observation being through small peep holes in the cardboard

0028–0836/81/200152—04$01.00

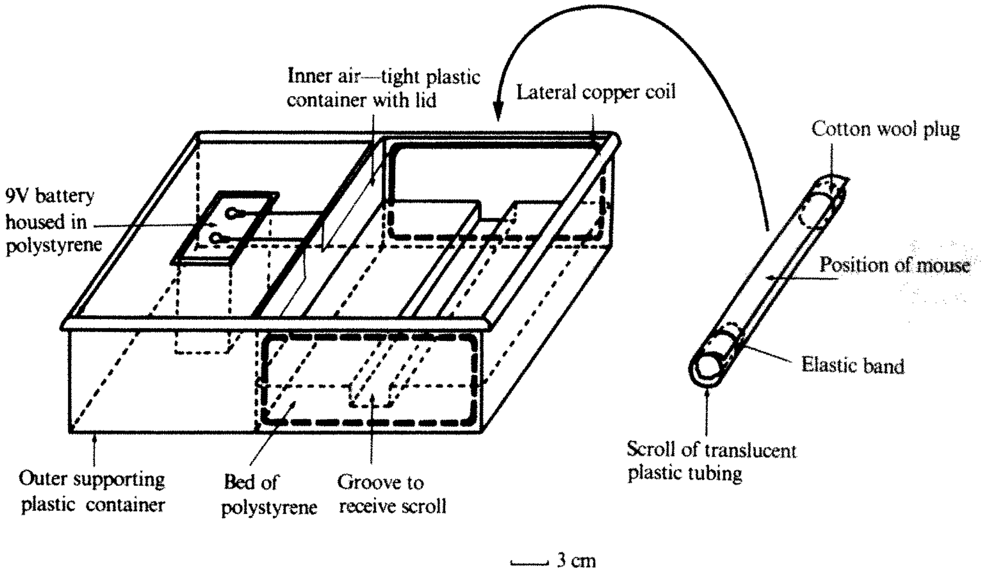

Fig. 1 The transportation cage consisted of a translucent air-tight plastic container (18 × 18 × 9 cm), the inside of which supported lateral coils made from 100 turns of 20 standard wire gauge insulated copper wire, and powered by a 9 V battery. An 82-Ω resistor in the circuit resulted in a current of 65 mA, producing a magnetic field of ~0.37 G between the coils. When this field was directly opposed to the horizontal component of the Earth's normal magnetic field, a near mirror image of the local geomagnetic field was produced. The vertical field at the animal's position was changed by less than 5% whereas the horizontal field was reversed and brought to within 115% of the natural value. This gave a total field strength of 0.52 G. As a result, the magnetic field through the experimental animal could be adjusted so that when the cage was orientated along the north–south axis (as it was during experimental displacement of the test animals), the horizontal component of the ambient magnetic field could be shifted by 180°. Alternatively, the battery could be disconnected so that an animal in the centre of the deactivated transportation cage would experience the Earth's unchanged magnetic field, and could therefore serve as a control. The animal was retained in a plastic scroll, the diameter of which could be adjusted by loosening two supporting elastic bands. This ensured both that the mouse remained in the same orientation (facing direction of travel) during transport to the test site, and that the tube was loose enough for the animal to suffer no ill effects. A cottonwool plug at either end retained the animal in the central part of the scroll, which was then placed in a groove in a bed of polystyrene inside the transportation cage.

box. (We have shown previously that observer position has no significant effect on the orientation response of rodents in this design of experiment[7]. In fact, the present investigation had a built-in control in that as long as observer position remained constant following both control and experimental displacements, any influence of observer position could not account for differences in the orientation of the two groups. Nevertheless, the observers' location was always neutral (at 90°) to the home direction and changed from east to west half-way through the experimental series.) After each test, the orientation cage was covered by a black polythene bag and used to return the animal to its point of capture.

Twenty different animals were tested (13 males), no animal being used on two consecutive days[7]. The first series of experiments consisted of 33 separate displacement occasions, 16 of which used a reversed magnetic field (Fig. 1) during the outward journey. Another 17 displacements served as controls, the coils being disconnected during displacement, the animals thereby experiencing the Earth's normal magnetic field. The influence of smell of previous occupant was controlled by maintaining the orientation cage in the same physical orientation (the same arm pointing north) during testing, and arranging the tests in a sequence of two 'activated' displacements followed by two controls.

Statistical analysis was carried out in two stages, as described by Batschelet[8-10]. Time spent in each of the four arms of the orientation cage was used in a first-order analysis to calculate the mean vector (r, θ) for each 4-min test, where r is the length and θ the mean angle. The mean angles were then subjected to second-order analysis[10]. Non-uniformity was examined by Rayleigh's Z-test[8], and clustering around a predicted direction by the V-test[9]. The Watson $U^2_{n,m}$ non-parametric two-sample test (test statistic U^2)[8] was also used. Statistics are presented with home direction as 0°.

Table 1 Orientation performance in the test apparatus; summary of second-order analysis

Variable	No. of tests	Mean angle (θ)	Mean vector (r)	Z	u (versus home 0°)
Normal field plus screen	17	+14°	0.416	2.940	2.353*
Reversed field plus screen	16	+131°	0.505	4.088†	−1.876
Reversed field no screen	20	+7°	0.483	4.662*	3.031‡

Z = Rayleigh's test, u = V-test.
*$P < 0.01$; †$P < 0.05$; ‡$P < 0.005$.

The results (see Table 1 and Fig. 2) show that there is a marked dichotomy in the directional preferences of the control and experimental animals, the distributions of direction for the two groups being significantly different ($U^2_{17,16} = 0.402$; $P < 0.001$). After transportation involving minimal exposure to visual and olfactory cues, but in the presence of the Earth's normal magnetic field, the mice showed homeward orientation (V-test, Table 1) despite the continuing restriction of these cues by the screen and perspex doors at the test site. When the magnetic vector was deflected by reversing the horizontal component of the magnetic field during displacement, subsequent orientation by the mice at the test site was shifted away from home by 131°, resulting in a 117° difference in the mean orientation of the two groups. Experimentals are significantly clustered about 180° from home ($u = 1.876$, $P < 0.05$), but are not quite significantly clustered about 180° from the mean angle for controls ($u = 1.298$, $P < 0.10$).

It has been suggested that the ability of animals to detect a magnetic field may be associated with deposits of magnetite which have been found in a variety of organisms[2]. In vertebrates, magnetic remanence has been found most often in the head region. We have undertaken pilot investigations into the possibility that similar deposits may exist in the rodent head.

Three species of rodents were used, the European woodmouse, *A. sylvaticus*, the bank vole, *Clethrionomys glareolus*, and the house mouse, *Mus musculus*, giving a total of 12 animals which had been deep frozen for up to 3 months before use. Each specimen was then embedded in a small block of deionized ice and retained in a plastic container for insertion into a par–astatic magnetometer. The heads were tested whole for natural remanence (NRM, a net field due to a preferential alignment among individual magnets), and inducible remanence (IRM, a measure of the total amount of magnetic material). Immediately before testing for IRM, the specimens were exposed to a

2,000-G field to align any permanently magnetic material. The heads were subsequently dissected, glass instruments being used to prevent possible contamination from metallic tools, and the various parts were retested for IRM (see Table 2).

All samples exhibited some NRM and even greater IRM, which was strongest in the anterior part of the head in an area associated roughly with the olfactory region but not directly with brain tissue. The level of magnetic remanence found in rodent heads is comparable with that found in pigeons (10^{-6}–10^{-5} e.m.u.)[11] and bees (10^{-6} e.m.u.)[12], but less than that found in the dolphin (10^{-5} e.m.u.)[13].

The fact that mice, which had experienced a reversed magnetic field during displacement and been allowed no visual or olfactory cues en route and only limited olfactory cues at the destination, orientated away from home suggests that route-based navigation (estimating home direction by monitoring the outward journey)[4] was taking place even in the absence of visual cues, and the involvement of a magnetic sense of direction in this ability. Alternatively, there could be short-term after-effects of exposure to altered magnetic fields. If so, fields experienced during transportation might affect subsequent navigation at the test site. However, we consider this interpretation improbable, particularly as the natural and artificial field strengths were so similar that it seems unlikely for the two to have differing effects.

Having found that we could disrupt the initial orientation response, by restoring visual and olfactory cues at the destination, a study of the involvement of these cues in location-based navigation (perceiving cues at the release site and from these determining home direction)[4] was possible. After the first series of experiments had been conducted, a second series was carried out in which the magnetic field was reversed during displacement, as before, but no screen (cardboard box) was placed around the orientation cage at the test site. All other procedures were identical except that the observers were sited 5 m away. In all, 20 different individuals (15 males) were tested once each (5 had been used in the first series of experiments), over a period of 6 days.

The results are presented in Fig. 2*c* and show that when animals experience a reversed magnetic field during displacement but are allowed relatively unrestricted access to visual cues at the test site, they orient not far away from home, as in Fig. 2*b*, but towards home (Fig. 2*c*). Comparison of the first-order mean angles of the two groups, which both experienced a reversed magnetic field during the outward journey, shows a significant difference ($U^2_{20,16} = 0.273$, $P < 0.01$), whereas the preferred directions of those animals experiencing a normal field plus screen and a reversed field but no screen are not significantly different ($U^2_{20,17} = 0.063$, $P > 0.1$).

Table 2 Summary of natural remanence (NRM) and inducible remanence (IRM) in various regions of the rodent head

		n	Mean magnetic moments ($\times 10^{-6}$e.m.u. g^{-1})	Range
Container				
Empty	NRM	4	0.63	0.28–1.05
Plus ice	NRM	4	0.83	0.59–1.23
	IRM	4	0.96	0.51–1.45
Whole head	NRM	11	1.33	0.29–7.81
	IRM	12	6.31	1.14–18.31
Head (IRM)				
Cranium		3	3.08	1.20–5.57
Lower jaw		7	0.75	0.43–1.64

Dorsal		6	1.92	0.71–4.01
Ventral		6	1.31	0.71–2.99

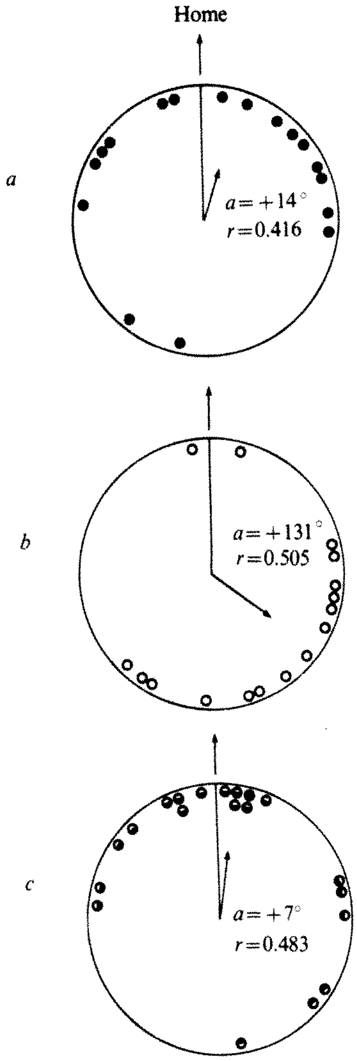

Fig. 2 Effect of conditions during displacement and at the release site on the goal orientation of woodmice. Each dot represents the mean angle (θ, first-order analysis) for an individual during a 4 min test period. Arrows within the circles show the second-order mean vectors of the estimates. Statistics show the mean angle ($a°$) and the length (r) of the mean vector. Angles are expressed with home direction 0°. *a*, Normal field plus screen; *b*, reversed field plus screen; *c*, reversed field, no screen.

Our experiments have shown that: (1) woodmice do have a magnetic sense of direction; (2) they can sample the magnetic field during experimental displacement and can use this information for route-based navigation; and (3) the magnetic information collected during the displacement journey may become subservient to other cues obtained at the test site if the information from the two sources conflict. We stress, therefore, the importance when studying route-based navigation of restricting cues available at the test site, and when investigating location-based navigation, of manipulating in a predictable way the animal's ability to monitor its outward journey.

We thank Dr P. Dagley and Professor F. Oldfield for advice on use of the magnetometer, Dr D. W. Yalden for woodmice specimens, and Mr and Mrs R. Kelly for their hospitality during the field work. This investigation was carried out while J.G.M. was receiving a SRC grant.

Stimulation of aldosterone production by β-melanotropin

Experimental and clinical evidence suggests that a non-ACTH pituitary factor(s) is important in the regulation of aldosterone secretion in certain conditions[1,2]. Earlier studies have suggested that β-melanotropin (β-MSH) has only weak steroidogenic potency on the adrenal gland in the rat[3,4], but recently Challis *et al.*[5] and Rudman *et al.*[6] have reported that α- and β-MSH have a trophic action on fetal adrenal gland. However, little is known about the effect of β-MSH on aldosterone production. We recently reported that β-lipotropin (β-LPH) stimulates aldosterone production in rat capsular cells[7]. As the amino acid sequence of β-MSH is contained within the β-LPH structure[8,9], we have now investigated the aldosterone-stimulating activity of synthetic β-MSH. Our results indicate that β-MSH causes a dose-dependent increase in aldosterone production in rat capsular cells which is blocked by a synthetic β-MSH analogue. The synthetic hormone does not increase corticosterone production in decapsular cells.

Collagenase-dispersed capsular (mainly zona glomerulosa cells) and decapsular (zona fasciculata and reticularis cells) adrenal cells from 20 female Sprague–Dawley rats on normal sodium diets were prepared for each experiment according to previously described methods[10]. In this capsular cell dispersion technique the degree of contamination with zona fasciculata cells has been reported to be less than 10% (ref. 11). Camel β-melanotropin (β_{Cl}-MSH) and the analogue, [Gly^{10}]-β_{Cl}-MSH, and ovine β-LPH were synthetic products as described previously[12–14].

As shown in Fig. 1*a*, 10^{-10} M [Asp^1, Ile^5]-angiotensin II (AII, Sigma) and ACTH$_{1-24}$ (Ciba) caused a significant increase in aldosterone production, maximal with 10^{-8} M AII or ACTH$_{1-24}$. Also, a significant increase in aldosterone was produced by 10^{-8} M β-MSH (from the control value 24.9 ± 3.6 (s.e.) ng per 100,000 capsular cells to 45.2 ± 3.9; $P < 0.01$) and maximum increase was obtained with 10^{-6} M β-MSH. The maximum aldosterone response obtained with β-MSH, however, is about the same as with AII. Figure 1*b* shows that ACTH$_{1-24}$ has a potent stimulating effect on corticosterone production by decapsular cells, whereas β-MSH has no effect. The effect of the β-MSH analogue on the response of capsular cells to half-maximal aldosterone-stimulating doses of β-MSH and β-LPH (3×10^{-8} M), and of ACTH$_{1-24}$ and AII (1.5×10^{-10} M) are shown in Fig. 2. The analogue caused ~30% inhibition of aldosterone production induced by β-MSH at a molar ratio of 100 : 1, and ~80% inhibition at a molar ratio of 1,000 : 1, and inhibited the β-LPH-induced aldosterone production to a similar extent at the same molar ratios. However, it did not affect ACTH$_{1-24}$ or AII-induced aldosterone production at molar ratios from 10 : 1 to 10,000 : 1. In one experiment we found that a 30,000 molar excess of β-MSH analogue did not affect ACTH-induced aldosterone production, and in another, that the β-MSH analogue itself has no effect on aldosterone production at doses from 10^{-9} M to 3×10^{-5} M.

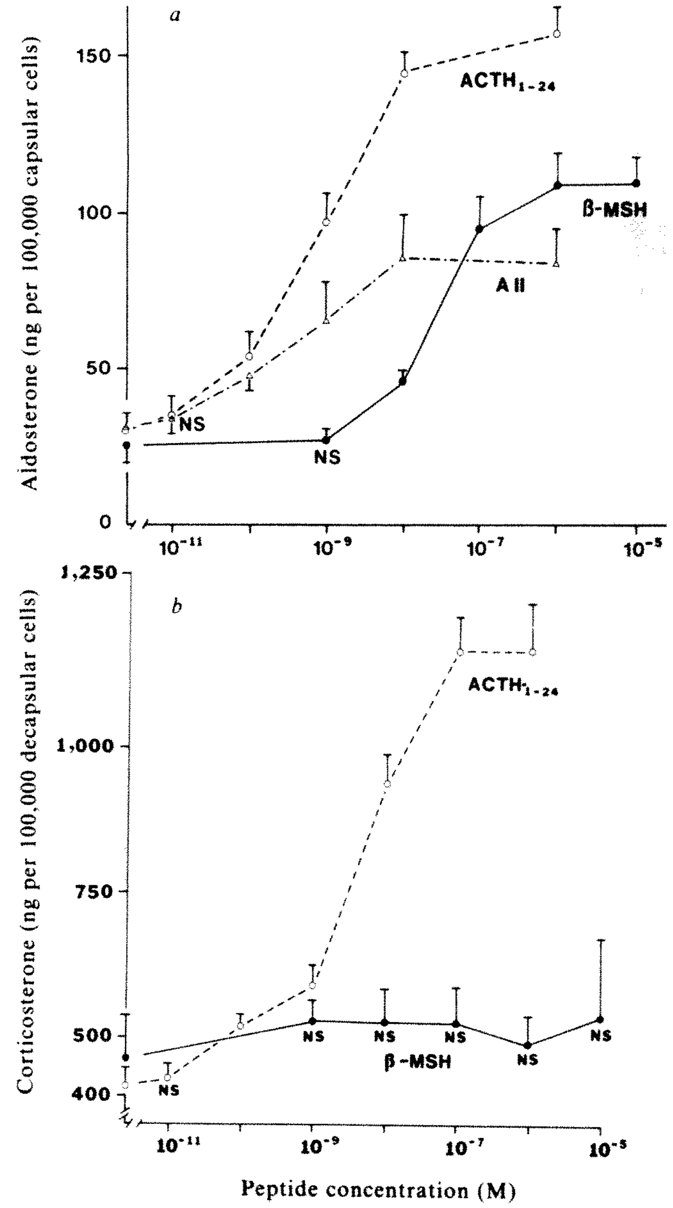

Fig. 1 *a*, Aldosterone production by AII, ACTH$_{1-24}$ and β-MSH in rat adrenal capsular cells. *b*, Corticosterone production by ACTH$_{1-24}$ and β-MSH in rat adrenal decapsular cells. Each point indicates mean ± s.e. from three different experiments. After decapitation, adrenal glands were removed and separated into capsular and decapsular portions. In *a*, capsular portions were minced into small pieces and incubated with collagenase (2 mg ml^{-1}) for 30 min. Collagenase-treated capsular cells were incubated in 1 ml medium 199 containing 2 mg ml^{-1} of bovine serum albumin in duplicate with various amounts of AII, ACTH$_{1-24}$ and β-MSH at 37 °C for 2 h. In *b*, collagenase-treated decapsular cells were incubated in duplicate with various amounts of ACTH$_{1-24}$ and β-MSH at 37 °C for 2 h. AII did not stimulate corticosterone production in decapsular cells (data not shown). NS: not significantly different from the control value; all other points significantly different from the control value ($P < 0.01$).

Studies by Page *et al.*[15] showed that α-MSH plus growth hormone stimulated aldosterone production in hypophysectomized sodium depleted rats. More recently, Vinson *et al.*[16]

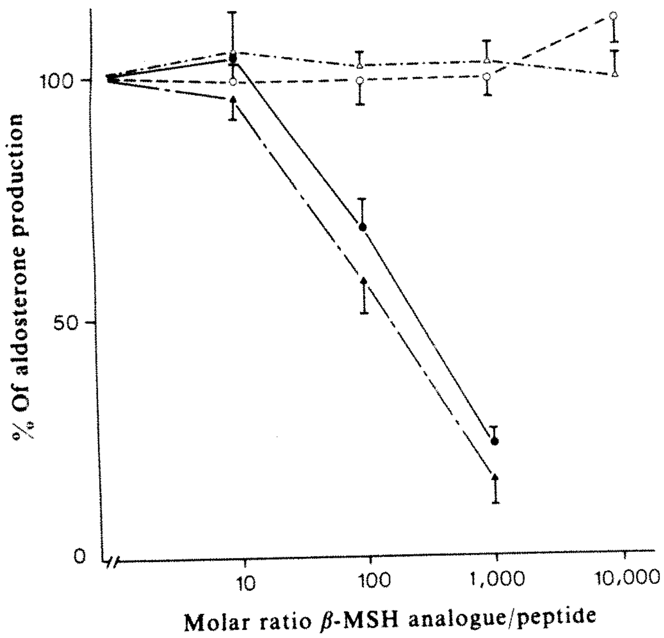

Fig. 2 Inhibition of aldosterone responses to half-maximal stimulating doses of β-MSH and β-LPH (3×10^{-8} M), and $ACTH_{1-24}$ and AII (1.5×10^{-10} M) by varying concentrations of β-MSH analogue. Collagenase-treated capsular cell suspensions were preincubated with various amounts (1.5×10^{-9} M to 3×10^{-5} M) of β-MSH analogue for 5 min and cell suspensions incubated with 3×10^{-8} M β-MSH or β-LPH, and with 1.5×10^{-10} M $ACTH_{1-24}$ or AII for 2 h. Each point shows mean ± s.e. from three different experiments. ●, β-MSH; ▲, β-LPH; ○, $ACTH_{1-24}$; △, AII.

reported that α-MSH has an adrenal zona glomerulosa-stimulating effect in the rat. The present data show that β-MSH has an aldosterone-stimulating effect on rat zona glomerulosa cells (Fig. 1*a*) and does not stimulate corticosterone production in rat adrenal decapsular cells (Fig. 1*b*). Although the concentration of β-MSH needed for half-maximal stimulation of aldosterone production was ~100 times greater than that of $ACTH_{1-24}$, we compared synthetic camel β-MSH with $ACTH_{1-24}$, which is known to be the biologically active sequence common to all species. As Lohmar *et al.*[17] and Lis *et al.*[18] reported some species differences in the lipolytic activity of β-LPH, it is possible that there are species differences in the aldosterone response to β-MSH. Moreover, recent evidence suggests that in humans β-MSH is an artefact due to degradation of β-LPH during extraction[19,20]. The physiological significance of β-MSH in the regulation of aldosterone secretion will therefore clearly require further study.

Because earlier studies showed that β-endorphin (β-LPH_{61-91}) has no steroidogenic properties[7], it seemed logical that γ-LPH (β-LPH_{1-58}) was the aldosterone-stimulating segment of β-LPH, and we have found that β-MSH (β-LPH_{41-58}), the carboxy-terminal segment of γ-LPH, contained aldosterone-stimulating activity. The demonstration that the β-MSH analogue inhibited both β-MSH and β-LPH activity to a similar extent suggests that the active core of β-LPH is β-MSH. Furthermore, the finding that the analogue inhibits β-LPH action but not $ACTH_{1-24}$ or AII actions suggests that the zona glomerulosa receptor for β-LPH or β-MSH may be different from the ACTH and AII receptors.

Circulating human pituitary pro-γ-melanotropin enhances the adrenal response to ACTH

Emad A. S. Al-Dujaili*‡, James Hope†, Fernando E. Estivariz†, Philip J. Lowry† & Christopher R. W. Edwards*

Departments of Endocrinology* and Chemical Pathology†,
St Bartholomew's Hospital, London EC1A 7BE, UK

The amino-terminal region of the common corticotropin/β-lipotropin (β-LPH) precursor has been identified in the AtT-20 mouse tumour cell as a glycopeptide with an apparent molecular weight of 16,000 (the '16K fragment')[1,2]. A third melanotropin core sequence or γ-MSH similar to that found in ACTH and β-LPH was predicted to occur in this glycopeptide from the complementary DNA sequence of mRNA isolated from bovine pituitary intermediate tissue[3]. Recently, the mouse 16K fragment has been found to have a small but significant potentiation on the corticosteroidogenesis elicited by ACTH in a static cell system, an effect that could be enhanced when the glycopeptide was pretreated with trypsin[4]. This synergism could also be mimicked by synthetic γ-MSH peptides *in vitro* and *in vivo*[5]. We report here the potentiating properties of a naturally occurring human pro-γ-MSH glycopeptide[6] on the ACTH-induced steroidogenic response of isolated perfused rat and human adrenocortical cells.

The *in vitro* superfusion studies of isolated adrenal cells used a modification of the system reported by Lowry and McMartin[7]. Female Wistar rats (200–220 g) were decapitated and the adrenal glands removed. The capsular tissue (namely zona glomerulosa cells) or the decapsulated tissue (zona fasciculata-reticularis cells) was then treated as previously described[8,9]. Two perfusion cell columns were prepared for each experiment; one column was always used as a control. The cells were checked for viability and counted before suspending in Bio-Gel. Each column contained $\sim1\times10^{6}$ cells. Using this technique the fasciculata-reticularis contamination of the glomerulosa preparation was 5–10% (ref. 10) as assessed by light microscopy and a Coulter counting system. For the preparation of isolated human adrenal cells, adrenocortical tissue obtained at total nephrectomy for renal carcinoma was treated in the same manner as described for rat adrenal tissue.

The cells were stimulated with $ACTH_{1-24}$ 1–5 ng l^{-1}, $ACTH_{1-39}$ 2–10 ng l^{-1}, Pro-γ-MSH_{1-77} (ref. 6) (γ-MSH precursor Trp 105 to Gln 29, numbering system of Nakanishi *et al.*[3]) 8×10^{-11}–5×10^{-9} mol l^{-1} (10-min pulses, 30–40 min between each pulse) alone or during γ-MSH precursor infusion and fractions were collected every 5 min. The concentrations of γ-MSH precursor used in these studies were based on the plasma levels of this polypeptide measured by radioimmunoassay[11]. The molecular size of the immunoactive γ-MSH

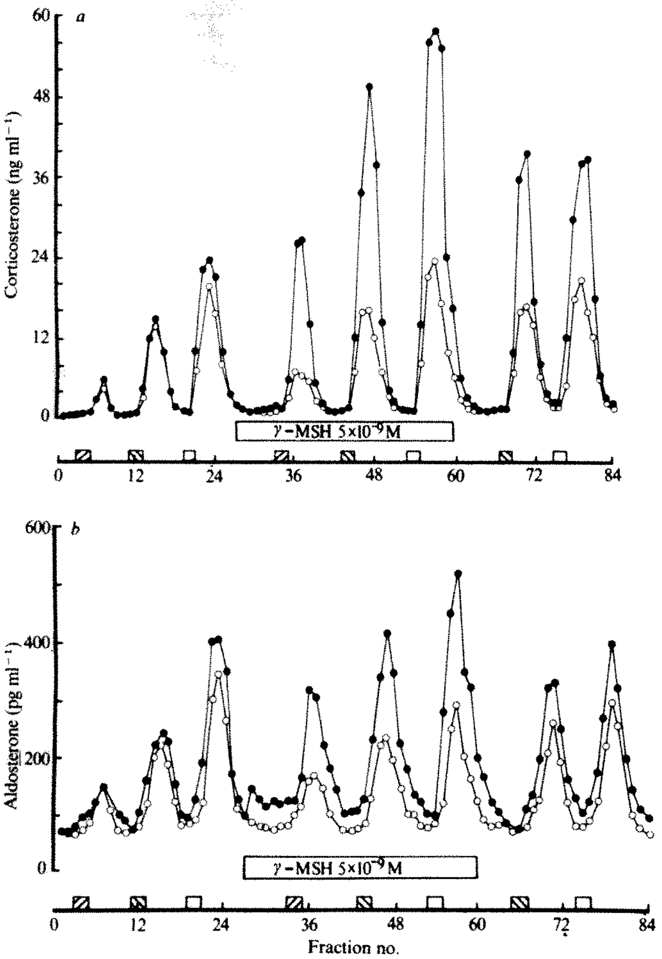

Fig. 1 Corticosterone (*a*) and aldosterone (*b*) secretion by isolated perfused rat zona glomerulosa cells in response to pulses of ACTH$_{1-24}$ given before, during and after an infusion of γ-MSH precursor (5×10^{-9} mol l^{-1}). The intact molecule of the precursor (77 amino acids) was found to circulate in the plasma of normal subjects and patients with ectopic ACTH syndrome, Nelson's syndrome and pituitary-dependent Cushing's disease as checked by affinity column chromatography. ACTH$_{1-24}$ and γ-MSH precursor were dissolved in 0.9% sodium chloride solution containing 10 mM HCl, 1 g l^{-1} bovine serum albumin, 1 g l^{-1} polypeptide (Sigma) and 100 mg l^{-1} lima bean trypsin inhibitor. Responses in the column infused with γ-MSH precursor (●) are compared with those in a control column (○). Doses of ACTH$_{1-24}$ given were 1 ng l^{-1} (▨), 2.5 ng l^{-1} (▧) and 5 ng l^{-1} (□). γ-MSH precursor was infused in the experimental columns only between fractions 27–60.

polypeptide in plasma corresponds to a 77-amino acid glycopeptide[11]. Aldosterone levels were measured in the superfusates by the specific, direct radioimmunoassay developed for human plasma[12], which as we have since shown[8,13] gives results comparable to those of methods which involve prior extraction of the aldosterone. Corticosterone was measured in the superfusates by a highly specific, direct radioimmunoassay[14], which has also been checked against techniques involving extraction[14]. The corticosterone assay uses ^{125}I-corticosterone–iodohistamine as ligand and highly specific corticosterone antiserum raised in rabbits against corticosterone-3-mono-oxime–bovine serum albumin immunogen. The specificity of the antibody was confirmed by the negligible cross-reactivities of this antiserum with potential interfering steroids.

ACTH$_{1-24}$ produced a dose-dependent increase in corticosterone and aldosterone production by rat zona glomerulosa cells (Fig. 1). When pro-γ-MSH$_{1-77}$ was infused in one column there was a significant potentiation of the corticosterone response to ACTH$_{1-24}$ which persisted even after the γ-MSH precursor infusion was stopped (Fig. 1*a*). The aldosterone response to ACTH was also potentiated by γ-MSH precursor but this potentiation was less marked than that observed for corticosterone (Fig. 1*b*). Similar results were obtained when rat zona glomerulosa cells were stimulated by ACTH$_{1-39}$ during γ-MSH precursor infusion. These findings were reproducible and Fig. 2 shows the responses of aldosterone and corticosterone produced by ACTH$_{1-24}$ and ACTH$_{1-39}$ using isolated superfused rat zona glomerulosa cells with or without the infusion of γ-MSH precursor (5×10^{-9} mol l^{-1}). There was a significant three- to fivefold increase ($P<0.001$) in corticosterone production and 0.75-fold ($P<0.01$) in aldosterone production by ACTH$_{1-24}$ and γ-MSH precursor infusion compared with ACTH$_{1-24}$ alone. ACTH$_{1-39}$ also produced a significant potentiation in corticosterone (1.5–2.5-fold, $P<0.001$) and aldosterone (1.0–2.0-fold, $P<0.001$) production during γ-MSH precursor infusion.

ACTH$_{1-24}$ and ACTH$_{1-39}$ produced a dose-dependent increase in corticosterone production by rat zona fasciculata-reticularis cells (Fig. 3*a*) which was also potentiated by continuous infusion of γ-MSH precursor, as can be seen by comparing the results in the experimental column with those produced by ACTH alone in the control column (Fig. 3*a*).

Pro-γ-MSH$_{1-77}$ alone (8×10^{-11}–4×10^{-9} mol l^{-1}) did not significantly increase steroidogenesis in either zona glomerulosa or zona fasciculata-reticularis cells, although a slight effect on aldosterone production was observed at the beginning of a continuous infusion (Fig. 1). Also, the precursor did not significantly potentiate the ACTH$_{1-24}$ response of cells of either tissue when given simultaneously with ACTH in bolus doses (as confirmed by Kruskal–Wallis one-way analysis of variance by ranks). The effect of an ACTH and γ-MSH precursor bolus dose on steroidogenesis was potentiated (Fig. 3*b*) following a 30-min priming dose of γ-MSH precursor (4×10^{-9} mol l^{-1}), and this effect could be maintained for some time by simultaneous bolus doses of the glycopeptide with ACTH. Isolated perfused human adrenal cells containing a mixture of zona glomerulosa and

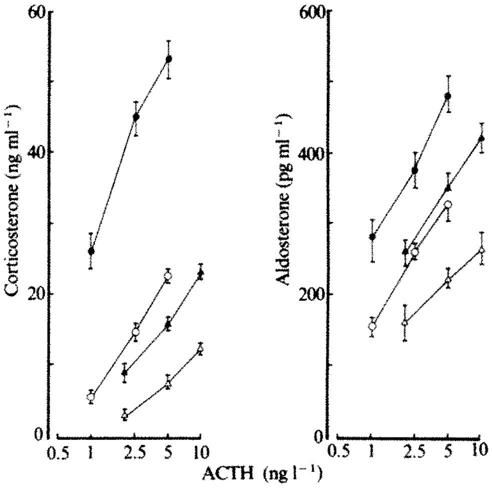

Fig. 2 A summary of the responses of aldosterone and corticosterone produced by ACTH$_{1-24}$ (1.0 ng l^{-1}, $n=5$; 2.5 ng l^{-1}, $n=5$; 5.0 ng l^{-1}, $n=6$) and ACTH$_{1-39}$ (2.0 ng l^{-1}, $n=6$; 5.0 ng l^{-1}, $n=4$; 10.0 ng l^{-1}, $n=5$) using isolated perfused rat zona glomerulosa cells with (●, ACTH$_{1-24}$; ▲, ACTH$_{1-39}$) or without (○, ACTH$_{1-24}$; △, ACTH$_{1-39}$) the infusion of pro-γ-MSH (5×10^{-9} mol l^{-1}). For corticosterone there was a three- to fivefold increase after ACTH$_{1-24}$ and pro-γ-MSH infusion compared with ACTH as bolus doses alone, which was significant ($P<0.001$) for all doses of ACTH$_{1-24}$. For aldosterone there was a 0.5–1.0-fold increase of the ACTH$_{1-24}$ and pro-γ-MSH infusion compared with ACTH alone. This potentiation was also significant ($P<0.01$ for ACTH 1.0 ng l^{-1}; $P<0.005$ for ACTH 2.5 ng l^{-1}; $P<0.001$ for ACTH 5.0 ng l^{-1}). For ACTH$_{1-39}$ the potentiation in corticosterone was 1.5–2.5-fold ($P<0.001$) and aldosterone 1.0–2.0-fold ($P<0.001$) during pro-γ-MSH infusion. Results are the mean ± s.e.m.

fasciculata-reticularis cells behaved similarly to rat adrenal cells, producing an increase in corticosterone (twofold) and aldosterone (20–40%) secretion to bolus doses of ACTH during an infusion of pro-γ-MSH (Table 1).

Thus, the intact pro-γ-MSH_{1-77} can potentiate the action of $ACTH_{1-24}$ or $ACTH_{1-39}$ on isolated superfused rat and human zona glomerulosa and zona fasciculata-reticularis cells to secrete corticosterone and aldosterone. This action was only apparent when the cells were exposed to a priming infusion or to a simultaneous continuous infusion and was more marked on corticosterone than on aldosterone production. It therefore seems that the potentiation of ACTH-induced steroidogenesis by the naturally occurrring intact form of pro-γ-MSH is time dependent. As there would be little or no degradation of pro-γ-MSH by contaminating peptidases in the superfused system used in our study, the physiological relationship to observations made with trypsin-treated 16K fragment[4] and synthetic γ-MSH[5] is unclear.

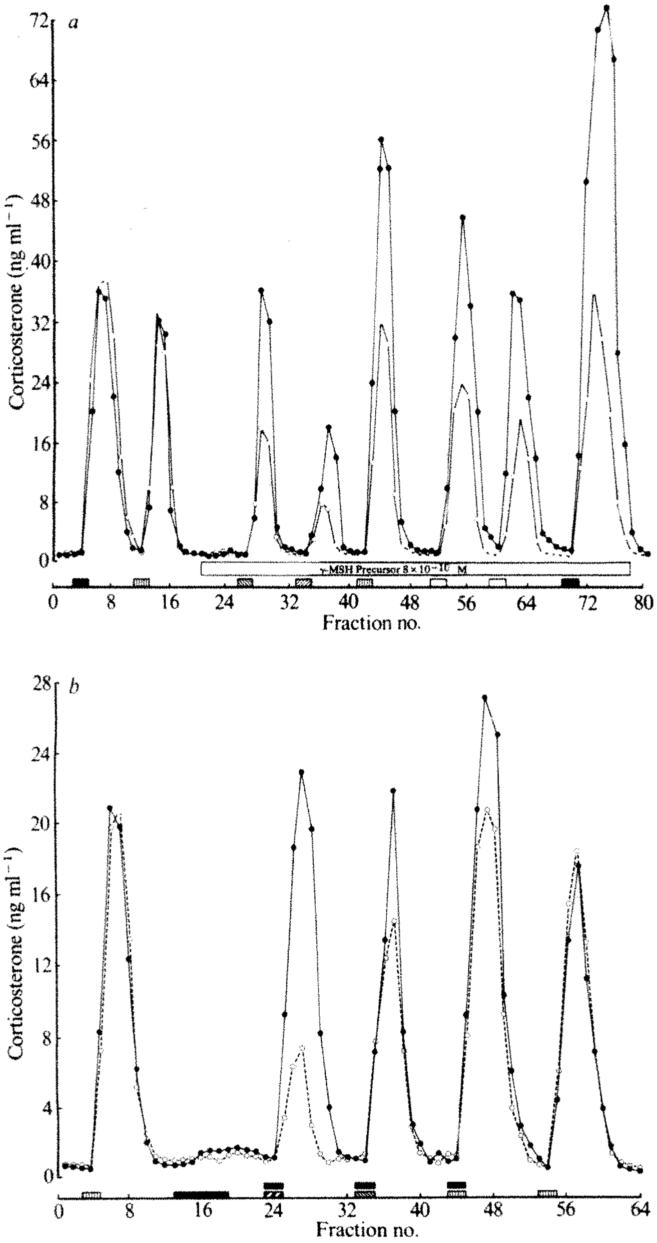

Fig. 3 *a*, Corticosterone secretion by isolated perfused rat zona fasciculata-reticularis cells in response to pulses of $ACTH_{1-24}$ and $ACTH_{1-39}$ given before, during and after an infusion of pro-γ-MSH (8×10^{-10} mol l^{-1}). Responses in the column infused with γ-MSH precursor (●) are compared with those in a control column (○). Doses of $ACTH_{1-24}$ given were 1 ng l^{-1} (☐), 2.5 ng l^{-1} (⬚) and 5 ng l^{-1} (■), and of $ACTH_{1-39}$, 2 ng l^{-1} (▨), 5 ng l^{-1} (▩) and 10 ng l^{-1} (▥). γ-MSH precursor was infused in the experimental column only between fractions 20–78. *b*, Corticosterone responses by isolated perfused rat zona glomerulosa cells in response to pulses of $ACTH_{1-24}$ (▨ 1 ng l^{-1}; ▩, 2.5 ng l^{-1}; ▥, 5 ng l^{-1}) given either alone in control column (○) or together with γ-MSH precursor (⬚, 4×10^{-9} mol l^{-1}) (●) after a 30-min priming infusion of γ-MSH precursor (⬚, fractions 13–19). The first and last bolus doses of ACTH in the experimental column were given without γ-MSH precursor.

Table 1 Aldosterone and corticosterone secretion by isolated perfused human adrenocortical cells in response to pulses of $ACTH_{1-24}$ (1–5 ng l^{-1}) given before and during an infusion of γ-MSH_{1-77}

Secretagogue		Aldosterone (pg ml^{-1}, mean ± s.d.)	Corticosterone (ng ml^{-1}, mean ± s.d.)
ACTH	Basal value	69.8 ± 9.0 (8)	0.5 ± 0.15 (8)
	ACTH (1 ng l^{-1})	135.0 ± 17.6 (5)	2.62 ± 0.45 (5)
	ACTH (2.5 ng l^{-1})	166.3 ± 17.8 (8)	3.28 ± 0.62 (8)
	ACTH (5 ng l^{-1})	183.3 ± 19.7 (5)	3.95 ± 0.92 (5)
ACTH + pro-γ-MSH (4×10^{-9} M)	Basal value	74.6 ± 11.6 (8)	0.55 ± 0.06 (8)
	ACTH (1 ng l^{-1})	187.5 ± 42.7* (4)	4.28 ± 0.83* (4)
	ACTH (2.5 ng l^{-1})	196.7 ± 5.8* (4)	5.74 ± 1.66* (4)
	ACTH (5 ng l^{-1})	250.0 ± 34.6* (4)	8.15 ± 2.98* (4)

* There was a significant potentiation ($P < 0.01$) in the response to ACTH during γ-MSH precursor infusion as confirmed by Mann-Whitney *U*-test. Values in parentheses represent the number of experiments.

We cannot altogether rule out the possibility that the potentiation of aldosterone production by zona glomerulosa cells is due to contaminating fasciculata cells providing the precursor corticosterone. This does occur in static systems but is less likely to occur in superfusion systems. Furthermore, the fact that ACTH and serotonin induce aldosterone secretion by our zona glomerulosa cells to a similar extent suggests that fasciculata contamination is not a major problem. We believe instead that the potentiation is related only to the effects of ACTH, a view confirmed by the lack of potentiating action of γ-MSH precursor on other zona glomerulosa stimulators such as angiotensin II, potassium or serotonin.

Our results suggest that the potentiating action of γ-MSH precursor may play an important part in modulating ACTH-induced steroidogenesis. A specific effect of two products of ACTH biosynthesis [α-MSH (ref. 15) and β-LPH (ref. 16)] on aldosterone production by zona glomerulosa cells has recently been observed and Pedersen *et al.*[5] have reported a direct effect of synthetic γ-MSH on adrenal cholesterol ester hydrolase activity. However, because, in our experiments γ-MSH precursor did not significantly induce steroidogenesis in the absence of ACTH it is uncertain whether the γ-MSH precursor has a direct steroidogenic action.

This work was supported by the MRC, the British Heart Foundation, the Joint Research Board, St Bartholomew's Hospital and the North East Thames Regional Research Scheme. We thank the surgeons in the Department of Urology, St Bartholomew's Hospital, for supplying human adrenal tissue and Dr B. C. Williams for collaboration in developing the direct radioimmunoassay for corticosterone.

The haematopoietic stem cells which produce colonies in the spleen of irradiated mice (CFU-S)[1] can differentiate into erythrocytes, granulocytes, megakaryocytes and B lymphocytes[2–4]. Although mast cell precursors are known to be present in the bone marrow[5], spleen[6], fetal liver[7] and peripheral blood[8] of mice, the relationship between the mast cell precursor and CFU-S has remained unclear. We have now made use of mice of two mutant genotypes to determine whether or not the tissue mast cell is a progeny of CFU-S. Giant granules of beige (C57BL/6-bg^J/bg^J, Chediak-Higashi syndrome) mice can be used for identification of the origin of both tissue mast cells[5] and granulocytes[9], and WBB6F$_1$-W/W^v mice are useful recipients because they lack tissue mast cells owing to a defect in mast cell precursors[10]. We injected the cells from a single spleen colony into each WBB6F$_1$-W/W^v mouse and demonstrated directly that the tissue mast cell is a progeny of CFU-S.

Mice of strain WBB6F$_1$ (WB-$W/+$X C57BL/6-$W^v/+$)F$_1$-W/W^v and C57BL/6-bg^J/bg^J, +/+ were obtained from the Jackson Laboratory, Bar Harbor, Maine. As the haemoglobin pattern of WBB6F$_1$-W/W^v mice (diffuse, Hbb^d/Hbb^s) can easily be distinguished from that of C57BL/6 mice (sharp, Hbb^s/Hbb^s), it was used to identify the origin of erythrocytes[11]. The experimental design is shown in Fig. 1. X ray-irradiated (800 rad) C57BL/6-+/+ mice were injected with a mixture of bone marrow cells from beige and normal C57BL/6 mice. The irradiated C57BL/6 mice were killed 12 days after injection of bone marrow cells, spleen colonies were enucleated under the dissection microscope and cells from each colony suspended in serum from C57BL/6 mice. An aliquot of suspended cells was smeared, stained with Sudan Black B and counterstained with Giemsa solution to examine the proportion and type of granulocytes (beige or normal)[9]. The rest of the cells were injected into a WBB6F$_1$-W/W^v mouse intravenously. A blood sample was obtained from a retroorbital sinus 15 weeks after the cell injection. Haemoglobin pattern was determined by cellulose acetate electrophoresis after modification of haemoglobin with cystamine[12] and smears were stained with Sudan Black B to follow the appearance of beige-type granulocytes. After the examination of peripheral blood, the WBB6F$_1$-W/W^v recipient mice were killed and tissue distribution of mast cell types was determined (Table 1). The interval of 15 weeks between cell injection and killing of the recipients was chosen because previous experiments showed that the number of mast cells increased in tissues of WBB6F$_1$-W/W^v mice until the fifteenth week after the bone marrow transplantation[6,10].

Table 1 Type of mast cells in tissues of WBB6F$_1$-W/W^v mice 15 weeks after injection of a single spleen colony each

Tissues	No. of mice in which mast cells of each type appeared Beige type only	Normal type only	Both types	Total
Skin	0	0	0	0
Mesentery	0	2	0	2
Caecum	2	4	0	6
Forestomach	2	6	2	10
Glandular stomach	3	7	2	12
Spleen	10	7	3	20
Whole body*	10	9	4	23

Tissues of 106 WBB6F$_1$-W/W^v mice were examined. Spleen, stomach, caecum and a piece of dorsal skin were removed and fixed in 10% buffered formalin (*p*H 7.2). The stretched preparation of the mesentery was also fixed in 10% formalin. Tissues were embedded in paraffin; sections (5 μm thick) and stretched mesentery were stained with acidified toluidene blue (*p*H 3.0). Criteria to determine the appearance of mast cells in the skin, mesentery, forestomach and glandular stomach are described elsewhere[6]. Mast cells were considered to have developed in the spleen when more than 20 mast cells were detected per longitudinal section.

* No. of mice in which mast cells appeared in more than one of above tissues.

A total of 117 discrete colonies were enucleated from the spleen possessing 1–3 colonies which developed after injecting the mixture of 10^4 beige and 10^4 normal bone marrow cells. In 36 out of 117 colonies, more than 10% of cells in one colony were granulocytes. Beige-type granulocytes with giant sudanophilic granules were predominant (>90%) in 19 out of 36 colonies, and normal-type granulocytes predominated in 16 colonies. A considerable number of granulocytes of both types were observed in only 1 of 36 colonies (15% beige type, 85% normal type). Thus, each spleen colony could easily be identified as from either a beige C57BL/6 mouse or a normal C57BL/6 mouse.

One hundred and six WBB6F$_1$-W/W^v mice which each received cells from a single spleen colony survived for 15 weeks. A change of haemoglobin pattern from diffuse to sharp was detected in 3 out of 106 WBB6F$_1$-W/W^v mice. Only 1 of 106 WBB6F$_1$-W/W^v mice showed beige-type granulocytes (3%) in the peripheral blood. As shown in Table 1, mast cells appeared in more than one of the tissues examined in 23 out of 106 WBB6F$_1$-W/W^v mice. All the mast cells scored were of either beige or normal type in 19 out of 23 mice. The type of granulocytes in the original spleen colony had been determined in 10 of 19 such cases. The relationship between the type of granulocytes and that of the mast cells is shown in Table 2. The type of the

granulocytes and that of the tissue mast cells were exclusively consistent in all cases.

In the above experiment, mast cells appeared in only 23 of 106 WBB6F$_1$-W/W^v mice after injecting cells from an individual spleen colony. Two experiments were carried out to obtain more information on this low acceptance of spleen-colony cells. First, as there is a possibility that colonies were not excised precisely from the spleen, cells from the other areas of the spleen (over a diameter of about 2 mm) rather than the colony were injected to WBB6F$_1$-W/W^v mice. No mast cells appeared in the examined tissues of the W/W^v recipients 15 weeks after the cell injection (Table 3). Second, in the experiment shown in Tables 1 and 2, discrete colonies were enucleated from the spleen possessing 1–3 colonies to minimize contamination of cells derived from more than two colonies. However, the number of mast cell precursors per colony might be dependent on the number of colonies per spleen because there are controversial reports about the effect of graft size on proliferation and differentiation of CFU-S[13,14]. Although the efficiency of mast cell development increased after injection of an individual colony enucleated from the spleen possessing 7–11 colonies, both beige and normal types of mast cells appeared in more than half cases (Table 3). The latter result illustrates the difficulty of enucleating an individual colony from a spleen with 7–11 colonies, so the increased efficiency of mast cell development could not simply be attributed to the effect of graft size.

The present results directly demonstrate that precursors of tissue mast cells are generated within a spleen colony produced by CFU-S. Because the type of granulocytes in the colony matched the type of mast cells in tissues of WBB6F$_1$-W/W^v mice, CFU-S seems to be a common precursor for granulocytes and tissue mast cells.

Although a considerable proportion of granulocytes was observed in only 36 out of 117 spleen colonies examined, most of the colonies contained a considerable proportion of erythroid cells. Since Wu *et al.*[2] have shown that erythroid cells and granulocytes in the individual spleen colony are derived from a single CFU-S, at least a portion of CFU-S seems to have the potential to differentiate into erythrocytes, granulocytes and tissue mast cells. In fact, after injection of a beige-type spleen colony into a WBB6F$_1$-W/W^v mouse (4141 in Table 2), haemoglobin pattern changed from diffuse to sharp, beige-type granulocytes appeared in the peripheral blood, and beige-type mast cells developed in the spleen, stomach and caecum.

Immunochemical evidence for hybrid sialoglycoproteins of human erythrocytes

W. J. Mawby*, D. J. Anstee† & M. J. A. Tanner*

* Department of Biochemistry, University of Bristol,
Bristol BS8 1TD, UK
† South Western Regional Blood Transfusion Centre, Southmead,
Bristol BS10 5ND, UK

The two major sialoglycoproteins of the human erythrocyte membrane (α and δ, glycophorins A and B[1,2]) have identical amino acid sequences for the first 26 residues from the amino terminus, except that α expresses M or N blood group antigen activity whereas δ carries only blood group N activity. In addition, the asparagine at position 26 on α carries an oligosaccharide chain which is absent from the same position on δ. The two sialoglycoproteins differ in their remaining amino acid sequence and δ expresses blood group Ss activity. There are also variant sialoglycoproteins which have properties of both the α and δ molecules[1,3] and may be hybrids of these. Using antibodies directed against different structural regions of the major sialoglycoprotein α, we confirm here that two variant erythrocytes (Miltenberger class V (MiV) and Ph) contain hybrid sialoglycoprotein molecules (Fig. 1). These hybrid sialoglycoproteins arise from cross-over events between the genes coding for α and δ. It is suggested that the two genes are closely associated in the order α, δ ($5' \rightarrow 3'$) on the chromosome.

The two antibodies used in this study were R18 and I16. R18 is specific for a portion of the extracellular region of α and I16 for the intracellular portion (and/or intramembranous portion; see Fig. 1). The R18 antibody (LICR.LON/R18) is a mouse monoclonal antibody that reacts with untreated and trypsin-treated normal erythrocytes but does not react with En(a−) erythrocytes which lack α (ref. 4). Trypsin removes part of the extracellular region of α, thus the binding site of the antibody lies between the extracellular residues 40 and 72 (ref. 4). I16 was produced in a rabbit by repeated subcutaneous injections of partially purified sialoglycoprotein α in Freund's complete adjuvant. The antigen was partially purified by butanol extraction of erythrocyte membranes[5], followed by chromatography on Sepharose 6B equilibrated in 5 mM sodium phosphate *p*H 8.0, 0.1% Ammonyx LO[6]. The rabbit was bled 7–10 days after the fourth and subsequent injections. The antibody was shown to be specific for α by two-dimensional immunoelectrophoresis and immunoprecipitation using detergent-solubilized radioiodinated erythrocytes. To remove antibodies specific for the extracellular portion of α, the antiserum was repeatedly absorbed with intact erythrocytes until no haemagglutination activity remained, and the amount of solubilized α immunoprecipitated remained unchanged. This antibody therefore recognizes determinants between residues 73 and 131 of α (ref. 7).

The two antibodies were used to immunoprecipitate membrane proteins of normal and variant human erythrocytes which had been labelled with ^{125}I using lactoperoxidase. The variant erythrocytes studied were MiV erythrocytes from both homozygous[8] and heterozygous individuals[1], and erythrocytes heterozygous for the Ph condition[3]. These variants contain abnormal sialoglycoproteins designated $(\alpha\text{–}\delta)^{\mathrm{MiV}}$ in MiV erythrocytes[1] and $(\delta\text{–}\alpha)^{\mathrm{Ph}}$ in Ph erythrocytes[3]. Figure 2 (*f*, *g*, *i*, *k*) shows that the $(\alpha\text{–}\delta)^{\mathrm{MiV}}$ component is immunoprecipitated by R18 but not by I16. This sialoglycoprotein therefore contains an antigenic determinant of α in the extracellular region between residues 40 and 72, but lacks the determinant recognized by I16 in the remaining C-terminal portion. Previous evidence suggested that $(\alpha\text{–}\delta)^{\mathrm{MiV}}$ has features of both α and δ components[1,8] as it carries weak blood group M, N antigen activity and has the characteristic trypsin sensitivity of normal α, but also carries blood group s activity which is associated with α[9,10]. The present results therefore provide independent confirmation that the variant sialoglycoprotein of MiV erythrocytes is a hybrid molecule consisting of the amino-terminal portion of α, and the carboxy-terminal portion of δ, or more accurately an unusual allele of δ[1,8].

Figure 2 (*h*, *l*) shows that the $(\delta\text{–}\alpha)^{\mathrm{Ph}}$ component of Ph erythrocytes is immunoprecipitated by I16 but not by R18. The $(\delta\text{–}\alpha)^{\mathrm{Ph}}$ sialoglycoprotein therefore contains an antigenic determinant of α in the intracellular or intramembranous regions, but does not contain the extracellular determinant recognized by R18. We have previously suggested that the $(\delta\text{–}\alpha)^{\mathrm{Ph}}$ component contains the amino-terminal portion of δ as it is trypsin resistant, lacks an *N*-glycosidically linked oligosaccharide and blood group M activity, but carries blood group N activity[3]. The present data confirm that the $(\delta\text{–}\alpha)^{\mathrm{Ph}}$ component has an amino-terminal portion which differs from that of normal α, and conclusively shows that the component contains a determinant of the carboxy-terminal region of α. This provides strong evidence that the $(\delta\text{–}\alpha)^{\mathrm{Ph}}$ component is a hybrid molecule consisting of the amino-terminal portion of δ and the carboxy-terminal portion of α.

We suggest that the hybrid molecules arise by a mechanism similar to that which produces the abnormal Lepore-type haemoglobins[11,12], which occur when misalignment of genes leads to unequal crossing-over and generates new genes with characteristics of both the parent genes. The misalignment of genes coding for α and δ may result from the sequence

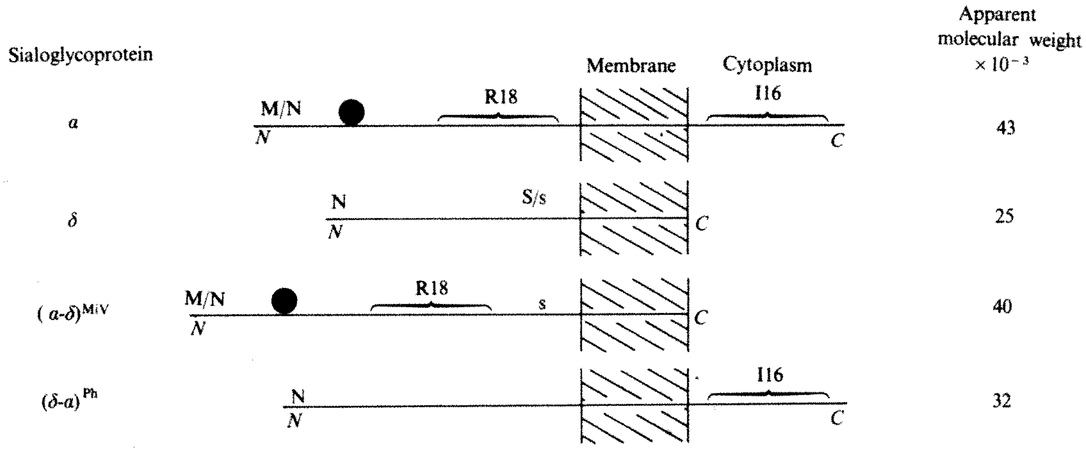

Fig. 1 Schematic diagram of the structures of normal and variant sialoglycoproteins. *N* and *C* represent the amino and carboxy termini of each sialoglycoprotein; M, N, S, s represent the blood group antigens associated with each molecule. The filled circle shows the approximate position of the asparagine-linked oligosaccharide when present. This oligosaccharide has been shown to be present on $(\alpha\text{–}\delta)^{\mathrm{MiV}}$ using a lectin binding technique[3] with the *Phaseolus vulgaris* lectin (phytohaemagglutinin, data not shown). Also shown are the approximate locations of the antigenic sites recognized by the antibodies R18 and I16. The apparent molecular weights are derived from the electrophoretic mobility of the proteins on SDS-polyacrylamide gels run in the same conditions as those described in Fig. 2 legend.

0028-0836/81/200161—02$01.00

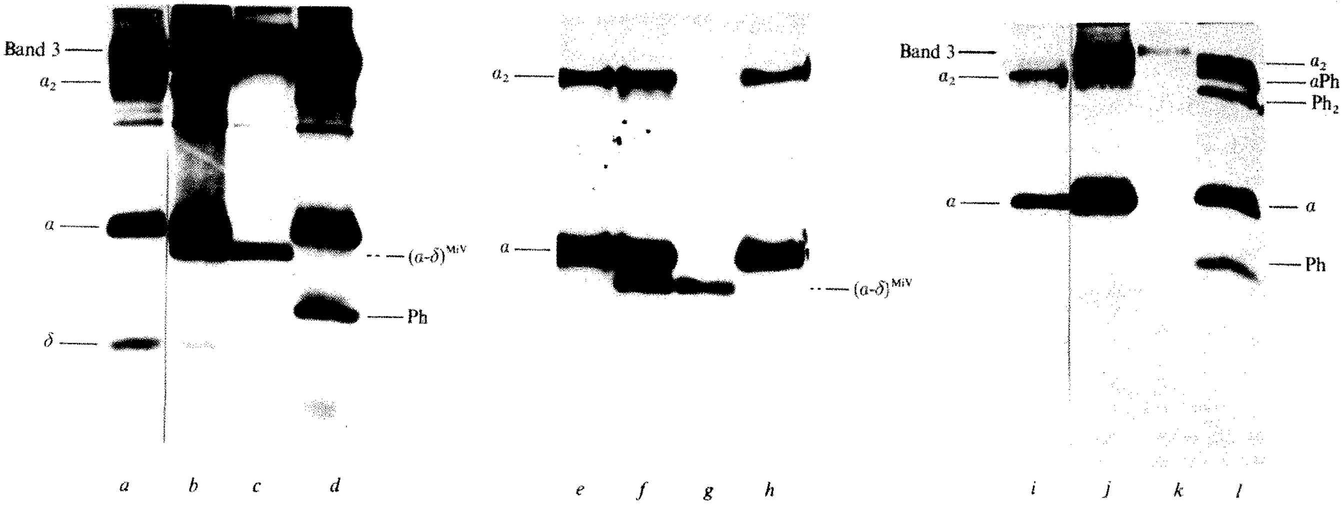

Fig. 2 Immunoprecipitation of labelled sialoglycoproteins from variant erythrocytes. Intact erythrocytes from donor M.P. (Ph variant), donor L.R. (heterozygous for the MiV phenotype), donor F.M. (homozygous for the MiV phenotype) and a normal donor were radioiodinated using lactoperoxidase[1]. The cells were washed and solubilized in 4 vol of 150 mM NaCl, 50 mM Tris-HCl pH 8.0, 1% w/v Na deoxycholate[16]. When using R18 the solubilized sample was initially treated with mouse non-immune serum for 1 h, followed by rabbit anti-mouse IgG for 30 min and 200 μl of a 10% suspension of fixed *Staphylococcus aureus* (strain Cowan I) for a further 30 min, all at 0 °C. The sample was then centrifuged and 10 μl of R18 antibody was added to the supernatant, followed by 10 μl of rabbit anti-mouse IgG (1 mg ml^{-1}) and 50 μl of 50% Protein-A Sepharose (Pharmacia); times and temperature as for the initial treatment. The mixture was centrifuged and the pellet washed three times with 0.15 M NaCl, 5 mM EDTA, 0.5% Triton X-100, all at 0 °C. The pellet was then suspended in 20 mM Tris pH 8.0, 5 mM EDTA, 5% SDS, 10% glycerol, 0.1 mg ml^{-1} bromophenol blue, 2% β-mercaptoethanol, boiled for 3 min, centrifuged and the supernatant electrophoresed in a 10% slab gel with a 5% overlay, using the buffer system of Laemmli[17]. When using I16 antibody the sample was first treated with normal rabbit IgG and *S. aureus* as above. The supernatant was immunoprecipitated with 10 μl of I16 followed by 50 μl protein-A Sepharose and the pellet treated as above. The SDS-polyacrylamide gels were run overnight and fixed in methanol/acetic acid/water (5:1:5) for 30 min, washed, dried and exposed to Kodak No-screen film for 1–5 days. *a–d*, Autoradiographs of radioiodinated intact erythrocytes before immunoprecipitation. *a*, Control erythrocytes; *b*, MiV heterozygous erythrocytes; *c*, MiV homozygous erythrocytes and *d*, Ph erythrocytes. *e–h*, Autoradiograph of ^{125}I-labelled components immunoprecipitated using R18. *e*, Control erythrocytes; *f*, MiV heterozygous erythrocytes; *g*, MiV homozygous erythrocytes and *h*, Ph erythrocytes. *i–l*, Autoradiograph of ^{125}I-labelled components immunoprecipitated using an IgG fraction of I16 antibody. *i*, Control erythrocytes; *j*, MiV heterozygous erythrocytes; *k*, MiV homozygous erythrocytes and *l*, Ph erythrocytes. The apparent molecular weights of the monomer bands are given in Fig. 1. α_2, αPh and Ph_2 represent the dimer of α, the complex of α with Ph and the dimer of Ph respectively. The band in lane *k* represents nonspecific background precipitation of band 3.

homology of the first 26 residues of the two proteins[9,10,13]. It follows from this interpretation of the origin of the hybrid sialoglycoproteins that the genes coding for α and δ are closely linked on the same chromosome. Furthermore, the gene coding for α must be on the 5′ side of that coding for δ as the event which gives rise to the α–δ hybrid sialoglycoprotein ($(\alpha\text{–}\delta)^{\mathrm{MiV}}$) also results in the absence of both normal α and δ[1,8], a situation similar to that occurring in Lepore-type haemoglobins. Conversely, the event which gives rise to a δ–α hybrid would not exclude normal α and δ, a situation analogous to the anti-Lepore haemoglobins. The $(\delta\text{–}\alpha)^{\mathrm{Ph}}$ component, a δ–α hybrid sialoglycoprotein, is associated with the presence of α but not δ[3]. This absence of δ is unexpected and we have attributed it to a cross-over event between a normal chromosome containing α and δ and one lacking δ. The latter are common in the black African population from which the variant originated[14].

This work was supported in part by a grant from the MRC. We thank Dr P. A. W. Edwards for the monoclonal antibody LICR/LON. R18.

Note added in proof: The genes giving rise to the MN and Ss antigens and thus α and δ have recently been assigned to the *q*28 or *q*31 region of chromosome 4 (ref. 15).

Properties of postsynaptic channels induced by acetylcholine in different frog muscle fibres

R. Miledi & O. D. Uchitel

Department of Biophysics, University College London,
Gower Street, London WC1E 6BT, UK

Skeletal muscles in the frog are composed of two distinct classes of muscle fibre: fast muscle fibres capable of propagating action potentials and twitches, and slow muscle fibres normally unable to generate action potentials or twitches[1,2]. In addition, amphibian muscles contain a spectrum of 'intermediate' fibres whose structural and functional properties lie between those of fast and slow fibres[3–6]. Much is now known about the characteristics of the channels opened by the transmitter acetylcholine (ACh) acting on the membrane of fast fibres[7,8], but the molecular action of ACh on the other fibre types is only poorly understood. We report here the existence of a muscle in the mandibular arch of the frog in which most, if not all, the fibres are multiply innervated and are capable of eliciting action potentials. We also report that the channels induced by the transmitter on the synaptic membrane of fast, slow and submaxillaris muscle fibres differ in their lifetimes and conductances.

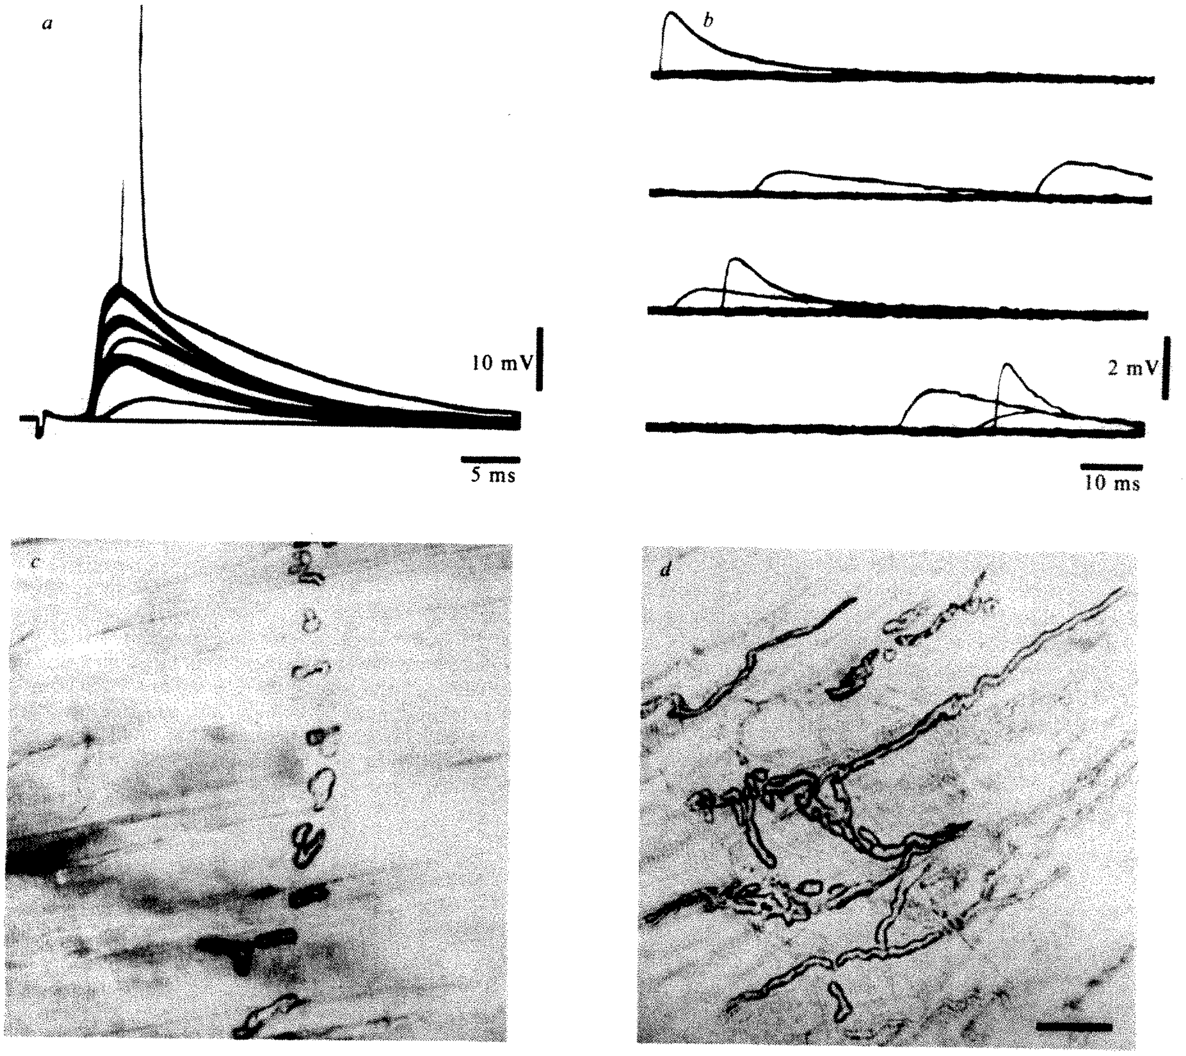

Fig. 1 Endplate potentials recorded intracellularly from a fibre in a submaxillaris muscle in Ringer with 5.4 mM Ca^{2+}. The muscle was preincubated in 2 M formamide for 90 min to block the contractile responses[23]. *a*, The superimposed records show five components obtained by increasing progressively the strength of the stimulus applied to the submaxillaris nerve. An action potential was elicited by the compound endplate potential (Resting potential, 85 mV, temperature, 22 °C.) *b*, Miniature endplate potentials recorded from a fibre in the same muscle as in *a*. *c*, *d*, Partial views of two different regions of the same submaxillaris muscle where cholinesterase was stained with Karnovsky and Roots method[24]. Scale bar, 20 μm.

Experiments were performed on fast and slow muscle fibres of the pyriformis muscle[9], and on the fibres of the submaxillaris muscle[9] of the frog *Rana temporaria*. The muscles, with their nerve supply, were isolated and bathed in normal Ringer solution (in mM: NaCl 115, KCl 2.5, $CaCl_2$ 1.8; buffered with HEPES at *p*H 7.3), or in low Ca^{2+}–high Mg^{2+} Ringer (same as normal, but $CaCl_2$ 0.3 mM and $MgCl_2$ 5 mM), kept at about 6 °C. The different types of muscle fibres were identified by one or more of the following characteristics: passive and active electrical membrane properties, innervation pattern and contractile behaviour[1–6,10,11].

While surveying the ACh sensitivity and distribution of cholinesterase in frog muscle, Couteaux and Miledi (unpublished) found that in the submaxillaris muscle the fibres were innervated at multiple sites and were capable of propagating action potentials. We decided to examine the muscle in more detail and, while the work was in progress, Kordylewski[5,6] reported a morphological study of this muscle, which he calls submandibular.

Muscle fibres in the submaxillaris muscle are 8–16 mm long and extend from a narrow central tendon to the jaw. They are relatively small (5–50 μm diameter) and even after impalement with two low-resistance microelectrodes their input resistance is several MΩ. All the fibres examined are able to generate an action potential when stimulated, directly with an intracellular microelectrode or indirectly through its motor nerve (Fig. 1*a*), and the action potential triggers a phasic contraction. All the muscle fibres are innervated by the submaxillaris nerve, but the posterior part of the muscle is also innervated by the subhyoideus nerve. When the submaxillaris nerve is stimulated, alone or together with the subhyoideus nerve, with stimuli of increasing intensity, the endplate potentials generated are made up of several discrete components (Fig. 1*a*), indicating that individual muscle fibres are innervated by several axons. Miniature endplate potentials are of low frequency and can be recorded anywhere along the muscle fibres down to their tendon ends. Their amplitude and time course are very variable (Fig. 1*b*), as would correspond to local events originating at various distances from the recording microelectrode.

As expected from the electrophysiological experiments, histochemical staining revealed synaptic contacts all over the muscle. Endplates vary in shape from simple small bouton-like contacts to long branched ones (Fig. 1*c*,*d*). Individual muscle fibres have 5–10 endplates distributed along their length, and both bouton and branched types seem to coexist on the same fibre.

Table 1 Characteristics of the synaptic ACh-activated channels obtained from power spectra of endplate current fluctuations

Muscle fibre type	τ noise (ms) Mean ± s.e. (range)	γ (pS) Mean ± s.e. (range)
Fast	4.78 ± 0.28 (3.8–5.89) $n = 7$	16.09 ± 0.58 (14.08–18.12) $n = 6$
Submaxillaris	6.87 ± 0.4 (5.9–8.85) $n = 9$	13.22 ± 0.73 (9.82–15.42) $n = 7$
Slow	14.8 ± 0.64 (12.3–17.68) $n = 8$	7.76 ± 0.57 (5.81–9.75) $n = 7$

n, Number of fibres; clamp potential, −90 mV; temperature 4–6 °C. τ, mean lifetime of channel; γ, mean conductance of single channel.

The time course of endplate currents induced by nerve stimulation was studied under membrane voltage clamp. Because both slow and submaxillaris muscle fibres have distributed innervation, it is necessary to discriminate synaptic events arising at the site of recording from those occurring elsewhere. One way of achieving this is to place the muscle in low Ca^{2+}–high Mg^{2+} solution and apply Ca^{2+} ionophoretically to a small region between the two microelectrodes used for clamping. In these conditions, nerve impulses continue to invade the nerve terminals but fail to release transmitter, unless an endplate lies close to the Ca^{2+} pipette, in which case release occurs but only from this junction (see ref. 12). To avoid further complications arising from time dispersal in the release of transmitter quanta[13], the efflux of Ca^{2+} from the pipette was adjusted so that nerve impulses released mainly single quanta. These unitary synaptic events, examples of which are shown in Fig. 2, were then used to measure the time course of transmitter action.

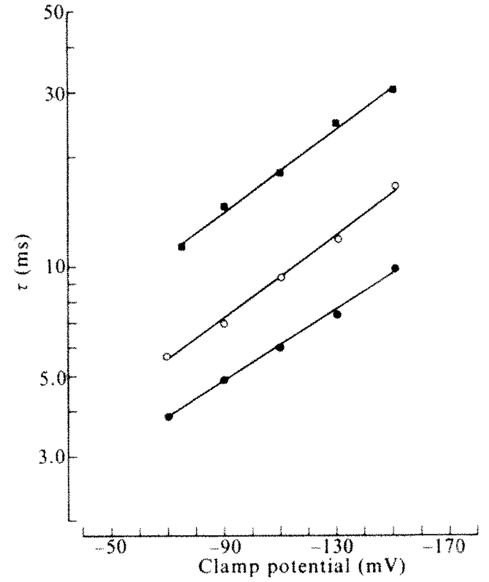

Fig. 3 Dependence of the time constant of decay of unitary endplate currents on membrane potential in a fast (●), a submaxillaris (○) and a slow (■) muscle fibre. Each point represents the mean of at least 10 unitary currents. An e-fold change in the time constant of decay was obtained when the muscle fibres were hyperpolarized by 84.5, 74.5 and 75.5 mV in the case of the fast, submaxillaris and slow muscle fibres, respectively. Normal Ringer at 6 °C.

The time constant of decay of unitary endplate currents, at a holding potential of −90 mV and at about 6 °C, was 5.0 ± 0.35 ms (mean ± s.e. of five fibres) in fast fibres and 14.67 ± 1.09 ms (six fibres) in slow fibres. Thus, the decay of transmitter action at slow muscle fibres is approximately three times slower than at fast fibres, a difference which resembles that found between fast and slow muscle fibres in the snake[14] and in the iliofibularis muscles[15]. In submaxillaris muscle fibres the decay constant of unitary endplate currents varied over a wide range (from 6.5 to 13.17 ms, mean 8.87 ± 0.56 ms, 13 fibres), even among fibres within the same muscle. The decay phase of the unitary endplate currents of the fast, submaxillaris and slow muscle fibres was prolonged as the membrane was hyperpolarized[16]. Moreover, as indicated by the slope of the voltage-decay time constant relation, the voltage sensitivity was approximately the same in the three types of fibres (Fig. 3). In contrast, the decay of spontaneous miniature endplate currents in slow fibres of the snake seems to be much less sensitive to voltage than in fast fibres[14]. We do not know if this difference is entirely due to the different species used (frog as compared with snake) or whether other factors are also involved.

To see if the different time courses of unitary endplate currents were due to differences in the lifetime of the channels opened by ACh in the various types of muscle fibres, we analysed the current fluctuations produced by ionophoretic application of ACh to the neuromuscular junction[7,8]. The mean lifetime (τ) of the junctional channels induced by ACh in submaxillaris muscle fibres was longer than in fast fibres, and the channel lifetime was longer still in slow fibres (Table 1). A close agreement was found between channel lifetime and the time constant of decay of unitary endplate currents in the three types of fibres, indicating that most of the ACh molecules, released from the motor nerve terminal at all these junctions, diffuse away from the ACh receptors or are destroyed by cholinesterase before they can exert repeated actions[17].

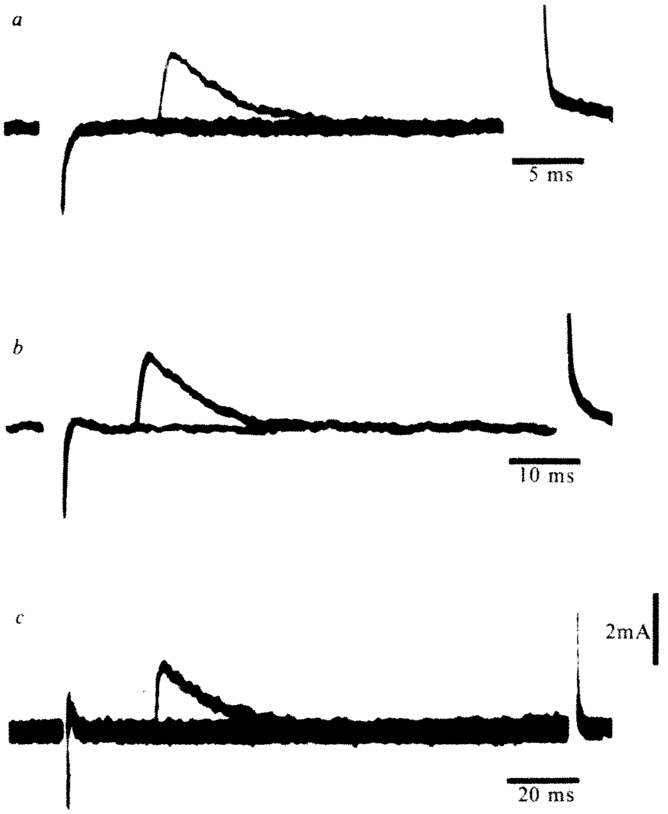

Fig. 2 Unitary (single quanta) endplate current responses to nerve stimulation, recorded from a fast (a), a submaxillaris (b) and a slow (c) muscle fibre. Muscles were in low Ca^{2+}–high Mg^{2+} solution at 6 °C. The artefact at the end of each trace indicates the start of the 800-ms pulse of Ca^{2+} used to restrict transmitter release to the endplate under study. Endplate currents were recorded under voltage clamp (−90 mV) through a 500-Hz low pass filter. The nerve was stimulated once every 1 or 2 s.

The equilibrium potential for ACh action was found to be near zero in the different types of fibres, and the single channel conductance (γ) was estimated from both the variance of the current noise and the zero frequency asymptote of the power spectra[7,8]. As shown in Table 1, junctional channels induced by ACh in fast fibres had larger conductance than the channels in submaxillaris fibres and these in turn had larger conductance than the channels in slow fibres. Here again, there seems to be a difference between frog and snake muscles, because fast and slow fibres in the snake appear to have the same single channel conductance[14].

Knowing the single channel conductance and the amplitude of the unitary endplate current, an estimate can be made of the number of channels opened by the release of one transmitter package[7]. The amplitudes of unitary endplate currents in fast, submaxillaris and slow fibres were, respectively (in nA), 1.98 ± 0.35 ($n = 6$), 1.76 ± 0.12 ($n = 13$) and 1.36 ± 0.16 ($n = 6$). This suggests that the mean number of channels opened by a single transmitter packet is ~1,370 in fast fibres, 1,480 in submaxillaris and 1,950 in the slow fibres. More experiments are needed to substantiate these preliminary estimates further, and to determine the cause of such a difference.

We conclude that the membrane channels activated by ACh at the three types of muscle fibres studied differ in the time they remain open and also in their conductance. Some properties of frog muscle fibres are known to be under neural control[18-22], and it is possible that the characteristics of the membrane channels induced by ACh on a given endplate are determined by the type of nerve which innervates it.

Relative proteolysis of the fibrinogen Bβ chain by thrombin and plasmin as a determinant of thrombosis

Hymie L. Nossel

Department of Medicine, College of Physicians & Surgeons of Columbia University, New York, New York 10032, USA

Thrombosis results, in part, from localized accumulation of fibrin, implying an imbalance between its rate of formation and dissolution. Astrup[1] postulated that patency of the vascular system depended on a dynamic equilibrium between constantly active coagulation and fibrinolytic systems. Reviews of this hypothesis have concluded that neither thrombin nor plasmin proteolysis makes a major contribution to fibrinogen turnover in normal individuals[2] and that the hypothesis of a dynamic equilibrium between clotting and lysis remains unproven[3]. Thus, the current view is that plasmin simply serves the function of a fibrinolytic enzyme digesting fibrin in the vascular system. Here, I promote the alternative view that the relative rates of proteolysis of the Bβ chain of fibrinogen by thrombin and plasmin determine the occurrence of thrombosis. This view is supported by recent data and can be used to make some readily testable predictions.

New biochemical information and technology now permit specific and quantitative analysis of the balance between thrombin and plasmin proteolysis of fibrinogen. Such analysis depends on measurement of the products of proteolysis which will briefly be reviewed. Thrombin cleaves fibrinogen to release sequentially fibrinopeptide A (FPA) and fibrinopeptide B (FPB)[4,5], implying two stages in fibrinogen–fibrin conversion with sequential activation of two sets of polymerization sites[6]. Removal of FPA exposes the A-binding domains in the NH_2-terminal region of fibrinogen which is now termed fibrin I. The A-domains of fibrin I bind to COOH-terminal domains termed 'a' in an adjacent molecule[7-10]. The removal of FPB produces fibrin II, in which a second set of binding sites is exposed—the B-domains which bind to the b-domains of an adjacent molecule. Laurent and Blombäck[11] observed that fibrin I polymers were less compact than those formed by fibrin II. Fibrin I was thought to form primarily end-to-end polymers and fibrin II both end-to-end and side-to-side polymers. Shen *et al.*[12] confirmed and extended these findings. They postulated that removal of FPA results in slow assembly of thin fibrin fibres and that rapid assembly to thick fibres depends on the removal of FPB. Hantigan and Hermans proposed that formation of protofibrils is a prerequisite for removal of FPB by thrombin, a step which is itself a prerequisite for rapid fibre formation and gelation[13]. In the early stages of plasmin proteolysis of fibrinogen, two-thirds of the COOH-terminal Aα chain and Bβ 1–42 from the NH_2-terminal Bβ chain are released to leave fragment X (refs 14–18). Hence, when fibrin I is the substrate, if the arginine (Bβ 14)–glycine (Bβ 15) bond is cleaved by thrombin, FPB is released and fibrin II formed, whereas if the arginine (Bβ 42)–alanine (Bβ 43) bond is cleaved by plasmin[17,19,20] the products are Bβ 1–42 and fragment X (Fig. 1). Fragment X

Fig. 1 Primary structure of the NH_2-terminal Bβ chain of fibrinogen. Bonds attacked by thrombin and plasmin are as indicated by Iwanaga *et al.*[19] and Wallen[20].

formed from fibrin I will form a clot but this is only 1% as rigid as that formed from intact fibrinogen[21], and α-polymer cross-links, a primary determinant of susceptibility to lysis by plasmin[22], do not form with fragment X[23,24]. Additionally, fibrin II is covalently cross-linked more rapidly than is fibrin I[25].

Some of these reactions can now be specifically quantified *in vivo*, as radioimmunoassays applicable *in vivo* have been developed for FPA reflecting fibrin I formation[26], thrombin-increasable FPB immunoreactivity (TIFPB) reflecting Bβ 1–42 and hence fragment X formation[27], and desarginine FPB reflecting fibrin II formation[28]. The mean normal plasma FPA level is 0.6 pmol ml^{-1} and elevated levels occur in acute venous and arterial thrombosis, pulmonary embolism, disseminated intravascular coagulation and other diseases[29–36]. It is evident that elevated FPA levels and hence fibrin I formation are not specific for thrombosis and that the effects of plasmin should also be considered. Peptide Bβ 1–42, reflecting the action of plasmin, can be identified in plasma as TIFPB[27]. In normal individuals the concentration of TIFPB is always higher than that of FPA, with a ratio of ~1.5–3 : 1. A reproducible sequence of changes in the concentration of FPA and TIFPB occurred in the blood of patients who received an intra-amniotic infusion of hypertonic saline to induce abortion[27]. First the FPA concentration increased and later the concentration of TIFPB rose, implying a sequence of fibrinogen proteolysis as shown in Fig. 2. If a single fibrinogen molecule is considered, in reaction (1), thrombin cleaves fibrinogen to yield free FPA and fibrin I monomer which polymerizes in reaction (2). Thrombin and plasmin then compete for the NH$_2$-terminal end of the Bβ chain (Fig. 1). If thrombin cleaves the Bβ chain before plasmin the products are FPB and fibrin II. If plasmin cleavage precedes that of thrombin the products are Bβ 1–42 and fragment X. Hence, plasmin cleavage of fibrin I serves as a major mechanism regulating the formation of fibrin II.

The facts that fibrin II forms more compact fibres than fibrin I and fibres with much greater tensile strength than fragment X and that elevated FPA levels are frequently found in conditions not associated with thrombosis prompt the hypothesis that the amount of fibrin II formed is important in thrombosis. The balance between the rates of fibrin II (reaction (3)) and fragment X (reaction (4)) formation would then determine the pathophysiological consequences of fibrin I generation. Predominant fibrin II formation results in thrombosis whereas predominant fragment X formation does not. The hypothesis explains and predicts phenomena, thus providing a means of testing its validity.

Phenomena predicted are that the ratio between peripheral blood FPA and TIFPB levels will demonstrate a greater association with thrombosis than FPA levels alone. Indices of fibrin II formation such as desarginine FPB levels may also be more closely associated with thrombosis than are indices of fibrin I formation. The thrombus itself should contain fibrin II. Although thrombosis does occur in the clinical syndrome of disseminated intravascular coagulation, there is often a marked dissociation between the degree of proteolysis of circulating fibrinogen and the extent of thrombosis found pathologically[37]. According to the above hypothesis, this discrepancy would result from a successful body defence mechanism for coping with a large amount of fibrin I formed—transformation to the less harmful fragment X. Hence, one would predict that much fragment X would be formed in disseminated intravascular coagulation and there are reports of the presence of this molecule in the plasma of patients with this disorder[38].

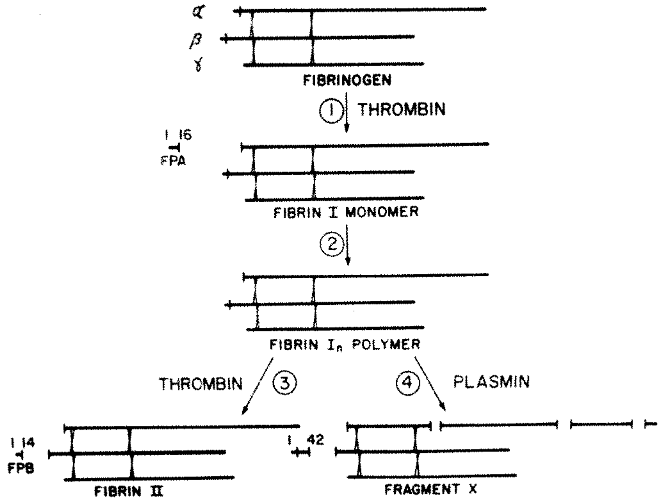

Fig. 2 Postulated scheme of fibrinogen proteolysis *in vivo*. Half fibrinogen molecules are depicted. Reaction (1), thrombin cleaves the Aα chain of fibrinogen to produce free FPA and fibrin I monomer. Reaction (2), polymerization occurs. Reaction (3), thrombin cleaves fibrin I to produce free FPB and fibrin II. Reaction (4), plasmin cleaves fibrin I to produce Bβ 1–42 and fragment X. Evidence that reaction (2) precedes reaction (3) is from Blombäck *et al.*[6]. Evidence that reaction (4) occurs preferentially to plasmin proteolysis of fibrinogen is from H.L.N. *et al.*[27]. Data have not been published on whether reaction (2) facilitates reaction (4).

The scheme shown in Fig. 2 implies that fragment X occurs as a polymer but the molecule seems to occur in monomeric form in plasma. Monomeric fragment X may be formed from depolymerization resulting from proteolysis or from plasmin proteolysis of fibrin I monomer. Ancrod and reptilase, which produce fibrin I[39,40] and not fibrin II, do not cause thrombosis and in fact are used in its therapy. Additional mechanisms for the lack of thrombosis with these enzymes are that Ancrod degrades the COOH-terminal portion of the Aα chain of fibrinogen and does not activate factor XIII and that neither enzyme aggregates platelets. Selectively increased thrombin concentration would favour reaction (3) and promote thrombosis, and congenital deficiency of antithrombin III, a condition expected to result in selective increase in thrombin concentration, is recognized as being associated with thrombosis[41,42]. Selectively decreased plasmin formation would decrease the rate of reaction (4), and conditions with decreased plasmin formation have also been reported to be associated with thrombosis[43–46]. Selectively increased plasmin activity due to decreased activity of α_2-antiplasmin may be associated with a bleeding tendency[47,48]. Finally, it is evident that although fibrin is an important component of thrombi, both platelets and the vessel wall constituents have important roles in thrombosis. Hence, the proposed hypothesis concerning fibrin formation and thrombosis deals with only a part of the process.

Epoxide hydrolase activity in the mitochondrial fraction of mouse liver

Sarjeet S. Gill & Bruce D. Hammock

Departments of Entomology and Environmental Toxicology,
University of California, Davis, California 95616, USA

The intense interest in the metabolic fate of epoxidized xenobiotics is due to several factors. For instance, epoxides are often intermediates in the lipophile to hydrophile conversions necessary for the excretion of olefinic and aromatic compounds by living systems[1], and are widely encountered in man's diet from both natural and man-made sources. Some of these epoxidized compounds may alkylate proteins and nucleic acids and thus include some of the most potent cytotoxins, mutagens and carcinogens known[2]. In mammals, epoxides may rearrange, deoxygenate to olefins, react with glutathione to form conjugates, or be hydrolysed by water to yield 1,2-diols with or without enzymatic catalysis[1,3,4]. The enzymes which catalyse the formation of diols are known as epoxide hydrolases (EC 3.3.2.3), and their subcellular distribution is the subject of this report. Early data showed that styrene oxide hydrolase activity was associated with the microsomal subcellular fraction[5]. Epoxide hydrolase activity was subsequently demonstrated on the nuclear[6], Golgi apparatus and plasma membranes[7], and in the cytosol of the cell[8,9], leaving the mitochondria as the last major cellular organelle assumed to be devoid of epoxide hydrolase activity. We now report strong evidence for the occurrence of substantial epoxide hydrolase activity in the mitochondria.

While studying the subcellular distribution of the microsomal epoxide hydrolase, Oesch *et al.*[5] reported substantial styrene oxide hydrolase activity in a crude mitochondrial fraction prepared in isotonic KCl. However, the same study showed that mitochondria prepared in isotonic sucrose had low styrene oxide hydrolase activity which was not significantly different from that of the microsomal marker enzyme glucose-6-phosphatase. Analogous subcellular distribution studies in this laboratory using an epoxidized terpene or fatty acid as substrate showed high epoxide hydrolase activity in the mitochondrial fraction[10,11]. However, in the case of these two substrates, the specific activity of the hydrolase was increased rather than decreased by repeated washing of the mitochondria. As no marker enzymes were used in these studies it was not possible to show definitively the presence of epoxide hydrolase activity in the mitochondria. Thus, the following experiments designed to yield 'pure mitochondria' were performed.

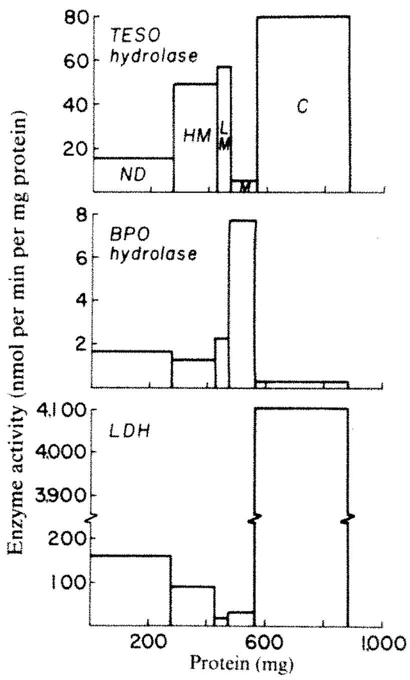

Fig. 1 Histograms of the subcellular distribution of epoxide hydrolase activity using TESO, *trans-β*-ethylstyrene oxide (upper), or BPO, benzo(*a*)pyrene 4,5-oxide (middle), as substrates and LDH, lactate dehydrogenase, with pyruvate as substrate (lower). Livers from 10-week old, male Swiss-Webster mice were rinsed in ice-cold 0.25 M sucrose and homogenized in 0.25 M sucrose/10 mM Tris-HCl, *p*H 7.4 buffer in a loose-fitting Potter-Elvejhem homogenizer to give a 10% w/v homogenate. The homogenate was centrifuged at 600*g* for 10 min, to give the nuclei and debris fraction (ND). The heavy mitochondria (HM) were pelleted at 6,500*g* for 10 min, the light mitochondria (LM) at 12,000*g* for 10 min, and the microsomes (M) at 100,000*g* for 60 min, leaving the cytosolic fraction (C) as the supernatant. Pelleted fractions were washed in the same conditions and resuspended in buffer (sodium phosphate, I = 0.2 M, *p*H 7.4 or Tris-HCl, 0.1 M, *p*H 9.0) for analysis. The ND, HM, LM, M and C fractions had 270, 160, 41, 87 and 320 mg of protein, respectively, from a preparation using three mouse livers. Separation of lysosomes and peroxisomes from mitochondria was achieved from livers, treated with Triton WR-1339 at 850 mg per kg 3.5 days before they were killed, by differential centrifugation as above followed by sucrose density gradient centrifugation[15]. The lysosomal and peroxisomal fractions had less than 2 and 28%, respectively, of the epoxide hydrolase activity in the crude mitochondrial fraction. The relatively high epoxide hydrolase activity in the peroxisomal fraction is probably due to mitochondrial contamination as the separation of these two fractions was not clear cut as determined by enzyme markers. Mitochondria were separated into inner membrane, outer membrane and the intermembrane and matrix fractions by swelling, shrinking and sonication, followed by sucrose density gradient centrifugation[16]. The values reported here are averages of two or three determinations from a preparation using three mouse livers. Of the total epoxide hydrolase activity present in the crude cell homogenate, 70 and 78% of the TESO and BPO hydrolysing activity is recovered in the various subcellular fractions.

Using the procedure described in Fig. 1 legend, the purity of the mitochondrial and submitochondrial fractions was monitored with several enzymes. Subcellular distribution of epoxide hydrolase activity was monitored with benzo(*a*)pyrene 4,5-oxide (BPO)[12] and *trans-β*-ethylstyrene oxide (TESO)[13] as

0028-0836/81/200167—02$01.00

substrates. Significant TESO hydrolase activity, ~25% of the total recovered in the subcellular fractions, was observed in the mitochondrial fraction (Fig. 1), although the highest level was found in the cytosol. The subcellular distribution of epoxide hydrolase activity is very similar when *trans*-stilbene oxide (TSO) is used as substrate. Both TESO and TSO are negligibly hydrated by the microsomal epoxide hydrolase and the immunologically similar nuclear epoxide hydrolase. In contrast, the mitochondrial fraction poorly hydrates BPO, a substrate widely used to monitor epoxide hydrolase activity. Further, the low specific activity of BPO hydrolase in the mitochondrial fraction indicates minimal contamination of this fraction by nuclear and/or microsomal membranes as BPO hydrolase is a good marker enzyme for the microsomal and nuclear membranes[1,6]. Repeated washing of the mitochondrial fractions leads to a substantial decrease in BPO hydrolase specific activity and most of this activity is associated with the outer mitochondrial membrane. As styrene oxide and BPO hydrolase activity in the microsomes are immunologically identical[14], our data support the hypothesis of Oesch[1] that styrene oxide hydrolase activity in the mitochondrial fraction is probably due to microsomes adhering to the outer mitochondrial membrane. In contrast, the TESO hydrolase specific activity in the mitochondrial fractions increases following repeated washings.

Using lactate dehydrogenase, a widely accepted marker for the cytosol, we demonstrated that epoxide hydrolase activity in the mitochondrial and nuclear fractions does not result from cytosolic contamination (Fig. 1). Results using additional marker enzymes including cytochrome oxidase[15], NADPH cytochrome *c* reductase[16], cytochrome P_{450} (ref. 17), citrate synthase[18] and adenylate kinase[19] also support the relative purity of the subcellular fractions. Use of citrate synthase and adenylate kinase also showed that the cytosolic epoxide hydrolase activity does not arise from mitochondrial lysis during homogenization, as only 0.6 and 2% of the mitochondrial activity of these enzymes, respectively, was found in the cytosol.

Subsequent experiments using livers from mice treated with Triton WR-1339 (ref. 15) indicated that lysosomes and peroxisomes, monitored by acid phosphatase[19] and urate oxidase[20], respectively, have minimal TESO hydrolase activity. As such, epoxide hydrolase activity in the mitochondrial fraction does not arise from contamination by these organelles. When mitochondria are disrupted, a preponderance of the epoxide hydrolase activity is associated with the matrix and intermembrane space fraction with TESO as substrate and less activity is associated with the inner and outer mitochondrial membranes. Most of the activity associated with either of these membranes can be removed with a single wash, indicating contamination by the matrix and intermembrane space fraction. The mitochondrial fraction is able to hydrate a wide variety of epoxidized compounds including epoxidized fatty acids and glycidal ethers, with a spectrum of activity similar to that of the cytosolic epoxide hydrolase, but distinct from that of the microsomal enzyme.

As the nuclei and mitochondria are excluded from the activation/deactivation systems used in many short-term mutagenicity assays[21], these systems may not provide a valid picture of the ability of cells to degrade potentially mutagenic epoxides. However, this effect may be more quantitative than qualitative, because the mitochondrial epoxide hydrolase demonstrates a spectrum of activity similar to that of the cytosolic epoxide hydrolase.

The present study and published literature[1,6,7,22] illustrate the apparently ubiquitous nature of epoxide hydrolases in cellular components. Although the information needed to understand fully the biological role of epoxide hydrolases is lacking, their ability to metabolize some xenobiotics is clear. The association of epoxide hydrolases with the mitochondria and nuclei of the cell may serve to protect the structural integrity of these organelles as well as their nucleic acid content. It was recently shown[23,24] that mitochondrial DNA is more easily alkylated by polyaromatic hydrocarbons and their diol-epoxides than nuclear DNA. Such results are not altogether surprising because of the nature of mitochondrial DNA and the oxidases occurring in the mitochondria[25,26] which can activate the polyaromatic hydrocarbons to reactive electrophiles. Although the mitochondrial epoxide hydrolase activity reported here does not appreciably metabolize BPO, these epoxide hydrolases can potentially protect the mitochondria from those reactive epoxides which are substrates. Therefore, our study certainly illustrates the need for increased research on these important enzymes using a variety of potential substrates in all subcellular components.

Corrigendum

In the letter 'A nonrandom component in cosmic rays of energy $\geqslant 10^{14}$ eV' by C. L. Bhat *et al.*, *Nature* **288,** 147–149 (1980), the RA values shown in Figs 2 and 3 have been found to be incorrect. The correct values are those obtained by subtracting the values given from 24 hours. This excludes the pulsar PSR 0525+21 as a possible origin. The results are consistent with a point-source origin in the RA range 20±3 hours.

MATTERS ARISING

Fortuitous oxidations by methane-utilizing bacteria

A MAJOR thesis of Higgins *et al.*[1] is that the wide substrate specificity shown by methane monooxygenase (MMO) has developed because of its survival value to the species by enabling the organisms to use ancillary carbon or energy sources.

In support of their thesis, the authors state that "such extraordinary lack of substrate specificity would be extremely unusual if it were entirely fortuitous". There are, however, many examples of oxygenases and other enzymes which have a wide substrate range but which are only metabolically functional for a single substrate. For example, ribulose bisphosphate carboxylase in all autotrophs has both carboxylation and oxygenation activities, the latter apparently leading to wasteful metabolism which has not been eliminated over a long period of biochemical evolution[2]. Nitrogenase, an enzyme which reduces many triply bonded substrates, also produces dihydrogen as an intrinsic part of the reduction process, clearly a wasteful mechanism[3]. If there were some survival value to the species there would be a strong selective pressure on the organism to eliminate these 'side' reactions or to retain, evolve or acquire those enzymes that were capable of assimilating the product into biomass. Although it is possible that acetate could arise as a result of β-oxidation of 1-phenylheptane and ω-oxidation of higher alkanes and may therefore subsequently yield reducing equivalents, there is no direct evidence that any of the biotransformation products given in ref. 1, Table 1 are incorporated into biomass. Indeed, the biotransformation of most of these substrates results in a net loss of available energy to the cell because they require NADH for oxygenation to the product.

It is possible, for example, that the oxidation of toluene to benzoic acid may result in a net gain in reducing equivalents due to the activity of nonspecific alcohol dehydrogenases; however, no NADH is generated. As MMO requires NAD(P)H *in vitro*[4–6] (and probably *in vivo* also), any oxidation that does not give rise to NAD(P)H may well be detrimental to the cell's overall energy balance. Furthermore, it has been calculated that the NAD(P)H-requiring MMO organisms are probably limited for NAD(P)H supply during growth on methane[7]. The fact that some of the products are certainly more toxic to the cell than the substrate also argues against the retention of a wide-specificity MMO. We therefore contend that these biotransformations, which are supposed to aid the survival of the organisms, probably have exactly the opposite effect.

On closer examination of the paper quoted by the authors on their own work using whole cells, one observes that they were using suspensions containing 70–80 mg dry weight of organisms per 20 ml to effect the biotransformations of these compounds over a 15–24-h period. The high cell concentration necessary to detect oxidation is clearly unrepresentative of the situation in the biosphere.

Therefore, we feel that the arguments for the wide substrate specificity of MMO having "substantial metabolic significance" are invalid. We re-affirm our belief that all these oxidations are purely fortuitous[8] and that there is no direct evidence for the oxidation of any substrate by MMO, other than methane, conferring a special advantage to the cell, whether it be as a supplementary carbon source or a provider of useful energy. We have always subscribed to the view that methanotrophs have a significant role in the oxidation of organic compounds and ammonia in the environment, but purely by a fortuitous mechanism and not one that has evolved or been retained to confer a substantial metabolic advantage to the cell.

Some methanotrophs, faced with a shortage of methane in the environment, may well oxidize any available ethane to acetate, but significant amounts of such acetate could be incorporated only by the type II methanotrophs (and not type I methanotrophs as the latter have an incomplete tricarboxylic acid cycle). Acetate could only serve as a source of carbon and not ATP because these organisms are unable to grow on acetate alone. Even so, it would still be necessary to generate NADH for ethane oxidation from the oxidation of methane to CO_2. But why is it necessary to do this for survival? All the methane oxidizers (where explored) seem to be able to form resting cells (cysts or exospores) which can survive in a hypobiotic state for years. Surely the elaboration of these protective mechanisms is far more relevant to survival than a catholic MMO enzyme able to scavenge trace amounts of carbon from the environment for the doubtful pleasure of making acetate?

HIGGINS *ET AL.* REPLY—We do not accept the argument that there is nothing unusual about the extreme lack of specificity of some methane monooxygenases (MMO). Most oxygenases have a relatively narrow substrate range, some of them only acting on one or two very similar compounds. Even in the case of enzymes closely related to MMO, the microbial alkane hydroxylases, each one is restricted to quite a narrow band of chain lengths. The only oxygenase of which we are aware that approaches MMO in its 'catholic taste' for substrates is the mammalian liver P450 LM fraction[1]. Here it is very probable that there has indeed been selection for broad specificity as this enzyme is essential to initiating processes for the removal of a wide range of toxic metabolites and xenobiotics from the body. In addition, in some methanotrophs the MMO seems to have a more restricted substrate range[2], showing that extreme lack of specificity is not a mechanistic dictum.

We accept that the lack of specificity of ribulose bisphosphate carboxylase and nitrogenase leads to wasteful metabolism in some circumstances and various species have developed mechanisms to minimize this in the former case. Nevertheless, compared with MMO these are highly specific enzymes. Indeed, ribulose bisphosphate carboxylase is specific for O_2 or CO_2.

In reply to the specific points raised by Stirling and Dalton:

(1) It is pointed out that many of the reactions catalysed are actually detrimental to the organisms because of reducing power consumption or the generation of toxic products. This point was made in our review. If this is the case, lack of development of more specific enzymes would seem to require some explanation. In fact, of course, this is something of a 'red herring' because most compounds of that type are not present in the environment in substantial amounts. Some have only recently been introduced as a result of the activities of the organic chemist. Therefore, we agree that many of these actual oxidations are probably purely fortuitous, although the ability to carry out some of these oxidations, we suggest, has been retained as a desirable characteristic. We did not imply that most of the reactions in our Table 1 lead to utilizable carbon or energy generation. The purpose of the table was simply to give an idea of the types of reactions catalysed. Such reactions may be of industrial value and may be involved in

0028–0836/81/200169—02$01.00

oxidation of a range of compounds in the environment.

The only substrates for MMO of significance *vis à vis* any selective value for broad-specificity enzymes are those which on subsequent metabolism yield acetate. There are two reasons for this. First, these compounds (long-chain alkanes, long-chain alkenes, phenylalkanes, carotenoids) are present in very substantial quantities in the environment; they are major components of biomass. Second, acetate once formed can act as a carbon source for methanotrophs and in the case of type II species which possess an intact tricarboxylic acid cycle, acetate can be oxidized to CO_2 yielding reducing power and ATP. It is well authenticated that acetate is extensively metabolized by type II species and leads to appreciable increases in growth yields when included in the medium[3]. Phenylalkanes are partially degraded by *Methylosinus trichosporium* to short-chain alkanoic acids and alkanes are oxidized to CO_2. The most likely mechanism for this is β-oxidation, the product of which is acetate. Further evidence for β-oxidation comes from the finding that C-odd phenylalkanes yield only C-odd phenylalkanoic acids and C-even phenylalkanes yield mainly C-even phenylalkanoic acids[4]. The example of 1-phenylheptane metabolism was given in our Table 1.

(2) There is accumulating evidence that methanotrophs possess other broad-specificity enzymes including secondary alcohol and aldehyde dehydrogenases[5,6] that facilitate the further oxidation of products of MMO activity. Some of these enzymes, such as the secondary alcohol dehydrogenase discovered by the Exxon group, have no known function in C-1 metabolism.

(3) The environmental significance of reactions observed in our experiments using high cell densities is questioned. Of course, it is always difficult to extrapolate from laboratory experiments to the environment. It is not necessary to use such high cell densities to detect products, but clearly at very low cell densities product detection is difficult for technical reasons. We have used high cell densities to obtain in a short time sufficient material from small-scale incubations for both detection and chemical identification. In addition, because some of these substances are toxic at high concentrations, appropriate ratios of organisms to test compounds are necessary.

(4) We agree that the formation of exospores or cysts has great survival value. Would it not be advantageous, however, to be able to survive in a vegetative state using ancillary carbon and energy sources while your competitors are encysting?

(5) The fact that methanotrophs do not grow on acetate alone is not proof that acetate can act only as a carbon source. Acetate substantially increases yields of type II organisms on methane, suggesting that NAD(P)H and/or ATP are generated from this compound. It seems likely that type II methanotrophs have retained an intact tricarboxylic acid cycle to facilitate acetate oxidation. The reasons for the inability to grow on acetate may well be found in the mechanisms of regulation of intermediary metabolism.

There are many examples of microbial co-oxidations in which ATP or NADH are generated from substances which are not growth substrates. Methanotrophs will not grow on formate but generate NADH (and possibly ATP) from this intermediate.

We suggest that more experimental work should be done to test our hypothesis that lack of specificity of MMO leads to useful supplementary metabolism and this is in progress in our laboratory.

Note added in proof: Dalton and colleagues have previously subscribed to the view that in the presence of methane small amounts of co-oxidizable compounds may well contribute significantly to the growth of methanotrophs and not just be merely oxidized without benefit to the organism[7,8].

Cycloheximide inhibits DNA synthesis in SV40-transformed cells

IDE *ET AL.*[1] reported that DNA synthesis in an SV40-transformed human cell line (SV80) is not inhibited by the protein synthesis inhibitor cycloheximide. This is an apparent exception to the repeated observation that inhibitors of protein synthesis are effective inhibitors of DNA and RNA (mostly ribosomal) synthesis[2,3]. Using various other cell types, both neoplastic and normal, we have found[4,5] that the inhibitory effect of these drugs is also exerted on several reactions in both the salvage and *de novo* pathways of nucleotide biosynthesis, such as the formation of CTP from uridine and aspartate and the formation of GTP from hypoxanthine, adenosine, deoxyadenosine and formate. CTP and GTP are not only required for RNA synthesis but are also intermediates in the formation of the deoxynucleoside triphosphate precursors, dCTP, dTTP and dGTP. Various lines of evidence emphasize the importance of maintaining normal pool sizes of these precursors for RNA and DNA synthesis[6,7], particularly for the latter, as the level of the deoxynucleoside triphosphates is very small in eukaryotic cells.

The SV40-transformed system could be pertinent to the question of whether DNA synthesis inhibition depends solely on the synthesis of some unknown protein(s) of short half life, in some way necessary for the polymerization reaction, or additionally on the levels of newly synthesized precursors. Thus, we had hoped to use the transformed cells to determine whether, in conditions in which DNA synthesis is not affected, the reactions leading to the biosynthesis of the precursors are similarly unaffected. Unfortunately, we are unable to confirm the observations of Ide *et al.* In our study, after addition of cycloheximide or puromycin in both the human SV80 line that Ide *et al.* used, and in an SV40-transformed mouse line (BALB/c SVA31), DNA synthesis was inhibited to the same extent as in the untransformed cell (BALB/c A31). In addition, all the effects on the nucleotide pool constituents that we observed with other cell types were seen with the SV40-transformed lines.

There is no apparent explanation for the differences between our results and those of Ide *et al.*, who suggest that the persistence in DNA synthesis in transformed cells is associated with the T-antigen content of SV40-transformed lines. T-antigen assays of our stocks showed that the BALB/c SVA31 and the SV80 lines are strongly positive whereas the untransformed BALB/c A31 is negative. We conclude that SV40-transformed cells are not exceptions to the statement[8] that "inhibition of protein synthesis by any mechanism results in almost immediate interruption of DNA replication."

Beaming of Jupiter's decametric radiation

POQUÉRUSSE AND LECACHEUX[1] reported the first direct measurement of the beaming of Jupiter's decametric radiation based on simultaneous observations of the jovian radio emission made with the Soviet spacecraft Mars 7, and at the ground level at Nancay, France on two different days. On one of them, 15 May 1974, activity was recorded at the spacecraft while none was observed at Nancay or at the University of Colorado site, and it was concluded that this effect was evidence of the narrow beaming of the jovian decametric radiation. We made complementary observations from the Maipú Radio Astronomy Observatory in Chile and from the University of Florida Radio Observatory: strong activity from Jupiter was recorded at the same time at a lower frequency and at a close frequency some 40 min earlier.

Table 1 shows the time and frequencies where the activity was recorded, including the spacecraft, Florida and Maipú. In Florida the emission was detected at 20.0 and 22.2 MHz, while in Maipú, Chile at 13.1, 16.7, 18.0, 22.2 and 27.6 MHz. jovian activity was recorded at 22.2, 18.0 and 16.7 MHz and at the same time the spacecraft detected activity at 30 MHz while that at 27.6 MHz was recorded some 40 min earlier.

The antennas used were linearly polarized Yagis except for those operating at 13.1, 16.7 and 22.2 MHz in Chile, which were crossed polarimeter Yagis. The receiving, recording and calibrating system at both observatories were identical, each channel consisting of a modified commercial communication receiver tuned to the corresponding centre frequency with a fixed bandwidth of 4 kHz, a chart recorder with a time constant close to 1 s was used, although a supplementary recording was available for better resolution of individual bursts. Temperature-limited noise diodes were used as standard calibrator. Occasionally, no calibration was made during the observation—the galactic background noise serving as an auxiliary calibrator.

The flux density for each channel was determined following the standard procedure of the Florida–Chile group[2,3].

The flux densities of mean and peak pulses calculated for the observed activity at Maipú and Florida during 15 May 1974 are also included in Table 1. The emission recorded was mostly of the S-bursts type (millisecond pulses) and right-hand circularly polarized (16.7 and 22.2 MHz, Chile). The minimum detectable flux density (threshold) at Maipú and Florida was of the order of 2.5×10^{-22} W m^{-2} Hz^{-1} at 22.2 MHz. The threshold of the University of Colorado spectrograph (7–41 MHz) was reported to be 5×10^{-22} m^{-2} Hz^{-1} (ref. 1), that is well below the flux density of any mean pulse recorded in Chile or Florida (see table 1). The lack of correlation between the data obtained in Maipú and Florida suggests a strong ionospheric disturbance along the line of sight of Jupiter as seen from Florida. The same disturbance also seems to have affected the observations at Colorado, where Jupiter was being observed at a large zenith angle. It might even be possible to consider some scattering produced by field-aligned ionospheric irregularities.

Table 1 Summary of observations, 15 May 1974

Site	Frequency	Activity time UT		Flux density (10^{-22} Wm^{-2} Hz^{-1})		Remarks
Spacecraft	30	10.35	11.06	—	80	Ref. 1
Nancay	25–38	—	—	—	—	Ref. 1
Colorado	7–45	—	—	—	—	Observing time: 09.00–12.00
Florida	20.0	11.26	12.00	12.7	48.2	Jupiter transit: 13.03
	22.2	11.19	12.13	21.5	83.0	
Maipú	13.1	10.20	10.40	52.2	205.9	Jupiter transit: 12.11; sunrise: 11.26
	16.7	09.40	11.27	76.3	172.1	Right-hand polarized
	18.0	09.40	11.33	23.2	52.0	
	22.2	09.42	11.25	19.9	45.6	Right-hand polarized
	27.6	09.45	09.55	50.0	202.1	Antenna breakdown at 09.55

Observing frequencies, beginning and ending times of the activity, and mean and peak flux density measurements are given for each site where activity was recorded. At the highest frequency in Maipú (27.6 MHz), the antenna had a major breakdown at 09.55 so that the jovian activity was only recorded up to ~40 min before the spacecraft started recording the emission from Jupiter.

We can thus add to Poquérusse and Lecacheux's result that Jupiter's strong beaming may hold only for a relatively narrow frequency bandwidth. As might be expected, the radiation beam appears wider when all frequencies are considered rather than a single frequency.

Corticosteroid-binding globulin and corticosterone interaction with progesterone receptors

IN their article[1] Al-Khouri and Greenstein claim to have shown "differences between progesterone receptors and CBG [corticosteroid-binding globulin] distribution in brain and uterus". We would like to point out that, in their studies, they have failed to take into consideration binding of ^{3}H-progesterone to other types of receptor sites, in particular glucocorticoid sites, and that for this reason they cannot conclude that "progesterone, the natural hormone, displaces the tritiated steroid from the receptor in brain and uterine cytosols more potently than does R5020".

In the conditions used by Al-Khouri and Greenstein (non-ovariectomized animals, not primed with oestrogens), progestin-binding sites (PR) are occupied by endogenous progesterone which cannot be exchanged with ^{3}H-progesterone within 2 h at 0 °C without loss of sites by degradation. Furthermore, even in the perfused brain and in optimal experimental conditions, the number of PR is low compared with the concentration of glucocorticoid binding sites (GR) and CBG. In the non-perfused uterus the relative quantity of PR compared with GR and CBG must be even smaller and ^{3}H-progesterone binding corresponds to the total binding of PR, GR and CBG and not to PR uniquely. Thus, in the displacement studies, cold R5020 displaces ^{3}H-progesterone primarily from PR and to a lesser extent from GR (note that competition of progesterone for GR is underestimated in screening assays because of trapping of progesterone by CBG) and cold corticosterone displaces ^{3}H-progesterone from GR and CBG. This explains why corticosterone is more effective in the non-perfused uterus still rich in CBG.

The results would have been completely different with ^{3}H-R5020 because, on account of its specificity, its absence of CBG binding and its much higher affinity for PR (slower dissociation of the receptor complex), progesterone can be nearly totally exchanged within 2 h at 0 °C.

^{3}H-R5020 thus measures virtually all PR and only PR[2,3].

Part of the aim of Al-Khouri and Greenstein's study was "to know the mechanism of action of progesterone in the brain". The progestin receptor measured with ^{3}H-R5020 has been shown to be implicated in progesterone activation of female sexual behaviour by comparing PR levels in conditions where progesterone is active or inactive in rats[4] and guinea pigs[5,6].

GREENSTEIN AND AL-KHOURI REPLY—There is a striking difference between the brain and the uterus in terms of the specificity of ^{3}H-progesterone binding and we feel they should be discussed separately.

As regards the brain, we showed that progesterone was far more potent than was corticosterone in displacing ^{3}H-progesterone from its binding sites in the cytosol. As corticosterone has a very high affinity for its own receptor ($K_d \sim 10^{-9}$ mol l^{-1})[1,2], one is constrained to conceive a situation in which corticosterone, but not progesterone, is denied access to the glucocorticoid receptor. Furthermore, progesterone has only one-third the affinity exhibited by corticosterone for the glucocorticoid receptor[1]. Raynaud and Moguilewsky stated that ^{3}H-progesterone did not displace endogenous progesterone from the progestin receptor, although they did not specify the tissue. It has been shown elsewhere, using ovariectomized rats, that there is rapid exchange between ^{3}H-progesterone and the unlabelled hormone at the neural progesterone receptor[3]. Whether this is a progestin receptor is by no means clear. From our results[4] the simplest conclusion is that ^{3}H-progesterone bound to a specific receptor from which it was displaced more readily by progesterone than by four other steroids.

In the uterus there is a completely different picture. We agree readily with Raynaud and Moguilewsky that there is extensive binding cross-reactivity between progesterone and corticosterone at their receptor sites. Indeed, this difference between brain and uterus is a central point of our paper. At this stage we cannot distinguish between the many components in uterine cytosol to which ^{3}H-progesterone was bound. As there is ample evidence that there is rapid and virtually complete exchange between progesterone and the tritiated steroid at 0 °C within 2 h *in vitro*, we are confident that ^{3}H-progesterone bound to progesterone receptors in cytosols from the uterus.

The substance R5020 is an interesting tool in studying the mechanism of action of progesterone, but the fact that there are moieties in brain and uterine cytosols which bind progesterone more strongly than they do R5020 militates in favour of the use of progesterone for studying progesterone receptors. In particular, if the corticosteroid-binding globulin-like material (to which R5020 does not bind) is involved in the actions of progesterone and corticosterone in the uterus, there is all the more reason to doubt whether the role of this protein will be elucidated through the use of R5020 alone.

Polar cap models for pulsars

ARDAVAN[1] has recently claimed on very general grounds that the emission from pulsars must be from the vicinity of the light cylinder. This seems to rule out polar cap models[2,3] in which the radiation is from particle bunches resulting from a plasma instability near the pulsar. However, the time scale with which the current distribution associated with these bunches fluctuates is much shorter than the pulsar period. A smoothed-out picture of the currents can be stationary in the rotating frame which is a reasonable starting point for theories of the magnetosphere[4]. However, such a smoothing process is unjustified in this context because radiated power varies as the square of a fluctuating current. A simple example is: N electrons moving uniformly round a circle with uncorrelated phases clearly radiate N times what each one does. No matter how large N is, we cannot calculate this radiation using the 'equivalent' steady current. In the present case, the smoothed-out current distribution still has the time dependence caused by the pulsar's rotation and hence radiates mainly from the vicinity of the light cylinder.

Because the fluctuations responsible for the radiation in polar cap models have been smoothed away by Ardavan[1], the final radiation pattern derived cannot be used to rule out these models.

RAJARAM NITYANANDA

Raman Research Institute,
Banglalore-560080, India

1. Ardavan, H. *Nature* **289**, 44–45 (1981).
2. Sturrock, P. A. *Astrophys. J.* **164**, 529–556 (1971).
3. Cheng, A. F. & Ruderman, M. A. *Astrophys. J.* **235**, 576–586 (1980).
4. Mestel, L. *Nature phys. Sci.* **233**, 149–152 (1971).

ARDAVAN REPLIES—The quasistatic condition[1] sets no restriction on the time scale of fluctuations of the electric current; it merely demands that the dependence of the current on azimuthal angle should be of the same form as its dependence on time. The arbitrary temporal fluctuations of the electric current are thus required to propagate longitudinally so as to create a rigidly rotating pattern. Indeed, unless the time scale with which the current distribution fluctuates is much shorter than the pulsar period, my analysis would predict no radiation in the range of observed frequencies: according to equations (9) and (10) of ref. 1, the power radiated into the higher order harmonics $m \gg 1$ is non-zero only when the Fourier representation of the current density as a function of $\hat{\varphi} \equiv \varphi - \omega_0 t$ contains the corresponding high-frequency amplitudes.

As long as the interparticle distances within the source do not exceed the wavelength of the radiation, the description based on smoothed-out macroscopic current densities is justified. In the example cited by Nityananda the radiation can in fact be calculated using a macroscopic description; the equivalent quasistatic current density would be

$$j_\varphi(r, z, \varphi; t) = \sum_{i=1}^{N} e\omega_0 \delta(z)\delta(r - r_0) \times \delta(\varphi - \omega_0 t - \varphi_i)$$

where the notation is the same as that of ref. 1. Furthermore, only when $N \to \infty$ does this current distribution cease to radiate[2,3], and then it does so because of the disappearance of all azimuthal fluctuations in the limit and not because of the macroscopic form or the quasistatic character of the current.

BOOK REVIEWS

Let them eat bread! But which bread?

John Yudkin

Medical Aspects of Dietary Fibre: A Report of the Royal College of Physicians. Pp.175. ISBN 0-272-79609-3. (Pitman Medical: 1980.) £5.50. *Medical Aspects of Dietary Fiber.* Edited by Gene A. Spiller and Ruth McPherson Kay. Pp.229. ISBN 0-306-40507-5. (Plenum Medical: 1980.) $32, £20.48.

DURING the past few years, the consumption of brown bread in Britain has increased more than threefold. It is not hard to see why this is. The Department of Health and the Health Education Council, and similar bodies in many other countries, advocate strongly the consumption of brown and wholemeal breads rather than white, and an increase in the consumption of vegetables and fruit, so as to ensure an adequate intake of dietary fibre. It is now widely accepted that brown is beautiful; and this even extends to an increased consumption of brown sugar and to an unprecedented demand for brown eggs.

Brown eggs, whatever their aesthetic attraction, have no nutritional advantage over white eggs. Brown sugar is better than white only in that a strict avoidance of the latter must lead, for most people, to a sizeable diminution in total sugar consumption. The question then remains whether there is any health benefit in eating brown or wholemeal bread rather than white.

Here are two books that summarize current knowledge, and opinion, of the effects of dietary fibre — the indigestible constituents of cereals, other vegetable foods and fruits which we used to call "roughage". The Plenum book consists of 14 chapters, by 21 different authors, describing in fair detail the research results that have been achieved in studies on the composition of fibre, patterns of consumption of fibre, patterns of consumption within and between different countries, its effects in experimental animals and in human volunteers, and its possible relation to human disease. As in all compilations of this sort, there is some overlap and repetition, as well as rather inadequate consideration of some topics. More interestingly, there are differences in the degree to which different authors are prepared to be hesitant, or enthusiastic, in accepting the largely inconclusive results of experiment as evidence of a role for dietary fibre in the prevention of human disease.

For a careful reading of the evidence shows that dietary fibre, in the quantities found in any ordinary diet, has only three certain effects that are of any consequence to human health. It can speed the passage of the gut contents, and increase the bulk of the faeces; thus, in many individuals, it will relieve constipation. It reduces the symptoms of diverticulitis, although it is often necessary to use more fibre than would normally be present in ordinary diets. Third, it reduces the absorption of some of the mineral elements, so that it may lead to deficiency, especially in the elderly.

The Plenum book, then, will be found useful by the large number of people who are nowadays engaged in studying dietary fibre. But the book would also be handy for the nutritionist or the gastroenterologist who is prepared to look in more detail at the justifications for some of the claims that have been made for dietary fibre.

The Royal College of Physicians book, on the other hand, should be read by every dietician, nutritionist and doctor. It was compiled by a committee of the RCP, whose members include some of those who wrote chapters for the Plenum volume. It covers the same ground but in the form of a simply-worded summary of the literature, with conclusions at the end of each chapter. Like the Plenum book, the diseases it considers include obesity, diabetes, ischaemic heart disease, diverticular disease and colon cancer. Here are some of its conclusions:

- ●Although societies which exist on fibre-rich diet have a low prevalence of obesity, this is not evidence that dietary fibre as such prevents obesity.
- ●No coherent pattern has emerged of the effects of fibre on the occurrence of ischaemic heart disease . . . . In view of the varying forms of fibre and their variable effects, it is not yet possible to give specific recommendations to the general public about its value in preventing heart attacks.
- ●Undoubtedly a reduction in the intake of fibre may cause constipation. Nevertheless, other factors may help to explain the commonness of constipation in Westernised communities.
- ●There are reasonable grounds for the statement that, in genetically susceptible persons, large bowel cancer could be favoured by a fibre-depleted diet, but other explanations for the commonness of this cancer in Westernised countries are possible.

But even this detached assessment of the evidence is occasionally clouded by the current all-pervading atmosphere that insists that dietary fibre plays an important role in the prevention of disease. The chapter on diabetes ends in this way: "In the long term, replacing refined carbohydrates with physically intact carbohydrate foods might also reduce the risk of diabetes by preventing or arresting obesity". Yet an earlier chapter says: "Dietary fibre has little if anything to do with preventing obesity".

With this careful appraisal of the evidence by such an authoritative body as the RCP, it becomes necessary to ask how it comes about that doctors, health educators, dieticians and nutritionists have almost with one voice been advocating an increase in the consumption of dietary fibre. The two books reviewed have themselves provided much of the answer. It is universally accepted that epidemiological study of populations with different prevalences of a particular diseases may reveal associations but not causes. Yet the major evidence still cited for the view that colonic cancer and several other diseases are caused by a lack of dietary fibre is that rural Africans are much less prone to suffer from these conditions that are urban Westerners. The difference in disease prevalence is indeed likely to be due to differences in environmental conditions, but these differences are many. Some are non-dietary, and include cigarette smoking, physical activity and competitive stress; some are dietary, and include total calories, animal protein, fat, sucrose, calcium and vitamin B_{12}, and not only dietary fibre.

In addition, there is straightforward human prejudice. Part of this derives from people's obsession with their bowels, and accounts for the belief that the many virtues attributed to dietary fibre lie in its ability to cure constipation; in 1979, they spent in the UK more than £6 million in buying non-prescriptive laxatives. Moreover, they are convinced that constipation is in turn the cause of many other and more alarming ills. With the greatest enthusiasm, then, they seized on the suggestion that all this happens because they have been eating white bread.

But the rapid acceptance of the virtues of dietary fibre is not due solely to the hope that it will relieve imaginary maladies. It is also caused — and it is still largely upheld — by the phrase "refined carbohydrate". This refers both to white flour (or bread made from it) and to white sugar. The implication is that they share similar harmful properties; on the other hand, it is believed that wholemeal flour and raw sugar share similar beneficial properties. But raw sugar is already very much "refined" compared with the sugar cane from which it is made, whereas wholemeal flower really does contain the whole of the wheat berry. Much more importantly, white flour and even pure starch have metabolic properties very different from those of sugar (sucrose).

Denis Burkitt, who, probably more than anyone else, was responsible for the revival of the view that the lack of dietary fibre is the major cause of the ills with which Western countries are plagued, ends his chapter in the Plenum book thus:

> The attitude that decries change until a case is proven is both illogical and morally indefensible. Medical history is full of instances in which effective action was taken to reduce the incidence of a disease by avoiding situations known to be associated with it, long before the cause of the disease was known or the mechanisms involved in its causation understood.

Although they write in a somewhat different context, I much prefer the statement by the authors of another chapter in the same book, as a comment on the too-hasty acceptance of epidemiological evidence unsupported by experiment:

> Such an attitude does not seem justified in view of the past continuously preached emphasis on high-fat diet as a plausible risk factor in the etiology of coronary heart disease, which has kept research in preventive cardiology at a standstill for the past 20 years.

Let us by all means eat brown or wholemeal bread if we like it. But let us not delude ourselves that it will make us healthier or prolong our lives. ☐

John Yudkin is Emeritus Professor of Nutrition at the University of London.

Incomplete expression of genes

Jay Greenberg

Cell Biology: A Comprehensive Treatise. Edited by L. Goldstein and D.M. Prescott. Vol. 3 *Gene Expression: The Production of RNAs*, pp. 684, ISBN 0-12-289503-7. Vol. 4 *Gene Expression: Translation and the Behavior of Proteins*, pp. 496, ISBN 0-12-289504-5. (Academic: 1980.) Vol. 3 $65, £36.40; Vol.4 $49, £27.60.

THESE volumes consist of a collection of articles by different authors on various aspects of gene expression. (Volumes 1 and 2 in the series dealt with cell inheritance and its molecular basis.) They represent a much-needed attempt to fill the gap between reports of original research and the conventional textbook, and they will be of greatest use to students and more advanced scientists who wish to broaden the scope of their knowledge. For the most part, the chapters are not (nor are they intended to be) in-depth, up-to-the-minute reviews for specialists. However, some of them contain detailed, well-referenced information, and they will no doubt be appreciated by experts as well as by less knowledgeable readers.

To a considerable extent these volumes succeed in fulfilling their purpose. However, they are not without shortcomings. Some of the articles are less complete, informative, scholarly and readable than others; furthermore, there is a good deal of overlap between contributions. To some extent, this is the unavoidable result of different authors writing independently of one another; however, the number of redundant passages could have been minimized by more extensive editing.

The chapters are logically organized around gene expression at the level of RNA transcription and processing (Vol. 3), and translation and post-translational behaviour of proteins (Vol. 4). Unfortunately, however, this arrangement precludes integrated discussions of systems in which gene expression has been investigated at multiple levels. Another problem is that the current rate of progress in cell biology is such that many of the chapters were out of date prior to publication. This is especially true of Vol. 3, which was published late in 1980. However, the references cited in many of the chapters do not go beyond 1978.

Probably the greatest fault (no doubt related to the preceding one) is that neither volume is truly comprehensive. Many aspects of gene expression currently of interest are barely touched. These include such general phenomena as introns, gene splicing and the cytoskeleton, as well as more specific topics such as *Drosophila* heat shock genes, immunoglobulin, globin and ovalbumin genes, and small nuclear RNAs. Control of translation in cell-free systems and virus-infected cells is discussed, as well as regulation of protein synthesis in embryogenesis (masked messengers). However, other phenomena in which translational control plays an important part are not mentioned, for example, mitosis and heat shock. There is little on gene expression in mitochondria and chloroplasts. Apparently, no additional volumes are planned even though the current series is far from complete in its treatment of cell biology. ☐

Jay Greenberg is a Staff Scientist at the Worcester Foundation for Experimental Biology, Shrewsbury, Massachusetts.

Cosmology at school

Joseph Silk

Physical Cosmology: Les Houches 1979, Session XXXII. Edited by Roger Balian, Jean Audouze and David N. Schramm. Pp.665. ISBN 0-444-85433-9. (North-Holland: 1980.) $109.75, Dfl.225.

WHAT is the cosmos made of? For all that astronomers can tell, it could be puppy dogs' tails, or back issues of *Nature*, or a host of slightly less exotic possibilities that range from snowballs to giant planets or black holes. All suggestions are equally unproven. What we do know is that the preponderance of matter in the Universe, 90 per cent or more, consists of unknown stuff, for which the term "massonium" was coined at Les Houches by the cosmologist P.J.E. Peebles. Massonium resides in galaxy halos and in the depths of intergalactic space. We infer its presence from its gravitational effect on the observable regions of galaxies. To discover the mystery of massonium is the cosmologists' dream. That it seems destined to remain so is one of the messages that is brought out in *Physical Cosmology*, the report of the 32nd session of the Les Houches Summer School in 1979.

Another elusive cosmological goal is to decide whether the Universe is closed, destined to ultimately collapse to a fiery fate or is open, to expand indefinitely to a cold and ever bleaker future. Here, the evidence presented on the one hand by Peebles and on the other hand by Gustav Tamman, Amos Yahil and Alan Sandage appears to be in conflict. Peebles cites evidence that substantial mass is present in the outer regions of galaxies and galaxy clusters, concluding that within the experimental uncertainties the Universe could be closed. On the other hand, Tamman and his colleagues measure the expansion rate out to a distance from the Milky Way galaxy of some 20 megaparsecs, and find it to be remarkably uniform. This result favours an open Universe, in which the kinetic energy of expansion greatly exceeds the gravitational potential energy that could eventually cause a contraction.

Many of the other topics in *Physical Cosmology*, which span a vast range of astrophysics, are less controversial and provide a good review of the consensus viewpoint towards cosmological issues. As might be anticipated in a lecture course arranged by nuclear astrophysicists Audouze and Schramm, cosmological nucleosynthesis receives a thorough treatment in lectures by Robert Wagoner, Yves David and Hubert Reeves. Helium is the second most abundant element in the Universe, and can be observed in a variety of astronomical objects, from the Sun and nearby HII regions to distant galaxies and remote quasars. Remarkably, astronomers find one nucleus of helium for ten of hydrogen in practically every environment that can be studied, whereas the abundances of carbon or of iron may vary by one or two orders of magnitude The big bang theory in its simplest form predicts not just the synthesis of helium when the Universe was one minute old, but even the observed abundance And this prediction is insensitive to the controversy over whether the Universe is open or closed. Cosmologists have pounced on this coincidence as evidence for the big bang theory itself

Deuterium is another element that may reflect the history of the early Universe A by-product of the synthesis of helium, deuterium is also destroyed very effectively, first almost immediately after it forms if the density of the Universe is sufficiently great, and second when stars form The high temperature achieved in the interior of a star as its nuclear fuel supply of hydrogen burns into helium results in the burning of any pre-existing deuterium By searching for matter that has not yet undergone this stellar cookery, astronomers have succeeded in detecting deuterium in very young stars and in interstellar matter The deuterium is believed to have originated along with helium in the big bang, if so, the Universe must be of low density and open in order for a significant quantity to have been synthesized

Those cosmologists who prefer a dense Universe are unhappy with this result Fortunately, the discovery announced in 1980 of the possible existence of a mass for the neutrino has managed to satisfy practically everyone Now, one has the prospect of a dense Universe dominated by neutrinos At the epoch of nucleosynthesis, the neutrinos play no role, and the Universe behaves as though it had a much lower density, corresponding to that of the protons and producing deuterium in the desired quantity The massive neutrino promises also to affect many other results in cosmology, especially the work on galaxy formation that is reviewed in the Les Houches lectures by Richard Gott, Brandon Carter and Peter Mészáros

One of the obvious omissions is the discussion of the pancake theory of galaxy formation The Moscow school of cosmologists is its most ardent protagonist Great structures form on the scales of clusters of galaxies, and provide an intriguing picture of the Universe as it appears to be on very large scales, full of sheet-like arrays, filaments and gaping holes. But on the largest scales of all, on the order of and beyond the present horizon, homogeneity is very much apparent, as the lectures of Martin Rees bring out

One of the joys of *Physical Cosmology* is its illustrations of the lecturers in action From Wagoner on the grass to Rees at the blackboard, these candid shots add a dash of vitality that provides an extra reward for those brave souls who have mortgaged their possessions to buy this book □

Sites of special spiritual importance

Kenneth Mellanby

The IBP Survey of Conservation Sites. An Experimental Study IBP, 24 Edited by A R Clapham Pp.344 ISBN 0-521-22697-X (Cambridge University Press. 1980.) £25, $57 50

ONLY within the past hundred years have there been attempts to conserve wildlife for its own sake, and to establish nature reserves in which plants and animals can continue to exist under something approaching natural conditions It has not always been easy to decide upon what criteria nature reserves, national parks and other protected areas should be selected In the early days we relied on the instincts of a few dedicated naturalists. Today, many would like to use more scientific methods.

The International Biological Programme (IBP) was established in 1964, to try to obtain a better understanding of the environment as a basis for rational management of natural resources Much of its work concerned productivity and potential food production in a world with a growing population Its Terrestrial Conservation Section (CT) decided "to initiate a world-wide study of the great variety of terrestrial ecosystems, leading to the selection of representative samples of all the more important ones" This book contains the results of the survey

The method used to evaluate sites was the IBP check-sheet survey 13,000 copies of the check-sheet, details of which are given in a 22-page appendix, were distributed world-wide 3,010 were returned, 2,690 satisfactorily completed Most returns came from the developed countries, Britain, the USA, Europe (where Poland excelled), Japan and Australia These results may seem disappointing, but they gave much more information than had previously been available on a world scale. The book describes how the information was processed, and includes critical discussions of the methodology It should be of great value to those concerned with the survey and classification of vegetation on an international and a national scale With its appendices dealing with different techniques for vegetational classification it will be a useful tool for others involved in this field, though it can hardly be recommended as a good read even for the most dedicated ecologist

No one can doubt the scientific value of this study, as an academic exercise in ecology Its value in the selection of potential nature reserves is more doubtful In the past most reserves have been established because the area has appealed to the emotions of the selector, and because it has been available. The process has been essentially hit or miss — it may be surprising that there have been so many hits, and that so many of the older reserves are still obviously of considerable value There are many who still consider that this is the best method of selection, particularly in Britain where most of the treasured sites have been profoundly altered by human activities Many of the scientific reasons for nature conservation, such as maintenance of a large heterogeneous gene-pool or the perpetuation of the full diversity of the world's plant and animal communities, have been described as rationalizations of decisions made for aesthetic and emotional reasons. It has even been suggested that Sites of Special Scientific Interest might be better designated Sites of Special Spiritual Importance.

I believe that these subjective emotions are often the reason why many of us are interested in wildlife conservation However, this does not mean that a scientific study of the results of emotions is not still valuable. So this exercise is to be welcomed as giving us a clearer picture of the world scene, and if its application means that more unspoiled areas can be preserved for future generations we should all be grateful for those who completed what, to me, would have been a very tedious operation □

Kenneth Mellanby is President of the Bedfordshire and Huntingdonshire Naturalist Trust His latest book, Farming and Wildlife, *will be published by Collins on June 14*

Polyhedra for chemists (and aesthetes)

Michael Mingos

Transition Metal Clusters Edited by B F.G Johnson Pp 681 ISBN 0-471-27817-3 (Wiley 1980) £33, $88 15

THE scientific interest in polyhedra can be traced back to ancient Greece, and the understanding of the mathematical properties of polyhedra developed then and subsequently have often proved to be relevant to physics and chemistry With this long tradition, therefore, it is not surprising that during the past 20 years transition metal chemists have been particularly interested in synthesizing new "cluster" compounds which have between four and forty metal atoms bonded together in a wide variety of polyhedral arrangements Aside from the aesthetic satisfaction of elucidating the structures of these beautiful molecules, such compounds have provided a range of interesting theoretical valency problems and have stretched to the limits the techniques currently available to chemists for characterizing molecules. In addition, they have stimulated the interest of industrial chemists and molecular biologists, the former because of the potential of the compounds as homogeneous and heterogeneous catalysts, and the latter because iron sulphur clusters have been found to be important components of ferredoxin and nitrogenase.

Transition Metal Clusters therefore represents a timely attempt to bring together under one cover some of the developments in this area.

The book covers most of the important aspects of cluster compounds, with P. R. Raithby reviewing the geometries of more than 1,000 cluster compounds whose structures have been elucidated using X-ray and neutron diffraction techniques. K. Wade and R. G. Wooley have contributed two very different views of the bonding in these polyhedral molecules, J. A. Connor has provided a balanced and critical account of the thermochemical estimation of metal–metal bond strengths in cluster compounds, and B. F. G. Johnson and R. E. Benfield have discussed their fluxional characteristics. The biological significance of cluster compounds is stressed by C. D. Garner, in a chapter dealing with cubane clusters, and R. Whyman has attempted to evaluate whether cluster compounds do actually function as effective catalysts by reviewing the relevant academic and patent literature. There is also a detailed review by A. J. Deeming on the reactions of metal carbonyl cluster compounds.

The book gains by drawing on the expertise of the authors to provide a reasonably up-to-date (literature references up to the end of 1978) and broad view of the field, but suffers from an uneven view of the potential readership of the book. Thus although some chapters are written at a level which would be appreciated by a third-year undergraduate, others are in the style of a research paper or a terse contribution to a Chemical Society *Specialist Periodical Report*. Therefore, although I wholeheartedly agree with the editor that this book will serve as a "source of reference to workers in the field", I very much doubt if it will be used much as "an advanced text for undergraduates or graduates in chemistry". □

Michael Mingos is a Lecturer in Inorganic Chemistry and Fellow of Keble College at the University of Oxford. He was recently awarded the Corday Morgan Medal of the Chemical Society for his experimental and theoretical contributions to organometallic and cluster chemistry.

Animals: their use and their abuse

Michael F.W. Festing

Animal Suffering: The Science of Animal Welfare. By Marian Stamp Dawkins. Pp. 149. Hbk ISBN 0-412-22580-8, pbk ISBN 0-412-22590-5. (Chapman & Hall: 1980.) Hbk £7.50, pbk £3.95.

ON AVERAGE, a person living in a developed country such as the UK will be responsible for the death of about 600 chickens, 22 pigs, 20 sheep and 7 cows for food and 5 mice, 2 rats, 1 chicken, a third of a guinea-pig and two-hundredths of a cat and dog for medical research during their 75-year life span. They will also be responsible for the deaths of countless fish, both for food and for sport. Their food supplies and health will also be maintained at the cost of the death by poison or trapping of an unknown, but large number of mammals and birds classified as pests. Who can doubt that the production, maintenance and killing of all these animals involves a certain amount of suffering? The problem for us as individuals, and as a society, is to decide what to do about it, if anything.

In order to make some progress, we must sort out our moral attitudes to animals and to our fellow human beings, and we must attempt to strike a balance between the amount of suffering which we cause and the benefits which we derive from the animals. This is an extremely difficult problem, because it is almost impossible to quantify either the benefits of, say, using animals in medical research, or the amount of suffering that we cause. This book is an attempt to summarize our knowledge about suffering in animals, and also point out many inconsistencies in our attitudes to other species.

Following an introductory chapter, the assessment of animal suffering is considered from several different points of view. These include suffering and health, "productivity", the "unnatural" life, the physiology of suffering, behaviour, what animals choose and analogies with ourselves.

Physical health is seen to be a necessary, but certainly not a sufficient condition for freedom from suffering, and is probably the single most useful criterion of animal welfare. Productivity, in the sense used in agriculture, is more concerned with economics than animal welfare. A higher productivity (i.e. profit) may well be achieved by putting an additional chicken into a battery cage, but this does not reduce the suffering of those already in occupation. In fact, reading these chapters it becomes clear that there is no single way in which the suffering of an animal can be clearly quantified. Ideally, it would be nice to be able to measure some physiological or biochemical variable which could be used as an index of "stress". Unfortunately, although certain parameters can be measured which give an indication of the state of the general adaptation syndrome, there is no evidence that a complete absence of "stress" (which can itself be defined in many different ways) is necessarily beneficial to an animal. Nor can we say that an animal suffers because it is forced to lead an "unnatural" life. In nature many animals have a relatively short life-span, quickly succumbing to predators, disease, exposure or starvation. Their death may be lingering and painful. Even allowing animals to choose the conditions under which they will live does not always help. Animals sometimes choose a course of action which is not in their best interests; few domestic pets enjoy a visit to the vet, even though this is usually for their benefit.

Does this mean that we are unable to assess animal suffering at all? Dr Dawkins is clearly concerned that the general tone of these early chapters "may have seemed rather negative", and she goes on to provide a list of questions which we must ask ourselves in order to determine whether an animal is suffering unduly. We must consider the conditions in which the animals are kept, whether they are healthy, whether they appear physiologically or behaviourally abnormal, and if so what is likely to be the cause of these abnormalities. If possible we should also determine what conditions the animals themselves prefer. And in the end, the assessment will have to be subjective. "There is no formula for giving a clear yes/no answer to the question of whether an animal is suffering." Even if we could answer the question unequivocally, we would still have to decide how much suffering we should permit in relation to the benefits we obtain from animals. That, however, is a whole new subject which falls more in the field of ethics than biology.

Dr Dawkins has produced an excellent review of the state of our ignorance about suffering in animals, and has highlighted many inconsistencies in our attitudes. This book should be read by all those involved with farm and laboratory animals, in the hope that they will endeavour to reduce needless suffering wherever it occurs. If we must cause suffering to animals in the name of agriculture or medical research, let us at least make sure that it is not caused unnecessarily through our ignorance of the needs of those creatures that provide us with so many benefits. □

British universities must win lost friends

For British universities, the crisis of the past several years is about to reach another climax. Last week, the University Grants Committee sent off its promised letter, which emerged as a restatement of a now familiar problem. Next month, universities will be told individually what they will be able to count on from central government in the next three years. Then, with this academic year almost over, universities will know whether the prospect for the immediate future is a bad as they have been fearing these past several months, or not quite as bad. There is no chance that they will be pleasantly surprised, although it will be of some comfort that the government has now promised that the misery ordained to begin this summer will at least be assured for a full three years. At the end of that time, the British university system will be transformed. Almost certainly, it will be smaller. Nobody knows quite how.

The nature of the impending change is by now well understood. From the beginning of this academic year, the central government's support for universities has been decreased by the notional cost of educating overseas students, which the universities are expected to recover by charging economic fees. If the market for British higher education were insensitive to price, the financial consequences would be negligible. In practice, since unknown proportions of overseas students will now go elsewhere, a substantial amount of money will be taken out of the system. The consequence may be a reduction of up to seven per cent in the aggregate income of the universities, but the consequences will not be uniformly spread. Some universities will fare worse than others, but to a degree quite unrelated to their intrinsic worth. The British government has also decided that there should be a reduction in the resources made available to the universities. This will amount to just over 3 per cent next year, and to 8.5 per cent in three years. Throughout the university system, committees have been working hard, making lists of the steps they may have to take in the months ahead. Getting rid of academic departments, and of people, appears on most prospectuses. Shutting down whole universities has been canvassed as a possibility, but is unlikely.

Many universities and university teachers are bewildered by the abruptness of the change that has overtaken them. Gone for good are the happy 1960s, when both Conservative and Labour governments urged expansion (so as to increase the proportion of young people going on to higher education) and appeared willing to provide the means. What can have changed? And why has the change come so suddenly? Many academics are still plaintively asking these questions. The answer is that the change is not nearly as abrupt as it may seem. The climate has been changing since the early 1970s, since when public support for the universities and their research has stagnated. For most of that time, academics have been foolishly complacent, often behaving as if the deterioration of their institutions was the responsibility only of the central government, aided and abetted by the University Grants Committee. Now, the government can fall back on the thin excuse that further impoverishment is justified by the impending reduction of the age groups from which university students are recruited. The underlying truth, however, is that the British universities have lost their political friends. Many in the House of Commons will be sympathetic to the plight of the universities in the next few months, but few elected politicians would use up political capital by defending the universities from the cuts ahead.

The universities are not blameless. From time to time, they have almost courted unpopularity. Student troubles have not helped, even though the British university has been less threatened by them than many others. Even now, however, minor issues concerning students affect the capacity of the universities to keep their political friends. Is it right, for example, that the cost of running students' unions, hitherto a charge on local authorities, should now be paid from the dwindling budget of the University Grants Committee? Why should not students pay? The more serious alienation of the universities from their traditional supporters in the House of Commons springs more directly from the assumption of the universities that even in times of rapid and painful social change, the structure of the university system itself should remain untouched, changing only if the universities so decide. One result is that even those outside the system who value academic freedom are asking whether academic freedom necessarily requires lifelong tenure for all. Then those among the universities' natural friends who accept that scholarship is an indispensable part of the institution of the university are unconvinced that the universities are vigilant enough in distinguishing good scholarship from the less good or even the downright bad. The universities have lost many potential friends by their unimaginative, even unhelpful, responses to several attempts to reform the transition in the British system from school to university. And their proper insistence that universities are self-governing institutions is weakened by their frequent demonstrable failure to manage their own affairs effectively.

Hard words such as these are not inappropriate even in hard times. Indeed, if the universities do not now acknowledge that they are partly responsible for the plight in which they find themselves, they will be less able to meet the crisis the British government has unthinkingly forced on them. They will, in particular, be less able to make the plain argument that the policy of retrenchment being forced on them is a foolish policy, innocent of clear objectives, marred by vindictiveness and almost calculated to ensure the British taxpayers get even less value for the diminished sums of their money to be spent on higher education in the next few years. For several years, it has been clear that the most urgent need in British higher education is for a reconsideration of what it is for, how it should be financed and how different kinds of institutions, universities included, should contribute. Probably it is now too late for that reappraisal to be carried out deliberately. But radical thinking by threatened institutions might still do wonders.

It would be a useful start if the universities would decide where they stand in relationship to each other and to comparable institutions, the polytechnics for example. In the past few months, it has been fashionable among the enemies of higher education to say that there are too many universities. That assertion is unverifiable, and probably untrue. But there are too many universities of the same kind, or too many universities striving after an idealized vision of what a university should be — perhaps a cross between Oxbridge and the Harvard Business School. All except Scottish universities insist that, for most students, three years of undergraduate teaching is sufficient for a first degree. All insist that scholarship is inseparable from teaching and, more literally, that there must be a full range of research programmes undertaken on the premises. Most of them are so balkanized internally, with power and responsibility delegated to separate departments and colleges, that academic policy is a kind of statistical amalgam of different people's inclinations. And most universities scorn most other kinds of higher education than their own — the British polytechnics or

0028 0836/81/210177-02$01.00

liberal arts colleges on the pattern of the United States

Breaking this log-jam of prejudice against change is desirable in itself but could also have practical consequences in the present crisis Given the quality of their students and the scale of their research programmes, many universities would be better off if they could become liberal arts colleges in the best sense — providing students with a general education (which includes an education in science) without the encumbrance of in-house research programmes (which does not imply that academics need not be scholars) Other universities, by contrast, might make their way more successfully in the world by concentrating more vigorously on the kind of vocational education that has made institutions such as the Cranfield Institute of Technology (not strictly a part of the university system because it is financed directly from central government) both successful and valuable British universities will be the more able to turn the tight corner ahead if they come to believe that diversity within the system should be an objective — and if the University Grants Committee can devise an incentive for helping them stay with such objectives

Hotchpotch

The hotchpotch system of financing universities also needs reform Money for day to day purposes reaches university treasurers from three principal sources — from the Department of Education and Science on the recommendation of the University Grants Committee, from local education authorities which pay the fees of all home students (and which are reimbursed by the Department of the Environment) and from individual students from overseas, who must pay their own tuition fees as they go along But the local authorities are also required by law to provide many students with a maintenance grant calculated after allowing for parental income Most universities have only a negligible income to call their own, although many of the Oxbridge colleges are still well-heeled In most universities, tuition fees now exceed twenty per cent of direct subvention while maintenance grants paid from public funds to university students are probably close on forty per cent of direct income The government seems for the time being to have given up its ambition to replace maintenance grants by loans, but the impending crisis is caused largely by its threatened reduction of the direct grant But in this crisis, there must be room for a redistribution of these substantial funds When the interest of students in their education is matched by the universities' anxiety to survive, however, there must be places where it would be in everybody's interest — even the government's — that funds were transferred from the maintenance grant to the general budgets of the universities The simple way of doing this would be to require that students should work for the institutions that educate them, thus reducing general costs British students might in the process lose their unique status as perpetual dependants, but the world would not thereby end

Hardship

Academics must also be prepared for hardship The impending crisis has already raised questions about security of tenure — and many universities are dangling the prospect of early retirement before their staffs In the period ahead, however, the universities may not be able to afford this dubious luxury — and the government is unlikely to help So academics may have to make do with less pay, at least in real terms Will they? The Association of University Teachers is already up in arms at the cuts in prospect, and is holding out the hollow threat of a strike The academic profession will, however, be further discredited if, after decades of high-sounding (and cogent) argument in defence of the university as a social institution, academics let universities collapse by insisting that national agreements on pay must apply to everybody Indeed, they should go further than be flexible on pay and agree to be flexible about the work they do Research, they rightly insist, is inseparable from the university, but so is teaching And those who do less research must be prepared to do more teaching

Such developments, even when designed to meet the immediate crisis, cannot easily be brought about Few British universities have mechanisms by which their academic members can agree on the allocation of car parking space, let alone on matters even of academic policy Yet academics are understandably suspicious of ceding such responsibilities to the university administrators So even when the going is good, too little is decided At times like the present, when ingrained suspicions are heightened, paralysis tends to supervene Yet the crisis requires that universities should be individually equipped to make decisions of two sharply different kinds

First, there will have to be decisions about the academic qualities of individual academics Whose research is worth continued support? Who might fairly take on more teaching? Who may have to be asked to leave? And which departments are more dispensable than others? Traditionally, academics have avoided such decisions because they are invidious If they do so now, decisions will nevertheless be made but in an unseemly way — or by drawing lots And the universities as well as unlucky academics will be the losers

Second, universities need ways of deciding strategies for survival Committees of academics are ill-equipped for such tasks, or even comprehensively to list the alternatives (Courses of action unpalatable to some are rarely heard of) The standard compromise is to appoint a committee with an external and supposedly independent chairman to suggest what might be done — the mechanism is now being followed by the University of London The trouble is that the recommendations that follow have no force, and can be endlessly disputed As things have turned out, there is no choice for the universities but to agree that their administrators have a duty to draw up the agenda for the inevitable debate on what course should be followed — and also a right to bring an end to argument In reaching what must be painful decisions, the universities singly would benefit from some means of knowing that they are not all rushing off in the same direction but, rather, moving towards diversity

Self-interest

The peculiar difficulty of the problems with which the universities are now confronted is that their own narrow self-interest may not coincide with the long-term interests of the university system as a whole or with the interests of their customers — in the last resort, their potential students and those prepared to sponsor students, ultimately the taxpayers Plainly, however, it will serve no useful purpose if individual universities decide to concentrate on courses for which there is no demand, or on fields of research for which there are no sponsors Up to a point, such market forces will keep individual universities moving in prudent directions But the market for higher education is far from perfect — and should in everybody's interest remain so It would be tragic, and a travesty of the idea of a university, if students' choices of courses were determined exclusively by short-term economic considerations, or if grant-making bodies made grants for research on the basis of expected communal benefit Both students and the sponsors of research are known to make mistakes And the social value of universities derives directly from their capacity to help devise an uncertain future

These are the steps that British universities must take in the weeks immediately ahead There is another course of action that they cannot neglect The government's decision that there must be a cut in university funds has been plucked like a rabbit from a hat The consequences have not apparently been considered except by those among the government's economists concerned with the size of the borrowing requirement So far, both the University Grants Committee and the universities have been willing to administer this sudden change of policy without any but the mildest protests Lacking friends, the universities may think they have no choice But, in the long run, the present crisis will seriously damage the interests of a large part of the British population It is time that the universities abandoned good manners, and told the government what will be the consequences of its action And it is not too soon to set out to win back the lost constituency of friends, presumably first among parents whose children will, on present form, be deprived of higher education

Creationism again an issue in Arkansas

Civil liberties take suit against law

Little Rock, Arkansas

The American Civil Liberties Union (ACLU) has decided to engage in a full-scale confrontation with the growing creationist movement over the teaching of evolution in US public schools. Early next month, ACLU is planning to file a complaint against the State of Arkansas arguing that a law passed by the state legislature in March — which requires that "creation-science" be given equal time with the theory of evolution whenever the latter is discussed in public school classrooms — is unconstitutional, since it ignores the required separation of church and state.

The ACLU case may well find its way up to the US Supreme Court. It seems certain to generate as much controversy as the last time that the organization confronted the creationist arguments. This was in 1928 when Clarence Darrow, acting as an ACLU volunteer attorney, defended Tennessee biology teacher John Scopes against the charge that he had violated state laws by teaching evolutionary theory in the classroom.

Although Scopes was convicted and fined $100, Darrow won a moral victory — and, over the following decades, individual states removed from their statute books laws which prevented Darwinian evolution from being taught.

This time, however, the tables have been turned. The creationists have spent many years developing the argument that their ideas can be described as "scientific", and in eliminating all explicit religious references from public school textbooks promoting the idea that the world originated in the hands of a divine creator. More recently, they have spent an equal amount of legal effort in eliminating all explicit religious references from proposed legislation at both the state and the federal level, demanding equal time for what are described as two rival scientific theories.

The legislation introduced in Arkansas, for example, has been carefully crafted by a creationist group in South Carolina, with advice from sympathetic lawyers across the country, to answer precisely the type of challenge which ACLU is planning to mount.

Various other states have been discussing similar "equal time" bills over the past two years. Last year, for example, the Georgia legislature just failed to approve a bill in the closing minutes of its 1980 session. And according to Mr Paul Ellwanger, head of the group in Anderson, South Carolina, which wrote the Arkansas bill (known as the Citizens for Fairness in Education), seventeen other states have been considering similar or identical bills in their current or recently-ended sessions.

Mr Ellwanger emphasizes that his own group is not formally linked to any political or religious organization. In Arkansas, however, two significant factors seem to have played a major role in getting the "equal time" legislation on to the statute book. The first was the important role played by groups such as the state branch of the Moral Majority and the Little-Rock-based organization Family, Life, America, God (FLAG) in stimulating support for conservative candidates — such as Arkansas' current governor, Mr Frank White — in last year's election. The second was the speed with which state lawmakers were prepared to push the bill through both houses of the legislature.

The bill was introduced into the Senate by Mr Jim Holsted, a first-term Senator from North Little Rock, a wealthy suburb of the state capital. He has admitted that he knows little about creation-science, but as a "born-again" Christian is a firm believer in the book of Genesis. According to Holsted, he was given the bill in virtually completed form by a mathematics teacher at a Jacksonville High School, who had already been attempting to persuade the local school board to require "equal time" for creationism and evolution in the schools under its jurisdiction (a tactic which has already been successful in several states).

The bill was passed overwhelmingly on the floor of the state Senate. Several members of the Senate said later that, although they did not necessarily agree with the content of the bill, they had been reluctant to vote against it, since to have done so would have been interpreted as a vote against God — a heavy risk to take in a strongly Bible-oriented state.

The bill was introduced almost immediately into the House of Representatives by a business neighbour of Mr Holsted's, Representative Cliff Hoofman. It passed to the education committee, where the bill's supporters and opponents were each given five minutes to put their case — the sum total of public discussion of the bill's contents. A motion to delay the committee vote was refused by the

Arkansas legislation reflects old quarrels

The Arkansas law, passed in March (and introduced in virtually identical versions in seventeen other states), is known as the "Balanced Treatment for Creation-Science and Evolution-Science Act". Its principal requirement is that "public schools within this state shall give balanced treatment to creation-science and to evolution-science. Balanced treatment of these two models shall be given in classroom lectures and in textbook materials taken as a whole for each course, and in library materials and other educational programs".

"Creation-science" is defined as the scientific evidence for creation and inferences from that evidence. This includes evidence of: sudden creation of the Universe, energy and life from nothing; the insufficiency of mutation and natural selection in bringing about development of all living kinds from a single organism; changes only within fixed limits of originally-created kinds of plants and animals; separate ancestry for man and apes; explanation of the Earth's geology by catastrophism, including the occurrence of world-wide flood; and a relatively recent inception of the Earth and living kinds.

The bill contrasts this with the teaching of "evolution-science" — referred to earlier as the theory of evolution — and the evidence which is held to support it. Whereas previously both creation and evolution had been referred to as "theories" to which equal time should be given in the science classroom, the bill passed in Arkansas refers to the two "scientific models" of evolution-science and creation-science; it also states as a "finding of fact" that "only evolution-science is presented to students in virtually all of those courses that discuss the theory of origins. Public schools generally censor creation-science and evidence contrary to evolution".

Particularly controversial has been a passage in the bill which states that one of its purposes is to prevent "establishment of theologically liberal, humanist, nontheist or atheist religions". The bill goes on to state that public school presentation of "evolution-science" is unconstitutional, because "it produces hostility toward many theistic religions and brings preference to technological liberalism, humanism, nontheistic religions and atheism, in that these religious faiths generally (*sic*) include a religious belief in evolution".

The Arkansas law also states, in a key passage designed to provide protection against the anticipated challenge, that: "public school presentation of both evolution-science and creation-science would not violate the constitution's prohibition against establishment of religion, because it would involve presentation of the scientific evidences and related inferences for each model rather than any religious instruction".

0028-0836/81/210179-02$01.00

chairman, and after a short discussion it was passed and sent onto the floor of the House, where it was brought up and hurriedly passed in the closing hours of the 1981 session at the end of March.

Governor White lost no time in signing the bill, admitting later that he had not read it before doing so. His decision provoked a storm of protest from scientists in the state, most of whom were unaware of the bill until it had been passed into law. The Arkansas Academy of Sciences at its annual meeting passed a resolution urging that the law be rescinded, as did 300 faculty members of the University of Arkansas at Fayetteville, who complained that the act would hurt the university's reputation.

Governor White, however, has made it clear that he does not intend to take any steps to repeal the law unless it is judged as unconstitutional. And many Little Rock observers feel that he is likely to stick to this position, given the extent to which his surprise victory over incumbent Democrat Governor Bill Clinton last November seems to have been helped by the active involvement of groups such as FLAG and the Moral Majority in encouraging the conservative vote.

As a result, the spotlight is now focused on the ACLU complaint, which both sides see as setting important precedents. Groups which are likely to support ACLU include the National Association of Biology Teachers, which has long campaigned about allowing creationist theories to be placed on the same level as evolution in school biology classes. And the President of the Arkansas Academy of Sciences, Professor John Kenneth Beadles, head of the State University of Arkansas' biology department, is suggesting to fellow academy members that they add their support to the ACLU effort.

The creationists are getting ready to meet the challenge. One of the principal advisers on the drafting of the Arkansas Bill is said to have been Wendell Bird, an attorney who was at one time an editor of the *Yale University Law Review,* and who now works with the Institute for Creation Research in San Diego, California. The institute, as a tax-exempt organization, takes pains not to be seen to be involved in legislative campaigns; however, Mr Bird's writings are referred to by Mr Ellwanger and others as powerful support for the argument that the teaching of creation-science can be defended by referring to rights guaranteed by the constitution.

If ACLU wins its case, either at the district court level, during the appeals process, or in the Supreme Court, it will be a major setback not only for the creationist movement — which now claims over 750 scientists among its ranks — but also for the broader poltitical strategy of the conservative right. If it loses, it will be a significant boost to creationists, who are already predicting that bills similar to that passed in Arkansas are likely to be introduced in 40 state assemblies next year.

Pressure is also building up at a federal level. Several Congressman have received a model bill promoting research support for "creation-science", from a group, also headed by Mr Ellwanger, called the Citizens Against Federal Establishment of Evolutionary Dogma. It seems only a matter of time before some congressman introduces the legislation.

The two sides are as far apart as ever. Mr Ellwanger argues that "fairness should not be an option; we now have the tools to insist that fairness be mandated by law, in the interests of academic honesty". The Arkansas *Gazette*, which has carried out an uncompromising campaign against the bill, warns that it will brand the state as a "bastion of know-nothingness in the teaching of science." The court case is unlikely to stay polite.

David Dickson

Scopes again?

The present is not the first occasion when Arkansas has been the focus of national attention on the constitutionality of efforts to influence the teaching of evolution in public schools. In 1968 the US Supreme Court struck down a law, introduced into the state in 1928, which made it illegal for any teacher and educational institution supported by state funds to teach "the theory or doctrine that mankind ascended from a lower order of animals".

Following the Scopes trial, no serious attempts seem to have been made to enforce this law. However, the case was passed to the Supreme Court after the statute had been unsuccessfully challenged in the state's Supreme Court by a biology teacher in Little Rock's Central High School, Mrs John O. Epperson.

In declaring the state law unconstitutional, Justice Abe Fortas argued that the 1928 law, enacted in a popular initiative, was a clear effort inspired by the Scopes trial to outlaw all but the "Bible story" of creation. "There can be no doubt that Arkansas has sought to prevent its teachers from discussing the theory of evolution because it is contrary to the belief of some that the Book of Genesis must be the exclusive source of doctrine as the origin of man" he said.

At the time of the trial, Arkansas and Mississippi were the only states to maintain an anti-evolution law. The fact that the law preventing the teaching of evolution was judged by the Supreme Court to infringe the "establishment of religion" clause in the constitution is expected to be used by the American Civil Liberties Union in its attack on the new law. Scopes himself, then living in Louisiana, hailed the Epperson decision as "what I have been working for all along". His own conviction was quashed by an appeals court, so he was unable to challenge the constitutionality of the Tennessee law.

Sakharov conference

Birthday honour

New York

The two-day conference at Rockefeller University on 1–2 May in honour of Dr Andrei Sakharov was an ironic occasion. The opening day was celebrated in the Soviet Union with the customary package of approved slogans, the forty-first of which reads "Soviet scientists! Improve the effectiveness of research! May the alliance between creative thought and creative labour be much stronger!" Sakharov meanwhile remained in internal exile in Gor'kii.

The conference had been called in part to mark Sakharov's birthday on 21 May and consisted of three parts — Sakharov's work in science, for nuclear disarmament and for human rights. Among the scientific papers was one by John Archibald Wheeler (University of Texas) on Sakharov's "sausage-skin" cosmology, another by Harold Furth (Princeton) on Sakharov's contributions to fusion research and a third by Val Fitch (Princeton) on anti-matter asymmetry. Those present nostalgically recalled Sakharov's involvement with the international scientific community in the past twenty years and argued that his present isolation was tantamount to bringing his scientific career to an end.

The conference was at something of a loss to reconcile Sakharov's work on the Soviet thermonuclear bomb in the 1950s with his more recent concern for disarmament; the argument that by assisting in the strategic parity between East and West he was helping to satisfy one of the realistic preconditions of disarmament was regarded by some as artificial and by others as unnecessary.

Sakharov's own message to the conference (see page 184) was largely concerned with human rights and, in particular, with the plight of Soviet citizens other than himself. On the question of the relationship between professional scientists in the West and their Soviet colleagues, Antonino Zichichi, president of the European Physical Society, told the conference that more than a thousand scientists had undertaken that until the end of this year, all scientific papers submitted for publication would bear the legend "In honour of the 60th birthday of Andrei Dmitrevich Sakharov". For the time being, however, the disputed question of a scientific boycott of the Soviet Union such as that organized last year, although aired at the conference, has been allowed to lapse.

Another of the ironies of the timing of this month's conference is that it followed soon after the celebration of the twenty-fifth anniversary of the Joint Nuclear Research Institute at Dubna, south of Moscow. In a full-page feature in the daily newspaper *Sotsialisticheskaya Industriya,* attention was drawn to the search for

0028-0836/81/210180-02$01.00

transuranic elements in the "island of stability" (atomic numbers 114–120), studies of black holes and quarks. Mr Leonid Brezhnev, at the twenty-sixth Party congress, had emphasized the need for "fruitful cooperation of all states" on these problems, yet Sakharov has been unable to meet or correspond with his colleagues abroad since 22 January 1980.

Vera Rich

UK industrial research

All change

Britain's Department of Industry has reorganized the way in which it supports industrial research, seemingly to counter criticism that it has been poor at defining priorities and has relied too heavily on reacting to research proposals from industry. The nine research and development requirements boards, each aimed at a particular sector of industry, have been replaced by five boards, each dealing with a particular technology.

The five new boards are to cover the same spread of research as the old ones, the idea being that by increasing the spread of each board's responsibilities the government's definition of long-term objectives and priorities will be made easier. Hence for example, the new Mechanical and Electrical Engineering board will take over the work of the old Ship and Marine, Mechanical Engineering and Machine Tools and Electrical Technology boards. The old Chief Scientist's board, which considered topics not covered by the other boards, is to be incorporated into the new Textile and Other Manufactures board.

The other new boards are Electronics and Avionics which replaces Computer Systems and Electronics, Materials and Chemicals which replaces Chemicals and Minerals and Engineering Materials, and Metrology and Standards which remains the same under the chairmanship of Dr Duncan Davies, now called Chief Engineer and Scientist in the department.

The functions of the new boards will remain largely unchanged. Industry and universities will be able to apply to them for government support for industrial research and they will continue to place contracts for research of their own choosing within industry and the department's own research establishments. The arrangement whereby levies are charged on the profits accruing from research funded by more than 50 per cent by the department will remain. And each board will have an executive committee to approve projects. It is hoped that the reorganization will encourage the boards to place more contracts in priority areas of research. However, the fact that there are no plans to appoint subcommittees has led to some fears that the boards' remits could be too wide to be effective.

The department's budget for industrial research is to remain roughly constant. This year it is £600 million, £35 million of which will be spent in industry and £25 million in the department's research establishments. A small saving in funds will be made from the reduction in staff expected to follow the reorganization.

Judy Redfearn

Bioengineering hazards

Europe doubts

Brussels

An inconclusive meeting on the safety aspects of research on recombinant DNA was held here last week by the European Community's Economic and Social Committee (ESC). At this stage, it is hard to tell whether the meeting will influence the development of Community legislation on the subject — and, if so, in what direction that influence will be directed.

The discussions ranged from the long-term ethical problems posed by the possibility of tampering with human genes to the risks of accidentally releasing a new and dangerous strain of microorganism. The impetus for the meeting was the European Commission's draft recommendation on the registration of DNA research — ESC is required to give an opinion before the Council of Ministers make a decision.

Most participants seemed to agree that industry was already being over-cautious. By trying to avoid the mistakes of the nuclear industry, the safety measures recommended in the early 1970s for DNA research now seem to reflect exaggerated fears.

One pointer in this direction was the conclusion by the European Science Foundation's Liaison Committee on Recombinant DNA in January that recombinant DNA research as such entails no significant novel biohazards. It was also stressed that recombinant DNA techniques can be safer than conventional methods for studying pathogens and toxins. Safety guidelines for handling pathogenic viruses, it was argued, were far more necessary, and the World Heath Organization's guidelines are late in arriving. These are due to be published within the next few months.

It was over the social risks that most of the participants were divided. Representatives of trades unions pointed out that there was a danger that decision-making would be restricted to industry. British speakers pointed out that the British Genetic Manipulation Advisory Group has retained control, but French participants conceded that this was not the case in France and elsewhere. Several participants were convinced that the concentration of knowledge in the hands of industry will lead to commercial (or even military) applications not necessarily beneficial. Calls for less secrecy were, however, answered by reference to the fact that all patents are by definition publicly available.

But does the public have sufficient say over the uses to which the recombinant DNA techniques will be put? This issue overlapped with that of the role of the media in informing the public. By attempting to bridge the gap between the scientist and the layman, was there a danger that the press was exaggerating the dangers or speed of developments in this field?

Although many of the speakers argued that the DNA guidelines were safety regulations looking for a hazard, some members of ESC confirmed afterwards that they were in favour of legally enforced safety regulations, even if they needed to be frequently revised to take into account changes in risk assessment. It was suggested that the Community was merely going through the same process that had taken place in the United States a few years ago, but a little later because of the several countries involved.

Jasper Becker

US defence budget

Laser destruction

Washington

The US Senate last week proposed adding an extra $50 million to the budget of the Department of Defense to speed up the research and development of a space-based laser system designed to shoot down incoming enemy missiles. At the same time, a Senate appropriations committee has not passed on Mr Reagan's request for $20 million to be added to the Pentagon's construction funds for the current year to begin work on the production of binary chemicals weapons at the Pine Bluff arsenal in Arkansas, although this decision could be overturned in negotiations with the House of Representatives, which has already given its approval for the money.

The decision to add additional funds for the laser system is the result of growing pressure from the US military to respond to reports that the Soviet Union is already testing ways of using lasers to destroy missiles — and in the face of continuing scepticism from several quarters that space-based lasers can in fact be produced with the required degree of reliability and accuracy.

The proposed $50 million, which will include a detailed systems definition of a space-based laser weapons system, is a compromise between the $250 million being requested by some advocates of the system, and fiscal conservatives concerned about an unnecessarily large expansion of the arms budget, which the Senate approved at a record figure of $136,500 million for 1982.

Asked for comments on the original $250 million proposal, Dr John Foster of the Department of Defense's Defense Science Board said it was too soon to accelerate space-based laser development towards integrated space demonstration for any mission, and that "a push toward integrated on-orbit demonstrations would seriously endanger necessary [research and

0028-0836/81/210181-02$01.00

development] work''. However, according to Senator John Warner, the Defense Science Board has concluded that the potential utility of space-based lasers is significant and that an average of $50 million per year should be added to the programme.

The money for the binary chemical weapons facility which the Senate armed services appropriations subcommittee has left out of the supplemental request for the fiscal year 1981 would have been the first step towards renewed chemical weapons production which has been halted since 1968. The Administration is thought to be moving cautiously, aware of the public concern about the deployment of a new generation of chemical weapons in Europe. The main debate will probably take place later this year, when the details of next year's budget request, likely to contain substantially more funds for chemical weapons, are debated in Congress.

David Dickson

Soviet space

Romanian resources

Last Friday's launch of Soyuz-40, carrying into orbit Romanian cosmonaut–researcher Dumitru Prunariu for a week's stay aboard the Salyut-6 space station, completes the series of manned flights envisaged under the Comecon ''Interkosmos'' programme. Since the series was inaugurated with the flight of the Czech Vladimir Remek in March 1978, these ''international'' programmes have taken on a standard form, regularly including Earth-resources photography, astrophysics, biomedical studies and technological experiments. On each occasion there has been a smelting and crystallization experiment, using a Soviet ''Splav'' furnace and a capsule provided by the non-Soviet partner, with an appropriate patriotic code-name: ''Altai'' for Mongolia, ''Berolina'' for East Germany and in the latest case, ''Dacia'' for Romania.

Each joint programme, however, has also reflected the contribution made by the non-Soviet partner to the whole ''Interkosmos'' programme. In the case of Romania, the emphasis was initially on instrumentation. According to Dr Ioan Ursu, First Deputy Chairman of the Romanian National Council for Science and Technology, from the beginning of the programme in the late 1960s, Romania had specialized in the production of magnetometers, specially adapted spectrometers and radiation detectors. Romanian instruments, he said, had contributed considerably to the accumulation of data on the chemical composition of the upper atmosphere, variations of the Earth's magnetic field and particle physics. The current programme, according to Dr Eugen Mendescu, Secretary of the Romanian commission for space activity, will include the ''Astro'' experiment, which will attempt to capture super-heavy nuclei. Other innovations include an experiment on the behaviour of liquids in ''microgravitational'' conditions and the monitoring of dynamic disturbance of the space station itself, in order to determine possible effects on the experiments (the Polish ''Syrena'' crystallization experiments in 1978 seem to have run into trouble on this account).

What prospects the Soviet manned space programme now holds for international cooperation remains a mystery. Current plans for Soyuz–Salyut still include flights by a French and an Indian cosmonaut, and during last month's celebrations of the twentieth anniversary of Yurii Gagarin's flight it was suggested that Finland might also be invited to participate.

Future international cooperation may well have received a setback with the death last autumn of Academician Boris Petrov, head of the ''Interkosmos'' programme. Academician Petrov was a firm supporter of such international flights, unlike, for example, the President of the Soviet Academy of Sciences, Anatolii Aleksandrov, who on one occasion commented sourly that ''Solyuz is not a trolleybus''. Nevertheless, the options remain open. At a press conference in Berlin last month, cosmonauts Pavel Popovich and Vladimir Aksenov observed that a manned flight to Mars was a ''problem for the coming decades'' which could ''best be settled'' by means of international cooperation involving many countries.

Vera Rich

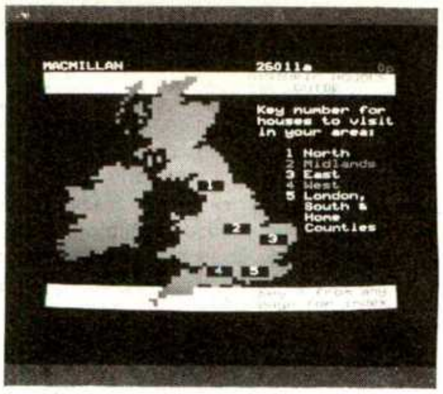
Viewdata systems

Battle joined

Although the British viewdata system, Prestel, was not expected to make a profit within the first eighteen months of operation, the results so far are disappointing. As yet only 1,288 people have bought the special television sets for domestic use. British Telecom's early hope that no home could do without its Prestel set seems to have been ill-founded. Sales to businesses, however, have been slightly brisker, although the 8,216 registered represent only a modest achievement.

British Telecom has, nevertheless, changed its marketing strategy, aiming at business rather than the domestic users. The National Economic Development Office hopes that business registrations will rise to 46,000 in the next eighteen months. The target for home registrations within that time is now 4,000.

The main lesson so far is that cost and the quality of information on the system are crucial to the home buyer. A custom-built Prestel set costs £400–500 more than an ordinary colour television set, although special adaptors costing about £200 are now coming onto the market. As well as ordinary telephone charges, a tariff for connection to a central computer is also levied, so the cost to home users who want only information on train timetables, local cinemas and so on can seem expensive. The recent decision to increase the computer connection charge for peak day-time use does not augur well.



MACMILLAN

Key number for houses to visit in your area:
1 North
2 Midlands
3 East
4 West
5 London, South & Home Counties
1
2
3
4
5

The quality of information at present stored on Prestel is variable. As yet nobody quite knows what type of information the domestic user is prepared to pay for, so two television supply companies are conducting a market survey in four provincial towns. Businesses, however, seem more prepared to pay for information, the greatest users so far being travel agents and financial companies.

One obstacle to further adoption by business is the increasing number of private viewdata systems, most of which are nevertheless compatible with Prestel. British Telecom regards these systems as complementary rather than competitive. It also hopes that the introduction next year of its Gateway system, whereby private databases can be linked to Prestel, will at least prevent British Telecom from being squeezed out of the market.

The teething problems of Prestel, the longest running public viewdata system in the world, will no doubt be watched with interest by competitors and potential buyers outside Britain. Although Prestel has been licensed to more telecommunications authorities than any of its rivals, the French Teletel and the Canadian Telidon may yet emerge on top. Arguments over which system should be recognized as a standard by the International Consultative Committee on Telephones and Telegraphs seem to have been resolved by all three being accepted. And the problem that no one system is compatible with either of the other two seems to have been resolved, at least for the French and British systems, by recent developments in software which will soon allow access by each system to the same computer.

Nevertheless, Telidon, which uses an alpha-numerical rather than an alpha-mosaic standard and is thus better at graphics, may have advantages over Prestel for some uses. What everyone wants to know is which system, if any, AT&T will choose in the United States. Some indication is expected to be given this week at Videotex '81 in Toronto.

0028-0836/81/210182-01$01.00

Coal liquefaction

Trial by post

The future of the United Kingdom's only serious programme in coal liquefaction technology has been placed in doubt by a tense exchange of letters between the chairman of the National Coal Board (NCB), Sir Derek Ezra, and the Chief Scientist of the Department of Energy, Dr Tony Challis.

NCB has been waiting a year for a reply from the department about its proposal to build a 25-tonne-a-day pilot liquefaction plant at the Point of Ayr in North Wales, using two alternative technologies and costing £65 million to the government. These plans have become part of an agreement between the department, NCB and the National Union of Miners.

But, claims Dr Challis in his letter, on the assumption that oil conservation measures take full effect, and that sufficient oil-fired boilers are converted to coal-burning, "it seems likely that the United Kingdom can maintain net self-sufficiency in transport fuels and chemical feedstocks well into the next century", and thus that the United Kingdom does not need to develop an indigenous coal liquefaction technology, particularly when British coal is expensive (relative to American and Australian coal) and "bearing in mind the formidable level of international effort already applied in this field".

Dr Challis admits that NCB technology could be 30 per cent more energy-efficient than rival processes — after all, his own staff collaborated in the calculation — but says this is not enough to counter the 6-year lead-time in scale enjoyed by, say, the 200-tonne-a-day Exxon Donor Solvent plant at Baytown, United States. Dr Challis's letter, was written just after his return from a visit to this plant, so it seems Exxon have successfully "sold" him their technology.

He also argues that a 1-tonne-a-day plant followed by a 200-tonne-a-day plant would make better sense than the intermediate 25-tonne-a-day liquefier planned by NCB. Also, according to Dr Challis, who was a chemical engineer himself, NCB has "lacked adequate strength or perspective in the translation from chemistry to chemical engineering", and the translation has been done in too much of a hurry.

Sir Derek Ezra, in reply to Dr Challis, chides him for the department's late change of heart — and expresses surprise at Challis's optimistic view of Britain's oil supply, "more optimistic than the official view of the Department of Energy". And it is not at all clear, says Sir Derek, that countries with cheap surplus coal would be prepared to supply it cheaply in the future, when coal is in greater demand — so the cost of our own coal is not relevant.

Sir Derek believes that liquefaction technology will be needed in the United Kingdom in the 1990s, and that NCB technology presents "a sufficient advance over the technologies being developed in the United States and Germany to merit support".

The American technology — and a similar plant under construction at Bottrop in West Germany — is, in fact, based largely on the wartime German technology (also employed at SASOL in South Africa) which splits the coal into monocarbon compounds, resynthesizing them to make light liquids. The resulting liquids possess only 30 per cent or so of the chemical energy of the original coal, whereas the NCB process which takes coal directly to light liquids, can promise 60–70 per cent efficiency.

British Petroleum is prepared to back the project, while NCB itself will contribute £18 million, and the project would receive about £12 million from the energy research fund of the European Community, if only the Department of Energy would give it their approval. Moreover, potential buyers of the technology in Canada and Australia will only show serious interest when a pilot plant is built.

However, despite Dr Challis's views, the department has not yet made a formal decision about the plant. The next step should be a meeting shortly between the minister for coal John Moore, Sir Derek Ezra, Dr Challis and the research director of NCB, Dr Joe Gibson. If they can reach agreement, their recommendation will then be forwarded to the Secretary of State for Energy for a decision.

Meanwhile, in the United States President Reagan has appointed an Oklahoma businessman, Mr Edward E. Noble, to be chairman of the Synthetic Fuels Corporation which will oversee synfuel development in the United States. Mr Noble is reported to be uneasy at the large numbers of US technologies aimed at producing gas, and uncertain that the mandated targets of 0.5 million barrels a day (oil equivalent) of synfuel by 1987 and 2 million by 1992 can be reached.

In London, the director of the International Energy Agency said that given uncertainties over nuclear and renewable sources of energy, coal was poised to become the "single most important energy contribution to the future of modern society".

Robert Walgate

From rank weeds to riches

New Delhi

Workers in India have found a way of converting water hyacinth (*Eichornia crassipes*) into paper, and in so doing may have solved one of the Third World's major problems. This free-floating and fast-growing weed is not only a menace to navigation and hydroelectric power generation in affected countries, but also offers a breeding ground for pests and insects. So far, all efforts have been directed at eradication of the weed. Now, the Regional Research Laboratory (RRL) in Hyderabad, controlled by the Council of Scientific and Industrial Research, is making writing paper, posters, even invitation cards, using the leaves of water hyacinth collected from the city's lakes. Because the raw material is virtually free the paper is cheap and may save some of the trees cut down to feed the paper industry.

Water hyacinth — paper power?

The technology for converting the weed into paper was developed through an international project initiated in 1978 by the London-based Commonwealth Science Council. The council, which identified water hyacinth as a major problem in the Third World, asked India to coordinate a project on the control and utilization of the weed and helped the collaborating countries to obtain a grant of $200,000 from the United Nations Development Programme. While Sri Lanka, Bangladesh and Malaysia worked on biological control and biogas production, India chose to investigate the use of the weed in paper making. And, when scientists from the collaborating countries recently visited the RRL pilot plant, they were so impressed that they now plan to set up similar plants in their own countries.

The emergence of water hyacinth as a source of raw material for the paper industry should have great impact in India, where at least four million hectares of water surface are covered with the weed. The average yield of water hyacinth is 50 tonnes per hectare, giving India 200 million tonnes of non-forest raw material for paper. If even half of this is used, and assuming a 10 per cent conversion efficiency, the country can provide 10 million tonnes of paper from the weed. The new paper-making factories can be set up wherever water hyacinth grows and the process is such that the paper can be hand-produced by unskilled workers.

K.S. Jayaraman

0028-0836/81/210183-01$01.00

The responsibility of scientists

from Andrei Sakharov

Because of the international nature of our profession, scientists form the one real worldwide community which exists today. There is no doubt about this with respect to the substance of science: Schrodinger's equation and the formula $e = mc^2$ are equally valid on all continents. But the integration of the scientific community has inevitably progressed beyond narrow professional interests and now embraces a broad range of universal issues, including ethical questions. And I believe this trend should and will continue.

Scientists, engineers and other specialists derive from their professional knowledge and the advantages of their occupations a broad and deep understanding of the potential benefits — but also the risks — entailed in the application of science and technology. They also develop an awareness of the positive and negative tendencies of progress generally, and its possible consequences.

Colossal opportunities exist for the application of recent advances in physics, chemistry and biochemistry; technology and engineering; computer science; medicine and genetics; physiology and hygiene; microbiology (including industrial microbiology); industrial and agricultural management techniques; psychology; and other exact and social sciences. And we can anticipate more achievements to come. We all share the responsibility to work for the full realization of the results of scientific research in a world where most people's lives have become more difficult, where so many are threatened by hunger, premature illness and untimely death.

The dangers of progress

But scientists and scholars cannot fail to think about the dangers stemming from uncontrolled progress, from unregulated industrial development, and especially from military applications of scientific achievements. There has been public discussion of topics related to scientific progress: nuclear power; the population explosion; genetic engineering; regulation of industry to protect the environment; protection of air quality, of flora and fauna, and of rivers, lakes, sea and oceans; the impact of mass media. Unfortunately, despite the urgent and serious nature of the issues at stake, such discussions are often uninformed, prejudiced or politicized, and sometimes simply dishonest. Experts, therefore, are under an obligation to subject these problems to unbiased and searching examination, making all socially significant information available to the public in direct, first-hand form, and not just in filtered versions. The discussion of nuclear power, a subject of prime importance, is an instructive example. I have expressed elsewhere my opinion that the dangers of nuclear power have been exaggerated in the West, and that such distortion is harmful.

With some important exceptions (primarily affecting totalitarian countries), scientists are not only better informed than the average person, but also strive for and enjoy more independence and freedom. Freedom, however, always entails responsibility. Scientists and other experts already influence or have the capacity to influence public opinion and their governments. (That influence should not be exaggerated, but it is substantial.) My view of the situation of scientists in the contemporary world has convinced me that they have special professional and social responsibilities. It is often difficult to separate one from the other — the communication of information, the popularization of scientific knowledge, and the publication of endorsements or warnings are examples of activities with both professional and social aspects.

Similar complications arise when scientists become involved in questions of disarmament: in developing strategy for or participating in international negotiations; in advancing proposals or issuing appeals to governments or to the public; and in alerting them to dangers. Disarmament is a separate, critically important issue which requires a profound, thorough and scientifically daring approach. I realize that more detailed treatment is needed, but now I will simply outline a few ideas. I consider disarmament necessary and possible only on the basis of strategic parity. Additional agreements covering all kinds of weapons of mass destruction are needed. After strategic parity in conventional arms has been achieved, a parity which takes account of all the political, psychological and geographical factors involved, and if totalitarian expansion is brought to an end, then agreements should be reached first prohibiting the use of nuclear weapons, and later, banning such weapons.

Defence of human rights

Another subject which is closely connected to questions of peace, trust and understanding among countries is the international defence of human rights. Freedom of opinion, freedom to exchange information and freedom of movement are necessary for true accountability of the authorities which in turn prevents abuses of power in domestic and international matters. I believe that such accountability would make impossible tragic mistakes like the Soviet invasion of Afghanistan and would inhibit manifestations of an expansionist foreign policy and acts of internal repression.

The unrestricted sale of newspapers, magazines and books published abroad would be a major step towards effective freedom of information in totalitarian countries. Perhaps even more significant would be the abolition of censorship which should concern first of all the scientists and intelligentsia of totalitarian countries. It is important to demand a halt to jamming of foreign broadcasts which deprives millions of access to the uncensored information needed to form an independent judgment of events. (Jamming was resumed in the USSR in August 1980 after a seven-year interval.)

I am convinced that support of Amnesty International's call for a general, worldwide amnesty for prisoners of conscience is of special importance. The political amnesties proclaimed by a number of countries in recent years have helped to improve the atmosphere. An amnesty for prisoners of conscience in the USSR, in Eastern Europe, and in all other countries where political prisoners or prisoners of conscience are detained would not only be of major humanitarian significance but could also enhance international confidence and security.

The worldwide character of the scientific community assumes particular importance when dealing with such problems. By its international defence of persecuted scientists and of all persons whose rights have been violated, the scientific community confirms its international mandate which is so essential for successful scientific work and for service to society.

Western scientists are familiar with the names of many Soviet colleagues who have been subjected to unlawful repressions. (I shall confine my discussion to the Soviet Union since I am better informed about it, but serious human rights violations occur in other countries including Eastern European countries.) The individuals I mention have neither advocated nor used violence since they consider publicity the only acceptable, effective and nonpernicious way of defending human rights. Thus, they are all prisoners of conscience as defined by Amnesty International. Their stories have much else in common. Their trials were conducted in flagrant violation of statutory procedures and in defiance of elementary common sense. My friend Sergei Kovalev was convicted in 1975 in the absence of the defendant and counsel, that is, with no possibility whatsoever of defence. He was sentenced to seven years in a labour camp and three years of internal exile for anti-Soviet agitation and propaganda allegedly contained in the samizdat news magazine *A Chronicle of Current Events*, but there was no examination of the substance of the charge.

Comparable breaches of law marked the trials of Yury Orlov, the founder of the Moscow Helsinki Group, and of other members of the Helsinki Groups and associated committees: Victor Nekipelov, Leonard Ternovsky, Mykola Rudenko, Alexander Podrabinek (and his brother Kirill), Gleb Yakunin, Vladimir Slepak, Malva Landa, Robert Nazarian, Eduard

0028-0836/81/210184-02$01.00

Arutyunian, Vyacheslav Bakhmin, Oles Berdnik, Oksana Meshko, Mykola Matusevich and his wife, and Miroslav Marinovich. Tatiana Osipova, Irina Grivnina and Felix Serebrov have been imprisoned pending trial. Yury Orlov's lawyer missed part of the trial proceedings when he was locked up forcibly in chambers adjoining the courtroom. Orlov's wife was frisked in a crude way and her clothing ripped during a search for written notes or a tape recorder, all from fear that the court's grotesque secrets might be revealed.

Mistreatment

In the labour camps, prisoners of conscience suffer cruel treatment: arbitrary confinement in punishment cells; torture by cold and hunger; infrequent family visits subject to capricious cancellation; and similar restrictions on correspondence.

E. Yantelevich

Andrei Sakharov at Gorky

They share all the rigours of the Soviet penal regimen for common criminals while suffering the added strain of pressure to "embark on the path of reform", that is, to renounce their beliefs. I would like to remind you that not once has any international organization, such as the Red Cross or a lawyers' association, been able to visit Soviet labour camps.

Political prisoners are often rearrested, and monstrous sentences imposed. Ornithologist Mart Niklus, poet Vasyl Stus, physics teacher Oleksei Tikhy, lawyer Levko Lukyanenko, philologist Viktoras Petkus and Balys Gajauskas have all received sentences of ten years in labour camp and five years internal exile as recidivists. A new trial is expected for Paruir Airikian who is still in labour camp. Within the past few days I have been shocked by the fifth (!) arrest of my friend Anatoly Marchenko, a worker and author of two talented and important books: *My Testimony* and *From Tarusa to Siberia*. Imprisoned religious believers include Rostislav Galetsky, Bishop Nikolai Goretoi, Alexander Ogorodnikov, and Boris Perchatkin. Imprisoned workers include Yury Grimm and Mikhail Kukobaka. Alexei Murzhenko and Yury Fedorov are still imprisoned. I shall name only a few scientists deprived of their freedom; many others could be added to the list: Anatoly Shcharansky, the young computer scientist now famous around the world; mathematicians Tatiana Velikanova, Alexander Lavut, Alexander Bolonkin and Vazif Meilanov; computer scientist Victor Brailovsky; economist Ida Nudel; engineers Reshat Dzhemilev and Antanas Terleckas; physicists Rolan Kadiyev, Iosif Zisels and Iosif Dyadkin; chemists Valery Abramkin and Juri Kukk; philologists Igor Ogurtsov and Mustafa Dzhemilev; and Vladimir Balakhonov.

A common violation of human rights, and one which especially affects scientists, is denial of permission to emigrate. The names of many "refusniks" are known to the West.

I was banished without a trial to Gorky more than a year ago and placed under a regimen of almost total isolation. A few days ago the KGB stole my manuscripts and notebooks which contained extracts from scientific books and journals. This is a new attempt to deprive me of any opportunity for intellectual activity, even in my solitude, and to rob me of my memory. For more than three years Elizaveta Alexeyeva, my son's fiancée, has been arbitrarily prevented from leaving the Soviet Union. I have mentioned my own situation because of the absence of any legal basis for the actions taken and because the detention of Elizaveta is undisguised blackmail directed against me. She is a hostage of the state.

Fight repression

I appeal to scientists everywhere to defend those who have been repressed. I believe that in order to protect innocent persons it is permissible and, in many cases, necessary to adopt extraordinary measures such as an interruption of scientific contacts or other types of boycott. I urge the use, as well, of all the possibilities of publicity and of diplomacy. In addressing the Soviet leaders, it is important to take into account that they do not know about — and probably do not want to know about — most letters and appeals directed to them. Therefore, personal interventions by Western officials who meet with their Soviet counterparts have particular significance. Western scientists should use their influence to press for such interventions.

I hope that carefully thought out and organized actions in defence of victims of repression will ease their lot and add strength, authority and energy to the international scientific community.

I have entitled this letter "The Responsibility of Scientists". Tatiana Velikanova, Yury Orlov, Sergei Kovalev and many others have decided this question for themselves by taking the path of active, self-sacrificing struggle for human rights and for an open society. Their sacrifices are enormous, but they are not in vain. These individuals are improving the ethical image of our world.

Many of their colleagues who live in totalitarian countries but who have not found within themselves the strength for such struggle, do try to fulfil honestly their professional responsibilities. It is, in fact, essential to work at one's profession. But has not the time come for those scientists, who often exhibit their perception and nonconformity when with close friends, to demonstrate their sense of responsibility in some fashion which has more social significance, and to take a more public stand, at least on issues such as the defence of their persecuted colleagues and control over the faithful execution of domestic laws and the performance of international obligations? Every true scientist should undoubtedly muster sufficient courage and integrity to resist the temptation and the habit of conformity. Unfortunately, we are familiar with too many counterexamples in the Soviet Union, sometimes using the excuse of protecting one's laboratory or institute (usually just a pretext), sometimes for the sake of one's career, sometimes for the sake of foreign travel (a major lure in a closed country such as ours). And was it not shameful for Yury Orlov's colleagues to expel him secretly from the Armenian Academy of Sciences while other colleagues in the USSR Academy of Sciences shut their eyes to the expulsion and also to his physical condition? (He is close to death.) Many active and passive accomplices in such affairs may themselves someday attract the growing appetite of Moloch. Nothing good can come of this. Better to avert it.

Western scientists face no threat of prison or labour camp for public stands; they cannot be bribed by an offer of foreign travel to forsake such activity. But this in no way diminishes their responsibility. Some Western intellectuals warn against social involvement as a form of politics. But I am not speaking about a struggle for power — it is not politics. It is a struggle to preserve peace and those ethical values which have been developed as our civilization evolved. By their example and by their fate, prisoners of conscience affirm that the defence of justice, the international defence of individual victims of violence, the defence of mankind's lasting interests are the responsibility of every scientist.

Gorky 24 March 1981

P.S. After this letter was written, I received word of the tragic death of Juri Kukk in a labour camp. Tatiana Osipova was sentenced to five years in a labour camp and five years internal exile on 2 April.

CORRESPONDENCE

Creationists persist

Sir — No doubt the opponents of evolution are delighted with the fireworks of disagreement that are now being displayed on this subject by biologists who write to *Nature*. Indeed, the critics of Copernicus took heart 400 years ago because scientists could not agree among themselves. However, it is not likely that the scientific process of argument betokens a swing to creationism.

During the Sacramento trial, 2–6 March, the creationists roared as gently as any sucking dove. They said, in the courtroom, that they were not seeking equal time for the teaching of creationism with evolution. In the corridors, talking to reporters, it was a different story. Their veteran leader, Mrs Nell Segraves, said: "We want 50 per cent of the tax dollar used for education to our point of view. We have a lot to undo. Creation/evolution is only the beginning."

The head of the Institute for Creation Research, San Diego, Henry Morris, PhD (Hydraulic Engineering), does not mince matters when he is writing for an audience of believers. He has said that "It is high time that Christians face the fact that the so-called geologic ages are essentially synonymous with the evolutionary theory of origins. The latter, in turn, is, at its ultimate roots, the anti-God conspiracy of Satan himself." He also says the fractures and scars of the Moon and Mars reflect a fight between good and bad angels.

However, the argument used for persuading school boards and legislatures is that "creation science" is a credible variant of conventional science, and deserves equal time. A creationist textbook has anticipated and countered Ashley Montagu's plea (*Nature* 23 April, p.623) that "perhaps the most remarkable and obvious [example of evolution in process] is the well-known case of industrial melanism in moths". Not so, say the creationists, "The moths are just the same as they were before the Industrial Revolution, and they are not becoming anything different . . . Darwin devoted his life in attempting to make it seem reasonable that all forms of life on Earth evolved from one or a few simple forms; this is a very different matter from birds selecting dark or light moths according to the type they can see more readily on a certain background". This argument is strengthened by recent observations that the black morphs are now disappearing because soot is disappearing from trees in the formerly smoky and unkind Midlands.

Creationism is on the march in Oregon, Florida, and Michigan. Governor Frank White signed the Arkansas Bill on 19 March requiring the "balanced treatment" of "creation-science" and evolution in public schools, and admitted afterwards that he had not read all of it. However, on 29 March he told a church congregation that creation-science "is a theory supported by documentation, and evolution-science is the same".

The "equal time for nonsense" position is not one that favours science; science is governed by merit, not fairness. As pointed out by Weber, the position that has the best evidence, has withstood prolonged criticism, and has the mass support from knowledgeable workers in the field, is the position that should be given the emphasis in education. In science, one theory is *not* just as good as another.

Theory upon theory

Sir — The author of the article "How true is the theory of evolution" (*Nature* 12 March, p.75) seemed to misapprehend Popper's refutation principle. He referred not only in the title to the "truth" of a theory but in the article also, where he compounded the error by writing about "proving" theories. Truth and Proof are precisely what Popper's refutation principle does not establish.

It is also unnecessarily narrow to apply Popper's demarcation principle as the exclusive arbitrator in a dispute over the scientific content of a theory. There is no known test or property that demonstrates unequivocally that a theory is scientific or otherwise (see, for example, *The Structure of Scientific Theory*, ed. F. Suppe, 1977). Popper's demarcation principle is not exceptional in this respect; it is probably an analysis most suitably used to explore the scientific content of the theories of physics rather than evolutionary theories, the latter have a historical component the former lack.

Historical theory is often formally different from scientific theory as defined by Popper, as the former can sometimes be confirmed by a finite number of observations. They are confirmed or refuted when all possible observations have been made. In this type of theory, refutation has no logical priority over confirmation — the state of affairs Popper claims for the theories he labels as scientific.

An example of the confirmation/refutation symmetry in historical theory may be found in the theory of evolution, where the gaps in the fossil record are explained sometimes as undiscovered transitional forms. This is theoretically a confirmable historical theory, though in practice the examination of every piece of the Earth's sedimentary rock would be an impossible task. In reality, this theory becomes irrefutable and therefore not scientific according to Popper, unless we interpret his "falsifiable in principle" to mean theoretically testable even if not testable in practice. Popper seems to interpret it thus, as in the *New Scientist* (21 August 1980) he claims historical theories are scientific, but this seems to upset his claim for the priority of refutability over confirmation as a property of scientific theories. On the other hand, should the interpretation be that the explanation of the gaps as transitional forms was in practice irrefutable, it is difficult to accept that finding transitional forms that fit the gaps is in no way a scientific activity.

I would also like to draw to the attention of the author of the article in *Nature* a conclusion of Feyerabend, for example, who states that "relativity theory does not modify Newtonian mechanics, it displaces the theory altogether". The displacement of one major theory by another, according to him, occurs because the two theories represent mutually exclusive universes of discourse and therefore do not have a common language. In this instance, because the two theories embrace incompatible concepts of motion, Newtonian mechanics and the theory of relativity therefore on Feyerabend's analysis do not have an analogous relationship to Lamarckism and neo-Darwinism. The author's conclusion that Lamarckism would modify neo-Darwinism was correct, but the analogy chosen was probably inappropriate.

Barrie Pearson

Winfrith, Dorchester, UK

Use the library

Sir — The recent letter from Andrew Brooks[1] indicates problems which are encountered by everyone engaged in research. As a Librarian/Information Officer in a small research institute, I often find that the information aspect of research work is approached the wrong way round. The laboratory work is done and a paper almost written before the library is consulted for relevant references. Senior research staff can be particularly guilty, relying strongly on the "old boy" network.

The information explosion of the past 15 years has greatly complicated the task of obtaining relevant information and sophisticated systems have been developed to make the job easier. *Chemical Abstracts* is perhaps the best known information retrieval tool in the sciences. This includes about half a million abstracts per year and anyone not knowing how to use it will have difficulty in retrieving any relevant information. Computerized data bases abound and a directory has been published[2]. *Chemical Abstracts* can also be searched on-line[3].

Training in how to obtain information from published sources is surely now essential. I feel it is time for a compulsory, assessed course in information retrieval for undergraduates to be introduced along with other core subject courses.

Gill Croft

Greenford, Mddx, UK

1. Brooks, A. *Nature* **291**, 7 (1981).
2. Hall, J.L. *On-line Bibliographic Data Bases* (Aslib, London, 1981).
3. Barker, F.H. *Aslib Proc.* **31**, 538 (1979).

Sir — Several months to carry out a literature search! Andrew Brooks' letter (*Nature* 7 May, p.7) amazes me and seems to reveal a lack of initiative by him and by his library. It is part of the job of an academic librarian to explain information handling techniques, whether informally or via a specialist course. In addition, most of us have access to computerized information sources and use them routinely to undertake literature searching for teaching and research staff. Surely a first task for any new researcher (or, indeed, lecturer) is to find out what services the library offers, just as he will investigate available computing facilities. Did Mr Brooks not do this? Conversely, though there are obviously difficulties in institutions with large numbers of researchers, librarians should seek out and make contact with new staff to explain their services. Nevertheless, the SRC might still usefully insist on a course of research methods, including techniques of information retrieval, as an initial part of any PhD programme.

Genes of lymphocytes II:
T-cell receptors, idiotypes and the MHC

from Miranda Robertson

OF the inexhaustible enigmas of the immune system, the focal one is certainly the T-cell receptor. Much recent work on the DNA of cloned T cells has been inspired by the hope that T cells, like B cells, recognize antigen by means of binding sites encoded by immunoglobulin variable-region genes. It is well established that T cells do not bear surface immunoglobulin, however, and the evidence that they express V genes is indirect. It is also central to the principal unifying theory of immune regulation.

The theory, originally formulated by Jerne for B cells alone[1], is based on the notion of an interacting network of antibodies which recognize antigenic determinants, known as idiotypes, on the antigen-binding sites of other antibodies. Binding to the idiotype by an anti-idiotype antibody may either induce or suppress the proliferation of the cell bearing it. But much of the immune response and its regulation depend on the activities of T cells: cytotoxic T cells, which kill infected cells; helper T cells, which induce the proliferation of cytotoxic T cells and of some B cells; and suppressor T cells, which suppress all these responses, probably in most cases by acting on the T helper cells that promote them.

One of the most important discoveries of the past decade, therefore, was the demonstration that T-cell help in antibody production could be induced or inhibited by an injection of anti-idiotype antibody[2]. This suggested that T cells bear the same idiotypes, and thus by implication the same antigen-binding sites, as B cells; and made it possible to see how they could participate in the idiotype–anti-idiotype regulatory network proposed by Jerne.

The T-cell receptor

The idea of a T-cell regulatory network based on idiotypes has been enthusiastically embraced by most cellular immunologists, although not all attempts to control immune responses with anti-idiotypic antisera have been uniformly successful. In the hope of clarifying both the cellular interactions and the molecular signals underlying such regulation, several laboratories have isolated antigen-specific T suppressor and T helper cells which carry idiotype-bearing factors on their surfaces. These factors are shed into the medium of T cells *in vitro,* or extracted from the cells, and can be shown to substitute for them in antigen-specific suppression or help.

The biochemical characterization of T-cell factors has, however, been slow, and is now being rapidly overtaken by the investigation of cloned T-cell lines at the DNA level. The rationale for these investigations is that if T cells are expressing receptors encoded by V-region genes, the V-region DNA of T cells should be rearranged as it is in B cells (see ref. 3 for details of the genes and their rearrangements). The idiotypes expressed by T cells seem to be encoded by heavy-chain V genes of immunoglobulin, so the investigators have used heavy-chain DNA probes to look at T-cell DNA. So far, the results have been negative.

Kurosawa *et al.*[4], using a J-region probe, have failed to find any functional rearrangement in a cytotoxic T-cell line. This is perhaps not entirely surprising, since cytotoxic T cells do not seem to express immunoglobulin idiotypes (though this in itself is a little unsettling for a network advocate). But at Salt Lake City*, T. Honjo (Osaka University) also reported, on the basis of preliminary data, failure to find rearrangements in T helper-cell lines.

What might these failures mean? One possibility is that the idiotypes expressed on T cells have nothing to do with the V-region genes of immunoglobulins. I. Weissman (Stanford University), playing devil's advocate, pointed out that the T15 idiotype characteristic of the anti-phosphorylcholine antibodies of certain mouse strains is recognized by a monoclonal antibody against Thy-1 antigen — a kind of cross-reaction that has been pointed out before in connection with other cell-surface molecules.

The alternative possibility, which depends on the fact that so far only J-gene probes have been used, is that in T cells, V_H genes recombine not with J_H genes but with an unknown set of T-cell J genes (J_T genes) elsewhere on the DNA. A report from F. Owen (Tufts University) on a genetically defined, heavy chain-linked T-cell marker mapping downstream of the Ig constant-region genes led to speculation that this might be the site of clusters of the putative J_T and C_T genes.

In any case, one might not expect to find precisely the same genes encoding the antigen-binding regions in T- and B-cell receptors, since the T-cell receptor repertoire is known to be more limited than that of the B cell. One of its most profound limitations is its inability to recognize antigen except when the antigen is associated with a 'self' major histocompatibility complex (MHC) molecule. The mechanism and ontogeny of this so-called MHC restriction are among the most disputed issues of modern immunology, the central questions being whether T cells see both foreign antigen and self-MHC antigen with the same or separate receptors; and whether the receptor repertoire is selected in the thymus — since selected it must be, in order that self MHC be tolerated when free of foreign antigen and attacked when associated with it.

An additional complication for immunologists working on idiotype-bearing T cells and their factors, therefore, is that they must show the appropriate MHC restriction. There are, in fact, several antigen-specific, idiotype-bearing T-cell factors; J. Kapp and her collaborators (Jewish Hospital of St Louis) have recently purified a 25,000-MW suppressor factor specific for GAT and bearing a mouse MHC I-J haplotype, that is particularly interesting because it acts in sub-nanogram quantities *in vivo.*

One of the questions constantly raised about T-cell factors in particular and anti-idiotypic regulation in general is whether they have any physiological relevance. Even the original Eichmann–Rajewsky experiments[2] are open to criticism on the grounds that they were done with xenogeneic anti-idiotype antisera. In their most recent experiments, Rajewsky and his colleagues used nanogram quantities of syngeneic anti-idiotypic antibodies to

---

enhance or suppress — depending on timing of administration and dosage of antibody — the responses of mice to hydroxynitrophenol (NP)[4]. Their very latest achievement is to have enhanced the idiotype-positive component of an antibody response to NP by injection of 10 μg of idiotype-bearing antibodies in advance of immunization with NP.

The major histocompatibility complex

If the T-cell receptor remains elusive, the MHC is about to yield up its mysteries to the inexorable advance of the DNA-cloning army. So far, however, the process has only just started, the sequencing has barely begun, and the data largely confirm the existing biochemistry — though there may be some surprises for the geneticists.

MHC antigens, known as HLA antigens in man and H-2 in mouse, are composed of two chains, the smaller of which, β_2 microglobulin, is relatively invariant. The structure of the protein chain shows considerable homology to the constant region of immunoglobulin, but a preliminary analysis of the human genomic DNA (J. Parnes, US National Institutes of Health) suggests that the distribution of introns may be more like that of the variable region.

The larger, α chain, which is highly polymorphic, has only more recently been recognized as having structural similarities to immunoglobulin[5]. Comparing amino acid sequences, J. Strominger (Harvard University) finds 35 per cent homology between the third domain of the α chain of HLA-A and the fourth domain of the immunoglobulin constant region. L. Hood (California Institute of Technology), who has used an HLA probe to identify the H-2 genes, has sequenced the cDNA coding for the third α domain and finds 50 per cent homology with the DNA encoding the fourth constant-region domain of mouse IgM. Moreover, he infers from analysis of the 'wobble' positions of the codons, which have 45 per cent homology instead of the 25 per cent that would be expected by chance, that the homology is due to divergent rather than convergent evolution.

The most startling news came from the California Institute of Technology where, according to E. Moore, densitometric analysis of genomic bands from the H-2 complex of the mouse suggest there may be 15 or so related genes[6] rather than the four or five predicted by the genetics. Similar data have since been reported by Cami *et al.*[7], and probably signify the existence of a multi-gene family possibly encoding lymphocyte differentiation antigens.

This raises the question, posed by L. Hood (California Institute of Technology), of how to identify the members of a multi-gene family without knowing what proteins they encode — a problem to which J. Sim (Columbia University) supplied the solution, at least for membrane proteins. She described a system for using cloned DNA to transform fibroblasts and for assaying the fibroblasts for new surface antigens with cytotoxic lymphocytes, or with antibodies — a technique she and her colleagues have used to identify a genomic clone containing an HLA antigen-encoding sequence.

Nothing in immunology is beyond the wit of man (or woman). T-cell receptor next. □

Blood lead concentrations reconsidered

from Philippe Grandjean

Two recent studies of blood lead concentrations have provided evidence that, compared with the usual average of 10–20 μg dl^{-1} found in Western Europe and North America, levels in remote societies are much lower. Poole and colleagues[1] found a mean blood lead concentration of 5 μg dl^{-1} in 100 children from an unpolluted area in Papua New Guinea and Piomelli and coworkers[2] established an average blood level of about 3 μg dl^{-1} in 103 Nepalese children and adults from the foothills of the Himalayas. The two investigations were carefully performed in order to avoid the contamination that has marred many lead assays in the past[3]. The results are supported by an earlier study of Venezuelan Indians[4] which also indicated low blood lead concentration — below 1 μg dl^{-1} — although the analytical techniques were perhaps subject to some doubt.

Atmospheric lead pollution spreads throughout the world so even population groups living in remote areas may be exposed to lead levels which are higher than natural, pre-industrial levels. One way in which natural levels can be assessed is by the analysis of prehistoric skeletal remains. Such samples, if uncontaminated, can be used to give accurate estimates, since lead accumulates in calcified tissues. Determination of lead in temporal bones and secondary dentine found in the sands of the Sahara has enabled lead levels in Sudanese Nubia to be assessed for the period from BC 3300 to AD 750 (ref.5). The results show that about 5,000 years ago, lead exposure at the Nile banks in Nubia was about one per cent of current exposures in Western Europe and North America. Later, during the Egyptian occupation and with the introduction of metallurgical techniques, tissue lead levels in Nubia increased considerably.

Further evidence comes from Ericson *et al.*[6] who examined calcified tissues of a small number of Peruvian mummies. Using sophisticated analyses, they estimated that present-day lead exposures may have increased by about 500-fold above pre-metallurgical levels in Peru.

A report from the US National Academy of Sciences (NAS)[7] also carefully evaluates the natural occurrence of lead in the environment. Without doubt, lead was never uniformly distributed in the biosphere, and even in pre-industrial times a range of natural exposures would be expected. The NAS committee concludes that current exposure levels in industrialized countries are about 10- to 1,000-fold above natural concentrations.

What is the significance of these figures for human health? Unfortunately, no clear answer is available. Although current background lead levels appear well above those which early man experienced, there is no definite evidence for the threshold at which lead begins to have a toxic effect. Most studies have examined effects at, say, concentrations of lead 1,000–10,000 times the natural level and compared them to a control group with a lead burden 100-fold greater than that. However, toxic effects of lead are now being found at increasingly low levels and the most recent evidence[8] suggests that they may be close to, or perhaps even below, current background levels.

Until proper studies of low-level lead toxicity, incorporating 'unpolluted' control groups, can be conducted, the recommendation of the NAS committee that "a serious effort should be made to reduce the baseline level of exposure to lead for general population of the United States" should be carefully considered in every industrialized country. □

Continental crust compromise

Pure Chemistry Library
SCIENCE COLLEGE
92, Upper Circular Road
CALCUTTA

from Keith Bell

THE evolution of the continental crust has been a subject of hot debate. Numerous models have been proposed (see, for example, refs 1–4), but most can be roughly placed into one of two groups. Proponents of the first group believe that most continental crust formed fairly early in Earth history, perhaps within the first 500 Myr or so, and that its subsequent reworking gave rise to a variety of granitic products. The alternative proposal argues for a more gradual evolution with additions to the crust being made at intervals throughout its history, either from island arcs at an accreting margin ('lateral accretion') or directly from below ('vertical accretion'). Implicit in some of these models is either an upper mantle that changed continuously or one that had its major differentiation shortly after the formation of the Earth. Also raised in this whole discussion is the origin of granites: are they extracted directly from the mantle? Do they simply represent reworked, older continental crust or are they produced by the mixing of both mantle and crustal components? Recent Sm–Nd work by DePaolo, reported on p.193 of this issue of *Nature*, answers at least some of these questions.

Gast's classic paper[5] was followed by further attempts to place constraints on the evolution of the crust–mantle system by isotopic means. One obvious approach was to use initial ^{87}Sr/^{86}Sr ratios but this produced surprising results: a large proportion of granitoid rocks were shown to have fairly low and variable initial ^{87}Sr/^{86}Sr ratios (<0.706) — a feature which, in its simplest interpretation, favoured a direct mantle origin. Low initial Sr ratios are, however, open to several interpretations including derivation of granites from a source with a similar, low Rb/Sr ratio to that of the mantle (lower crust ?); the mixing of continental material with 'primitive' Sr contained either in the mantle, lower crust or within a fluid phase; or derivation from a terrane that somehow had been swept clean of radiogenic Sr (granulite terranes ?). Isotopic data from one radiometric system were obviously inadequate to resolve many of the problems of crustal genesis, but the use of initial ^{87}Sr/^{86}Sr ratios in conjunction with common Pb data still hinted at a direct mantle origin for most granites[6].

A new and powerful tool for evaluating the evolution of the upper mantle and the origin of the crust has now been provided by the Sm–Nd method[7]. Because of the somewhat lengthy half life of ^{147}Sm (1.06×10^{11}yr), the ratio ^{143}Nd/^{144}Nd is usually measured as a fractional difference in parts per 10^4 relative to a reference chondritic reservoir ($\varepsilon_{\mathrm{Nd}}$). The systematics of Sm–Nd are very similar to those of the Rb–Sr system but because Sm and Nd are both rare earths, and hence have very similar chemical properties, both parent and daughter nuclides are considered difficult to separate one from another. Current findings suggest that they are not separated by remelting, metamorphism or sedimentary processes[8]. The early realization that the source of most magmas had a Sm–Nd ratio similar to that of chondritic meteorites suggested that the bulk earth had a chondritic composition, a feature supported by other geochemical and geophysical information[9]. As more measurements became available, small but significant differences from the bulk-earth development line were found, particularly the data from ocean-ridge basalts[10,11], which helped substantiate the steadily accumulating evidence for a chemically heterogeneous upper mantle. One extremely useful earth model attempts to integrate the isotopic results with what is known about the spatial distribution and volumetric relationships of large-scale basaltic magmatism[12]. Although Sm–Nd studies of granitoid rocks are few, the available data support the earlier interpretations of Sr and Pb isotope results from Archaean continental crust. A broad twofold division for all granitoid rocks into those of direct mantle origin and those derived from admixtures of mantle and crustal material is suggested by the isotopic data[13]. Both groups, however, seem to be temporally quite distinct. Granites younger than about 2,000 Myr contain some recycled crustal component, those older are considered primary and of direct mantle origin.

The paper by DePaolo concerns the continental evolution of part of the Proterozoic crust of the southwestern United States and bears, in greater detail, on some of these problems. DePaolo concludes from the Sm–Nd isotopic data that an early event in the Front Range of Colorado at about 1,800 Myr involved the formation of a large segment of continental crust that was derived directly from the mantle, while magmatism during the next 800 Myr, at 1,670, 1,400 and 1,000 Myr ago, involved the formation of granitic bodies from this new crustal segment. (It is interesting to note the very good agreement between the Sm–Nd and Rb–Sr isochron ages.) This story of early mantle material coupled with later crustal involvement agrees rather nicely with the picture emerging from initial ^{87}Sr/^{86}Sr ratios from granitoid plutons found in some orogenic belts of much younger age (such as the Canadian section of the Appalachian orogen[14]). A plot of initial ^{87}Sr/^{86}Sr ratios versus age shows that the older granitoid bodies have relatively low, mantle-like, initial ^{87}Sr/^{86}Sr ratios, while the younger plutons have initial ^{87}Sr/^{86}Sr ratios that are considerably higher (>0.710). The later plutons commonly occur as small, discrete bodies, are commonly peralkaline and sometimes are associated with fluorine, tin and uranium. The overall impression is that mantle-derived material was added to the crust fairly early in the orogenic cycle and that this was followed by substantially smaller amounts of material of quite different geochemical character, which became involved with, or was directly formed from, continental crust.

Of equal interest is the source of the 1,800 Myr material from the southwestern United States because it is relevant to the evolution of the mantle, in addition to placing further constraints on the use of Sm–Nd model ages. The isotopic signature of the older material, quite different from that expected of rocks derived from a chondritic-like source, suggests a depleted upper mantle with a higher Sm–Nd ratio than that of assumed undifferentiated material.

Previous ages from composites of North American continental crust tended to agree with the known geological and geochemical constraints. DePaolo argues, however, that these dates require revision: by using the Sm–Nd data from his depleted upper mantle, he brings them more into line with the known crystallization ages. Although the earlier model ages tend to be underestimated, those from Archaean composites hardly change.

Many problems raised by DePaolo's work are outside the scope of his present paper, which primarily concentrates on the Sm–Nd systematics of the Proterozoic material. One of the more intriguing, however, involves the nature of the early depletion, partly because it brings into focus the meaning of the term 'depleted mantle' and partly because it questions the role taken by this part of the mantle in later crustal generation. Geochemical variations in the mantle can be attributed to a variety of processes including melt extraction, mixing of different mantle zones or metasomatism. The implied widespread nature of DePaolo's depleted mantle suggests that it was formed by an event of planetary proportions. Whatever the nature of the early event (core ? crust ? formation) it seems to have resulted in a mantle with a higher Sm/Nd ratio than chondrites, which later either generated continental crust directly or became intimately involved with the continental

0028-0836/81/210189-02$01.00

crust during its formation. DePaolo's recalculation of crustal-separation model ages certainly implies that large segments of continental crust were derived from a depleted mantle. The question that begs to be asked is 'What are the geochemical implications of an isotopically depleted upper mantle?'. Recent findings, for example, have shown that although initial ^{143}Nd/^{144}Nd ratios from mantle xenoliths in alkalic basalts are variable (with some isotopic ratios indicating a depleted upper mantle), certain major elements, such as CaO and Al_2O_3, are still present in sufficient amounts to generate basaltic liquids[15]. But what of typical continental crust? Can it be derived from a mantle that on the basis of the Sm–Nd data seems to be depleted? A great deal may ultimately depend on the melt volumes extracted from the mantle, spreading rates and the composition of the melts, but the question still remains as to the number of times the same part of the mantle can provide or seemingly provide 'crustal components'.

DePaolo's paper also brings out the feature, already observed from Sr isotopic data, of little or no correlation between initial isotopic composition and rock type. Data from large crustal segments, island-arc volcanics and even ocean-ridge basalts all seem to lie on or close to the depleted, Sm–Nd, mantle development line. This may suggest that most of the chemical characteristics of the various rock types were probably acquired at or close to the time of their formation. In a melting model the chemical composition of the magma would be partly controlled by the minerals present in the mantle and the partitioning of the elements between the liquid and solid phases.

Perhaps additional clues about the evolution of the continental crust can be found elsewhere. In several cases open-system behaviour in the mantle, involving volatiles and CO_2-rich fluids, has been invoked to explain some of the rare earth abundances and isotopic data[16-18]. Several papers have proposed metasomatism in the mantle and terms like 'anomalous mantle' and 'metasomatized mantle' are creeping into the literature. The idea of relating mantle metasomatism to the evolution of the continental crust may seem remote, but the mere facts that it could be considered consistent with some of the isotopic findings and that many granites, such as leucogranites and megacrystic granites, are commonly associated with deep-seated fractures suggest that mantle metasomatism in this context should not be summarily dismissed.

What sort of mantle processes affected which parent–daughter ratios, and the timing of such events, are among the thorny problems that will have to be sorted out. Even in some of the more fertile parts of the mantle, such as those from which kimberlites are derived, the U–Pb and Rb–Sr ratios are quite different from those of chondrites, suggesting that this part of the mantle may have been affected by a process that left the chondritic Sm–Nd ratio unchanged[19]. Much, of course, depends on the nature of the starting material, when it was formed, and the distribution of the chemical heterogeneities within the upper mantle. In spite of these problems there is some indication that the concentrations of primary juvenile gases and their isotopic compositions in mantle-derived materials will help in their resolution. Such information, coupled with the isotopic data from more than one system, may provide further exciting results relevant to the study of the mantle–crust system. □

Clustering of ion channels at the node of Ranvier

from L.C. Fritz and J.P. Brockes

THE segregation or clustering of surface components into discrete and functionally significant domains is an important feature of neuronal cell biology. Obvious examples are the structure of the synapse with its postsynaptic configuration containing a high density of transmitter receptors, and the segregation of various other components to dendrites, cell bodies, axons, or even local domains within these three areas. Axonal calcium channels, for instance, are largely confined to the region of the nerve terminal where they mediate transmitter release. Two systems being used to investigate the mechanisms underlying these processes of segregation are the neuromuscular junction, where acetylcholine receptors are clustered on the postsynaptic muscle fibre, and the node of Ranvier in myelinated axons of the peripheral nervous system. The node is the unensheathed area of axon membrane that lies between two successive myelin segments laid down by Schwann cells. Recent evidence suggests that the nodal membrane contains a high density of certain molecules which mediate electrical excitability and that these molecules are not detectable in the internodal membrane of the myelinated axon.

The passage of the nerve impulse depends on the presence of voltage-sensitive sodium and potassium channels, and it has long been recognized that the nodes are the sites of large inward sodium currents that mediate the saltatory conduction of the action potential[1]. More recently, Ritchie and Rogart[2] have examined the distribution of sodium channels in myelinated frog axons by comparing the equilibrium level of binding of the specific ligand tritiated saxitoxin in intact and homogenized axons. Anatomical considerations strongly suggest that the internodal axolemma should not be accessible to ligand in the intact nerve and yet the specific binding did not increase after homogenization. The authors concluded that the sodium channels are present at high density (approximately 10,000 per μm^2 assuming one toxin molecule binds to one channel) in nodes and not detectable (<25 per μm^2) in internodes. Measurements of channel gating currents have also indicated a high density at the node[3].

The localization of potassium channels is uncertain. Using voltage-clamp techniques, Chiu and Ritchie[4] have observed that significant outward current, which is blocked by tetraethylammonium ion, can be measured only after osmotic shock or collagenase digestion which presumably loosens the association of the myelin sheath with the axon. This suggests an internodal or paranodal localization of the potassium channels. In contrast, Binah and Palti[5] have claimed to detect significant potassium currents at the normal node when particular attention is paid to the holding voltage. This important issue clearly requires further investigation.

There have been several reports of morphological correlates of nodal specialization. In freeze-fracture studies, the nodal membrane has been observed to

contain a high concentration of large intramembranous particles when compared with the internodal axolemma[6]. Furthermore, Waxman and his colleagues have shown that excitable nodes are specifically stained on the cytoplasmic surface of the membrane by a ferric ion ferrocyanide reagent (FeFCN)[7]. The suggestion that the particle distributions and staining properties of nodes indicate the presence of a high density of sodium channels has not yet been confirmed; these characteristics could relate directly to the channels or to other cytochemical features of excitable nodes.

One particularly interesting question is what role, if any, does neurone–Schwann cell interaction have in the formation of the nodal distribution of sodium channels[8]? The evidence is not decisive, but there are already some intriguing observations. Particle patches observed in freeze fracture, as well as deposition of the FeFCN stain, can be seen in developing axons before the elaboration of the myelin sheath[9,10]; the patches have also been seen in amyelinated regions of the spinal roots in the dystrophic mouse mutant[11,12]. These observations might suggest that these specializations exist in the axonal membrane before interaction with the Schwann cell. However, the Schwann cells were certainly in contact with axons in the developmental studies even if myelin had not yet been produced. On the other hand, the FeFCN stain has not been observed in amyelinated dystrophic axons[13], and it can be observed over long lengths of demyelinated axons[14]. These results might suggest that continuing axon–glial interaction is required for both the generation and maintenance of normal nodal specialization.

Nodal specialization and, in particular, the control of sodium channel clustering are not only interesting but have clinical significance in the recovery of conduction after demyelinating disease, a subject which we have not considered here. Further progress will probably be made with the development of specific cytochemical markers for sodium channels, and the exploitation of defined *in vitro* systems for resolving the nature of neurone–glial interaction. ☐

A new magnetic reconnection experiment in the laboratory

from Stanley W.H. Cowley

GREAT importance is attached to the magnetic reconnection process in plasma physics. To appreciate why this is so, it is necessary to consider the consequences of a common assumption made in theoretical plasma work, that of perfect electrical conductivity. In a medium with zero resistivity magnetic fields behave in a special way: the magnetic field lines can be considered as being 'frozen' into the medium and can be pictured as being convected along by the fluid motion. Thus, for example, the outer atmosphere of the Sun, which expands outwards at speeds ~ 400 km s^{-1}, also carries the solar magnetic field into the Solar System because this 'solar wind' gas is a highly conducting fully ionized hydrogen plasma.

An important consequence of the perfect conductivity approximation is that plasmas and fields from separate sources can never mix. When two such plasmas and their embedded fields meet, a thin boundary layer is formed between them which carries the current required by the field jump. No field lines can link across the boundary. However, if finite resistance of the plasma is taken into account, no matter how small, 'reconnection' of the field can occur. This process is sketched in Fig. *A*, where the dotted region represents the current sheet-separated plasma regions '1' and '2' with antiparallel fields, and the solid arrows give the direction of the plasma flow. The oppositely directed fields move towards each other and 'join' at the centre of the x where the magnetic field strength is zero. The 'reconnected' lines which now link the boundary are then carried away in regions '3' and '4'. Finite plasma resistivity at the field null is required to accomplish this process, allowing the field lines to diffuse through the plasma in this region. Reconnection can therefore only occur when the perfect conductivity approximation is relaxed, although the approximation may be very good elsewhere in the flow, away from the null. Strict antiparallelism of fields '1' and '2' is by no means necessary — fields transverse to the page may be added to the figure and reconnection may still occur under very general conditions.

Reconnection is important for two main reasons. First, it changes the topology of the magnetic field and creates direct flux linkages between separated regions, along which plasmas can mix rapidly. Second, energy is liberated from the magnetic field to the plasma in the process, as indicated by the contraction of the field lines in the flow in Fig. *A*. As a consequence, the plasma in regions '3' and '4' will in general exit as a hot jet. Both aspects are of vital impor-

tance, for example, in the Earth's magnetosphere, where reconnection between the Earth's field and the solar wind field results in the magnetic field in the Earth's polar regions being permanently connected to the Sun. On the Sun itself explosive reconnection is believed to be responsible for solar flares, while in the laboratory an apparently similar process occurs in Tokamak 'fusion' machines and results in a disruptive instability in the plasma.

Despite considerable research, the detailed characteristics of the reconnection process have remained elusive. The problem is theoretically difficult because of the requirement to treat the region surrounding the field null, where the approximations usually used in plasma physics are invalid. This is being overcome by computer simulations, but these are, as yet, relatively crude. On the experimental front, extremely detailed plasma and field observations have been obtained from spacecraft in the Earth's magnetosphere, and although ample evidence for an 'open' magnetosphere and particle acceleration has been obtained, it has proved very difficult to pin down the details of the large-scale and temporally varying reconnection processes from single-satellite data. A final approach is to model reconnection in laboratory plasma devices. This has the advantage of repeatability and parameter control, but the detailed diagnosis of the transient plasmas whch are produced has been difficult.

Recently, the first results of a new laboratory reconnection experiment have been published (Stenzel and Gekelman *J. geophys. Res.* **86**; 649, 1981; *J. geophys. Res.* **86**; 569, 1981; Wild *et al. Phys. Rev. Lett.* **46**; 339, 1981) in which the system is sufficiently reproducible and the plasma sufficiently accessible to small internal probes that very detailed diagnostics and analysis have become possible. The experimental arrangement is shown in Fig. *B*. A steady and highly spatially uniform argon plasma is first created inside a cylindrical vessel, which is 2 m long and 1.5 m in diameter, by a pulsed hot-cathode discharge. The plasma density is ~ 10^{18} particles m^{-3}, with electron and ion temperatures of 5 and 0.5 eV respectively, and it is confined radially by a 2×10^{-3} T (20 G) axial magnetic field produced by external coils. A large current is then passed down two internal parallel aluminium plates, returning along the metal wall of the vessel, by discharging a capacitor bank. The current profile so produced resembles that of a highly damped LC circuit; it reaches a peak of $\lesssim$ 25 kA after ~ 50 μs, after which it decays and, in fact, reverses after ~ 200 μs. At any given time the magnetic field which would be produced in the absence of plasma is indicated in Fig. *B*. Typically, the field strength is ~ 10^{-2} T (~ 100 G), but is much weaker between the plates, where an x-type null occurs.

During each experiment or 'shot', field and plasma measurements are obtained at fixed positions and are recorded digitally. For each probe position up to ten shots are recorded and averaged on-line to smooth out fluctuations. The probes are then moved to new positions and the process repeated, about 300 points being so recorded in each of several transverse planes between the plates. The highly detailed data thus obtained are later analysed on a main-frame computer.

The overall behaviour of the system during the experiment is expected to depend primarily on the conductivity of the plasma, which determines the time required for the imposed magnetic field to diffuse into it. If the latter time is long compared with the characteristic time of the experiment (~ 100 μs), the plasma will behave as a perfect conductor, the field will not substantially penetrate the plasma and no reconnection will occur. Instead the plasma should be squashed down into a small volume at the centre of the chamber, leaving a vacuum around the metal conductors containing the applied field, since the energy density of the latter exceeds the initial plasma pressure by a large factor. Alternatively, if the diffusion time is short compared with the characteristic experiment time, diffusion will be dominant and the field should not differ radically from that occurring in the absence of plasma. If the expected plasma conductivity is calculated from the 'classical' formulae based on particle scattering due to particle–particle collisions, then the diffusion time turns out to be ~ 500 μs. This time is fairly long compared with the experiment time, so we expect the perfect conductivity picture to be valid, at least initially. This turns out not to be the case; instead the applied magnetic field rapidly diffuses into the plasma and reconnects across the central field null which is established. However, the field does indeed differ substantially from the vacuum field as a result of the plasma currents. Near the null, in fact, the field does not resemble an x as illustrated in Fig. *A* but instead flattens into a magnetic neutral sheet as shown in Fig. *C*. The electron current layer separating the fields is found to be ~ 10 cm wide, although narrower, ~ 1 cm structures have been observed. Such field structures remain stable for ~ 80 μs, evolving in time in response to the changing applied current. During (and due to) the decay phase of the current, however, the sheet tears up to form a magnetic island, although neutral sheet conditions are resumed after the current has been reversed in sense (at 200 μs) and starts to increase again.

Such behaviour indicates that the plasma conductivity is much lower than expected, although not so low that diffusion is totally dominant. This conclusion is confirmed in detail by the experiment diagnostics, which allow a direct measurement of the conductivity to be made, simply by dividing the measured current density by the measured electric field. It is found that the real resistivity, although highly inhomogeneous, is on average 26 times the classical value. This reduces the diffusion time to a few tens of microseconds, comparable with the time scale of variation of the applied field.

The process resulting in this 'anomolous' resistivity has yet to be identified and is the subject of continuing experiments. The enhanced electron scattering may be due to large electric field fluctuations in the gas caused by an instability associated with the plasma current. The authors point out that significant, about 20 per cent, electron density fluctuations are observed, and that the known conditions for the excitation of ion-sound turbulence are satisfied in the plasma. However, they also note that the observed resistivity does not necessarily maximize in the regions of maximum current as might have been expected, and this requires explanation.

The final result of importance concerns the electric field and the energy deposited in the plasma by the reconnection process. The total electric field is the sum of induced and potential contributions, the first arising from Faraday's law of induction and being proportional to rate of change of the magnetic field (from which it is calculated), while the second contribution is produced by slight separations of electric charge in the plasma and is measured by Langmuir probes. In this experiment, the latter very nearly cancels the former. The variation of the applied field in the reconnection experiment induces an axial electric field of ~ 100 V m^{-1}. The oppositely directed potential field, however, is found to reduce the total field to ~ 10 V m^{-1} throughout the plasma, a value which is, in fact, close to the estimate obtained with Alfvén's (1968) simple neutral sheet model. This experimental result may be of significance in magnetospheric physics, where the role of induced electric fields in particle acceleration has recently been discussed. It also resolves an apparent discrepancy of earlier experiments concerning the energy deposited in the plasma from the field. The rate at which energy is released from the field to the plasma per unit volume is simply given by the product of the current density and the total electric field. If only the induced electric field is considered, as in previous work of this nature, then the energy input estimate will be about a factor of 10 too large due to the partial cancellation effect. In this experiment the energy actually goes largely into electron heating rather than into plasma bulk flows. As a result the electron temperature rises from an initial ~ 5 eV to ~ 15 eV, the peak heating rates and temperature increases occurring at the edges of the neutral sheet rather than at its centre. Electron temperature increases are, in fact, limited to ~ 15 eV by extensive ionization of residual neutral atoms in the vessel during the early phases of the experiment ($\lesssim$ 30 μs), and by the excitation of line radiation at later times. □

Neodymium isotopes in the Colorado Front Range and crust–mantle evolution in the Proterozoic

Donald J. DePaolo
Department of Earth and Space Sciences, University of California, Los Angeles, California 90024, USA

Initial $^{143}Nd/^{144}Nd$ determined for major rock types of the basement underlying the Rocky Mountains in Colorado indicate that this segment of continental crust was formed from a homogeneous and previously depleted source material in the upper mantle 1,800 Myr ago and contains no identifiable component of older crust. Subsequent magmatic events at 1,670, 1,400 and 1,000 Myr represent mainly intracrustal differentiation with small or no further additions to the crust from the mantle. These results imply that a major increase in the mass of the North American continent occurred over a narrow time interval 1,800 Myr ago. From the isotopic data an empirical model is constructed that may provide accurate crust-formation ages for rocks of all ages. Preliminary results suggest that existing estimates of crustal age distributions may require substantial revision.

UNDERSTANDING how the processes that have shaped and modified the Earth have changed through time is closely tied to the determination of the ages of rocks using radioactive isotopes. The Sm–Nd isotopic method[1–3] is particularly valuable. Because Sm and Nd have slightly different chemical properties, and because they are relatively immobile during low grade metamorphism, the radioactive decay of ^{147}Sm to ^{143}Nd, and the consequent increases in the ratio $^{143}Nd/^{144}Nd$, are reliable indications of when rock material that is now found in the Earth's crust was originally formed by the processes which create crust from the denser, more primitive materials of the mantle[4,5]. This information, which can be described as the 'crust-formation age' of a rock unit, as opposed to a crystallization age or an age of metamorphism, is crucial for determining if and how the size of the continents has changed through time.

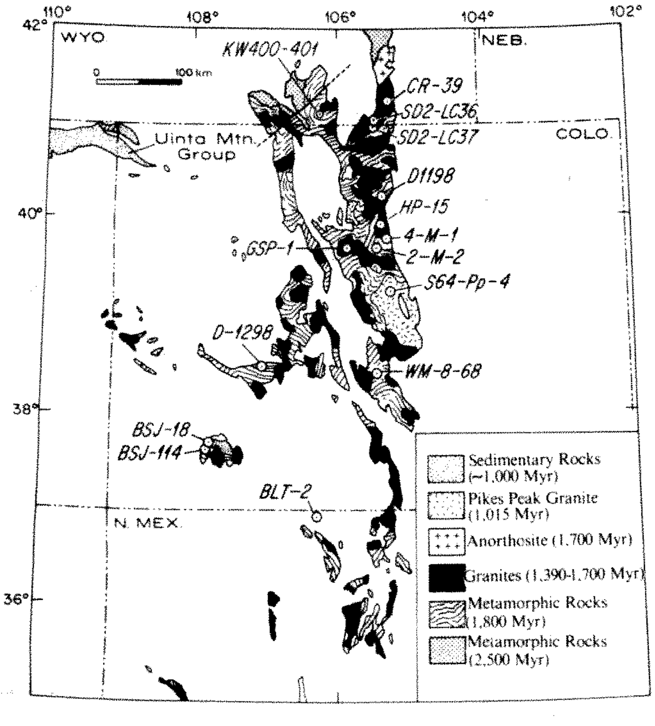

Fig. 1 Generalized basement geological map of the Southern Rocky Mountains, Colorado and New Mexico, USA, showing sample locations (adapted from ref. 11).

The definition of the Sm–Nd crust-formation age has been based on studies mainly of very old crustal rocks (≥2,500 Myr)[2,4–6]. Studies of young rocks have suggested that the model may have serious limitations for younger crust[7], but data on intermediate-aged rocks have been lacking so that the understanding of the apparent discrepancy between the oldest crust and the youngest crust has been poor. In this study, Sm–Nd isotopic measurements have been made on a previously well-characterized Precambrian basement terrain in the Front Range of Colorado[8–10], which has been dated to be 1,000–1,800 Myr old, the intermediate age range where data are lacking. This study was done to test the potential of Sm–Nd crust formation ages as well as to characterize the evolution of this continental province.

Exposures of Proterozoic Precambrian basement are extensive in Colorado in block faulted mountain ranges where Palaeozoic, Cretaceous and Tertiary uplift have exhumed the basement from beneath the Phanerozoic sediment cover (Fig. 1)[11]. The oldest rocks are gneisses which represent metamorphosed sedimentary and volcanic rocks, known as the Idaho Springs Formation[8,10]. Recent work has shown that metavolcanic rocks predominate in the northern and southern thirds of the state, whereas metapelitic rocks predominate in the central portion (ref. 12 and C. E. Hedge, personal communication). Depths of erosion have been estimated at 10–20 km; most of the rocks record an upper amphibolite facies metamorphism[13]. Three major intrusive episodes have been identified[8]. The oldest, the Boulder Creek intrusives, were associated with the regional metamorphism. They average granodiorite in composition; Rb–Sr whole rock dating has fixed the age at ~1,670 Myr. A second intrusive event at 1,400 Myr produced abundant granite with no associated regional metamorphism. The granites are of two-mica type (Silver Plume granite) in the regions where metapelites predominate in the Idaho Springs Formation, and are biotite granites (Sherman–Eolus type) in the regions dominated by metavolcanic rocks (C. E. Hedge, personal communication). The last major Precambrian intrusive event is represented by the Pikes Peak granite (1,015 Myr) which is limited to an outcrop area of ~3,400 km² at latitude 39 °N (Fig. 1). The Proterozoic terrain is bordered on the north by Archaean crust[14] and on the south by younger Proterozoic crust[15]. The contact with the Archaean terrain is a shear zone over most of its exposed length which marks a profound lithological discontinuity as well as an age province boundary[16]. The Colorado age province extends south-westwards to south-eastern California. It has been separated into two subprovinces

0028–0836/81/210193—04$01.00

of slightly different age on the basis of extensive U–Pb zircon dating[17,18]. The samples measured in this study are from the northern, slightly older subprovince.

Samples

Sample locations are shown in Fig. 1. All of the samples have been previously measured for Rb–Sr (and in some cases U–Pb) isotopes, and are currently being studied for major and trace element characteristics (ref. 8 and C. E. Hedge, personal communication). The 1,800 Myr metamorphic rocks include two samples of metavolcanic rocks from the Idaho Springs Formation in northern central Colorado and two from the time-correlative Twilight Gneiss in the San Juan Mountains ~300 km to the south-east (Table 1)[9]. Also included in the 1,800 Myr suite are two xenoliths of charnokitic granulite brought to the surface in a kimberlite diatreme near the Colorado–Wyoming border. Four samples of Boulder Creek-type intrusives have been measured, representing a range of chemical types (note Nd concentrations), and widely separated localities. The three samples of Silver Plume granite show strikingly different trace element chemistry (note Sm and Nd), which bracket the range of types found. One sample of typical Pikes Peak granite has been measured. This batholith includes a range of rock types from gabbro to granite, with granite greatly predominant[19]. One sample of the Sherman-type granite, from the type locality, has also been measured.

Analytical procedures

The procedures used for Sm and Nd isotopic measurements and the analytical uncertainties have been discussed elsewhere[20,21]. For this study the precision and accuracy of the determinations of the $^{147}Sm/^{144}Nd$ ratio are particularly important. Tracer solutions of ^{150}Nd and ^{147}Sm were calibrated using two ultrapure pieces of Sm and Nd metal (Ames Laboratory, Iowa) as gravimetric standards. Calculated concentrations for the tracers calibrated against these two standards agreed to ±0.05% for ^{147}Sm and to ±0.2% for ^{150}Nd. Relative to each other the $^{147}Sm/^{144}Nd$ ratios of the samples are precise to $\pm \leqslant 0.1\%$, but a systematic error of up to 0.25% could affect all samples. The effect on the calculated initial $^{143}Nd/^{144}Nd$ ratios measured have been normalized to be consistent with data previously reported from Caltech normalized to $^{150}Nd/^{142}Nd = 0.2096$ (Table 1). Interlaboratory comparison of Nd isotope ratios shows that $^{143}Nd/^{144}Nd$ ratios measured at UCLA should be comparable with those measured at Caltech to within ~0.002%[21], (equivalent to 0.2 ε units as defined below).

The $^{143}Nd/^{144}Nd$ ratio is also expressed here as $\varepsilon_{Nd}(T)$, the deviation from the value expected in a chondritic reservoir (CHUR), and is defined as[2]:

$$\varepsilon_{Nd}(T) = 10^4 \left[\frac{^{143}Nd/^{144}Nd_{rock}(T)}{^{143}Nd/^{144}Nd_{CHUR}(T)} - 1 \right]$$

where T is time measured backward from the present (age) and

$$^{143}Nd/^{144}Nd_{CHUR}(T) = 0.511836 - 0.1967[(\exp \lambda_{Sm} T) - 1]$$

where $\lambda_{Sm} = 6.54 \times 10^{-6}\ Myr^{-1}$ (see ref. 22). For a rock of age T, $\varepsilon_{Nd}(T)$ is the 'initial' value of ε_{Nd}; the value at the time of crystallization of the rock, and $\varepsilon_{Nd}(0)$ is the measured value.

Results

The results are given in Table 1 and Figs 2 and 3. The gneiss samples define an isochron corresponding to an age of 1,800 ± 90 Myr (2σ) (Fig. 2). These rocks are geographically remote from each other and cannot be cogenetic. There is no *a priori* reason why they should define an isochron as variations in initial $^{143}Nd/^{144}Nd$ are likely. The data therefore require that the 1,800 Myr age represents a true magmatic age within the age resolution and that the magma source which produced this crust 1,800 Myr ago was homogeneous over distances of several hundred kilometres. Note that the only types of young volcanic rocks which exhibit comparable Nd isotopic uniformity are oceanic island arc rocks[21]. Arcs located far from continental crust show a small range of ε_{Nd} worldwide (Fig. 3), whereas oceanic volcanics in general exhibit a total range from −2 to +13 (ref. 23). The data of Fig. 2 confirm the resistance of Nd isotopes to gross redistribution in crustal metamorphic processes.

The clustering of the initial ε_{Nd} values of the metamorphic rocks is shown in Fig. 3, where initial values for the plutonic rocks are also plotted. The average ε_{Nd} (1,800 Myr) of +3.7 is a

distinctly mantle-type value. Shown schematically is the typical value of ε_{Nd} (1,800 Myr) expected in the 2,700 Myr crust which borders the Colorado province to the north[24]. The ε_{Nd} values of 1,800 Myr gneisses give no evidence of influence from older crust. The data require that the Colorado crust be derived from the mantle *in toto* 1,800 Myr ago with the crust formation process involving no reconstitution of older crust.

The line $\varepsilon_{Nd}=0$ (Fig. 3) has been interpreted as the Nd isotopic evolution of the bulk Earth, or equivalently, of primitive mantle[4]. The initial ε_{Nd} of the 1,800 Myr samples demonstrates that this crust was not derived from primitive mantle, but from mantle which had previously acquired an elevated Sm/Nd ratio, a characteristic of parts of the mantle that have been depleted in 'crustal components'. The Colorado crust, therefore, seems to have been derived from depleted mantle, presumably part of the mantle that had been involved in producing crust during the Archaean. Based on data from island arcs[25] these conclusions also apply in general to crust being formed from the mantle at present, suggesting that the 'mantle magma source' vector shown in Fig. 3 may be a good approximation to the Nd isotopic evolution of the mantle source of continental crust over the past 2,000 Myr.

In contrast to the gneisses, the Boulder Creek intrusives show a small but distinct range of initial ε_{Nd} values ranging from the inferred mantle value near +3.7 down to +1.3. The Silver Plume and Sherman granite samples have ε_{Nd} values that are still lower, +0.1 to −2.5, and are far displaced from the mantle ε_{Nd} curve (Fig. 3). The Pikes Peak sample also has low ε_{Nd}, although it is not lower than those of the Silver Plume samples.

When all of the data on the intrusives are considered, there is a strong correlation between decreasing initial ε_{Nd} values and increasing time elapsed since the crust-forming event at 1,800 Myr. Furthermore, the ε_{Nd} values fall within or slightly below the approximate average ε_{Nd} evolution zone of the 1,800 Myr gneisses (Fig. 3). These observations strongly suggest that the intrusive events at 1,670, 1,400 and 1,000 Myr involved mainly melting of the 1,800 Myr crust rather than derivation of magmas from the mantle. However, two of the Boulder Creek samples have initial ε_{Nd} values identical to the inferred mantle value. This could indicate the presence of mantle-derived magma at 1,670 Myr, but would also be consistent with some of the Boulder Creek magmas being formed by melting of the high-Sm/Nd tholeiitic-type 1,800 Myr metabasaltic rocks such as samples 2-M-2 and BSJ-114. For the Silver Plume intrusives, the conclusion based on the isotopic data that they are crustally-derived, is perfectly compatible with their peraluminous bulk chemistry, which independently argues for derivation from the crust. The Sherman intrusives have less aluminous compositions, yet the initial ε_{Nd} of the sample measured is identical to the Silver Plume samples. This datum suggests that the Sherman-type granite was also crustally derived; the different bulk chemistry being presumably a reflection of the igneous, rather than sedimentary, character of the crust in northern Colorado.

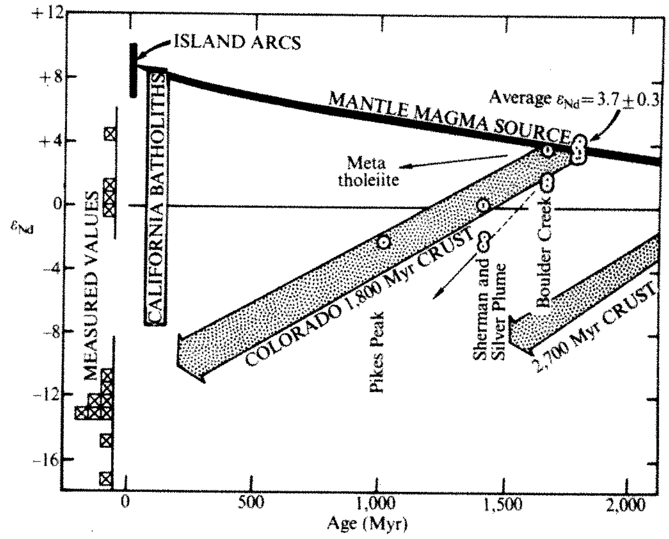

Fig. 3 Measured ε_{Nd} values are shown in histogram format at left (GSP-1 not shown). Large arrows show ε_{Nd} evolution for typical Colorado crust, and typical 2,700 Myr crust. The curve labelled 'mantle magma source' connects the average ε_{Nd} of the 1,800 Myr samples with the average for modern oceanic island arcs. Small arrows give the ε_{Nd} evolution for typical 1,800 Myr metatholeiitic basalt and the Silver Plume sample (GSP-1) with lowest initial ε_{Nd}. The Colorado crust seems to have been derived solely from the mantle at 1,800 Myr in contrast to the Mesozoic batholiths of California, which are mixtures of mantle-derived components and older crust[7].

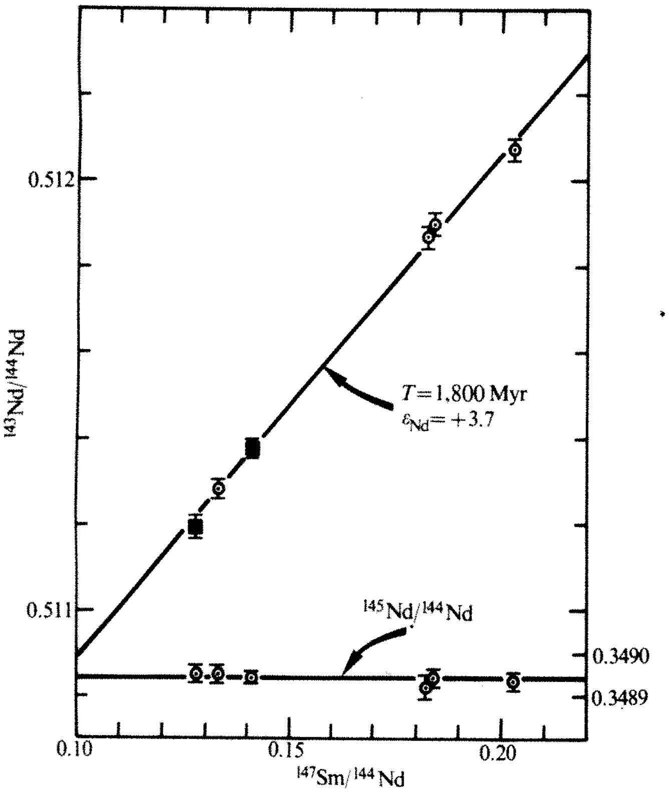

Fig. 2 Sm–Nd isotopic evolution diagram showing data for metamorphic rock samples from the Idaho Springs Formation and the Twilight Gneiss. All six data points lie within experimental uncertainty (95% confidence) of a line whose slope corresponds to an age of 1,800±90 Myr. Also shown are the measured ^{145}Nd/^{144}Nd ratios for the same samples, with the scale shown at the right. This ratio is invariant in natural samples and is measured in this laboratory as an internal check on the measurement techniques for ^{143}Nd/^{144}Nd. The measured values of ^{145}Nd/^{144}Nd for the six samples lie within error limits of the average value of 0.348945 measured for all samples to date. ⊙, Metavolcanic; ■, granulite xenoliths.

The interpretation of the Pikes Peak datum is more equivocal, as the alkalic composition of that intrusion represents a fundamentally different magma type[19]. It is possible that the Pikes Peak parent magma was derived from a mantle reservoir that had ε_{Nd} different from that shown in Fig. 3. However, petrological and other isotopic studies[19,25] indicate that the Pikes Peak granite represents the end product of a complex magmatic history of crystallization and crustal assimilation, beginning with a mantle-derived basaltic magma. This would leave the granite with a distinctly crustal isotopic composition even though the magmatism originated in the mantle. Further data on the more mafic lithologies of the Pikes Peak intrusion will be necessary to determine the Nd isotopic nature of the source of the parent basalt. The problem of mantle-derived magmas which assimilate copious amounts of continental crust has not been dealt with sufficiently and could also be a factor in the ultimate interpretation of the Silver Plume and Boulder Creek samples.

Conclusions

The present data suggest that the continental crust of Colorado was formed by differentiation from the mantle over a relatively narrow time interval at 1,800 ± 100 Myr ago. Subsequently little material was added to the crust from the mantle, with the possible exception of the Pikes Peak event at 1,000 Myr. The production of the Colorado continental crust was apparently not a continuing process, but a fairly sharply defined event. These conclusions, which could apply to the basement of much of the southwestern United States, in conjunction with previous findings[5], suggest a strong episodicity in the evolution of North America with regard to crust-forming events; crystallization and metamorphic ages show that tectonism and magmatism are more likely to be continuous, or at least to occur more frequently than major crust-forming events. The episodicity in crust production is difficult to understand in the context of current models of plate tectonics, which imply continuous crust production. More data are needed especially from other continents as an individual continent may not preserve a representative history of the crust-forming process.

The possibly well-defined evolution of $\varepsilon_{\mathrm{Nd}}$ in a mantle reservoir which has acted as the source of juvenile crust through the past 2,000 Myr has implications for the dating of crust-forming events and for crust–mantle evolution models. It had been suggested[4] that crust was derived from mantle reservoirs with $\varepsilon_{\mathrm{Nd}} = 0$ and this model was used to calculate[5] crust-formation ages, T_{CHUR}. However, as shown here, crust is not formed with $\varepsilon_{\mathrm{Nd}} = 0$ but from depleted mantle with $\varepsilon_{\mathrm{Nd}} > 0$. Hence T_{CHUR} does not give a reliable crust-formation age. Instead, crust-formation ages should be calculated relative to the mantle evolution curve shown in Fig. 3, which can be described by $\varepsilon_{\mathrm{Nd}}(T) = 0.25\ T^2 - 3T + 8.5$, where T is age. As mantle having this $\varepsilon_{\mathrm{Nd}}$ evolution can be assumed to be depleted with respect to so-called incompatible elements, we denote this revised model age T_{DM} (depleted mantle). As an example of the difference, the T_{CHUR} age of the Colorado samples range from 1,200 to 1,550 Myr, averaging about 1,350 Myr, for the samples with relatively low Sm/Nd. T_{DM} ages are 1,600–1,900 Myr, averaging 1,800 Myr. T_{CHUR} ages underestimate the true crustal age. T_{DM} ages for the Colorado rocks are relatively accurate despite crystallization ages that vary by 800 Myr. This confirms that the fractionated Sm/Nd ratios of crustal rocks relative to the mantle date mostly from the time of original crust formation.

When the crust formation ages of ref. 5 are revised to T_{DM}, calculated ages are plausible and consistent with known crystallization ages. For example, the T_{DM} age of a Grenville composite is 1,300 Myr, identical to the T_{DM} age of a granite from the Llano uplift of Texas, which has been interpreted to be part of the same province. T_{DM} of the North American shale composite becomes 1,750 Myr. Archaean ages change little due to offsetting errors related to revision of the CHUR curve[22]. T_{DM} ages provide a self-consistent, empirical model for evaluating the formation times of continental crust. This study and previous published Sm–Nd results suggest that earlier estimates of crustal age distributions based on Rb–Sr and K–Ar data[26] may have erred by underestimating the amount of old crust. More precise estimates should be possible using T_{DM} when more data become available.

The initial value of $\varepsilon_{\mathrm{Nd}}$ for 1,800 Myr crust could be accommodated for a model of a growing continental crust with no crustal recycling or for a model of a constant-mass crust with decreasing crustal recycling rates towards the present[27,28]. In either case it is required that the amount of mantle which interacts with the crust be limited to a small fraction (≤ 0.3) of the total mantle. This result supports a two-layered mantle model[28–30] and suggests that it applies over most of Earth history. The implication is that the basic tectonic–geochemical cycles involving the crust and mantle have not changed from the late Archaean to the present except possibly with respect to rates.

I thank Carl E. Hedge for well-documented samples and Tom Owens for assistance with analysis. This investigation was supported by NSF grant EAR78-12966.

Biological export of shelf carbon is a sink of the global CO_2 cycle

John J. Walsh[*], Gilbert T. Rowe[*], Richard L. Iverson[†] & C. Peter McRoy[‡]

[*] Oceanographic Sciences Division, Brookhaven National Laboratory, Upton, New York 11973, USA
[†] Department of Oceanography, Florida State University, Tallahassee, Florida 32306, USA
[‡] Institute of Marine Sciences, University of Alaska, College, Alaska 99701, USA

Measurements of carbon metabolism, production and exchange along food webs suggest that large fractions of the organic matter produced on continental shelves must be exported to continental slopes. The annual loss of organic matter from continental shelf ecosystems is far greater than in the open ocean. If part of the loss of nearshore primary production has increased in those coastal zones where anthropogenic inorganic nutrient supplies have been consistently increasing since the industrial revolution, then burial and diagenesis of this material in slope depocentres could represent the 'missing BMTs of carbon' in global CO_2 *budgets.*

0028–0836/81/210196—06$01.00

THE fate of anthropogenic CO_2 emissions associated with the industrial revolution is not fully known[1]. We cannot specify either the steady-state annual fluxes of carbon in a global CO_2 budget or the changes among the major reservoirs of CO_2 (atmosphere, land and ocean) over the past century. At a rate of increase in world fuel consumption of 4.3% yr^{-1}, a doubling of the CO_2 content of the atmosphere could lead to a 'greenhouse' effect[2], with a concomitant 2–3 °C increase in the ocean's temperature by 2035, similar to the temperature increase since the last glaciation.

The role of the marine biota as a carbon sink has been thought insignificant in the global CO_2 cycle because of nutrient limitation of carbon fixation in the open ocean[3]. We propose here, however, that a large amount of the CO_2 fixed each year during nutrient-unlimited photosynthesis on the continental shelves is apparently deposited as phytodetrital particles with a C/N weight ratio of ~5/1 on the adjacent continental slope. After return of nitrogen to the water column during early diagenesis, the refractory carbon particles in the sediment, with a C/N weight ratio of ~10/1, represent a major organic sink of the global carbon cycle. Part of the nitrogen source for the original coastal phytodetritus might even be manipulated to influence future CO_2 increases of the atmosphere.

Unbalanced global carbon budgets

Of the 5.2×10^9 tons C yr^{-1} now emitted from consumption of fossil fuel and cement production, about half[4–6] remains in the carbon pool of the atmosphere (Table 1). The equilibrium between the partial pressure of CO_2 in the atmosphere and that of the upper ocean is such that atmospheric CO_2 usually penetrates the upper mixed layer (~75 m) of the sea. During the spring bloom in high latitudes, for example, a primary production rate of only 1–2 g C m^{-2} day^{-1} so far exceeds the atmospheric CO_2 invasion rate that the upper 60 m becomes seasonally depleted of total CO_2 (D. Hood and L. Codispoti, personal communication). The photosynthetic and biogenic $CaCO_3$ sinks in world-wide surface waters causes the average total inorganic carbon concentration to increase with depth to a maximum at ~1,500 m, where a CO_2 source occurs within the O_2 minimum layer[7].

Because of this vertical gradient, it is not clear that a significant fraction of the CO_2 of the upper ocean actually diffuses down across the main thermocline, but surface CO_2 reaches the deeper layers due to bottom water formation at the polar boundaries. The atmospheric CO_2 which penetrates to the deep sea[8], and that formed by dissolution of the carbonate sediments beneath the main lysocline at ~3.7 km is stored as HCO_3^-. In this way ~37% (ref. 3) of the CO_2 emitted from burning fossil fuel, or ~2.0×10^9 tons C yr^{-1}, may be sequestered as HCO_3^-. Such a polar accumulation of CO_2, however, is offset to some unknown degree by outgassing of CO_2 at the air–sea interface in the equatorial regions. Without consideration to any other source terms of CO_2 (Table 1) ~0.65×10^9 tons C yr^{-1} is still 'missing' from such a chemical global budget.

The removal of land biota in undeveloped regions since 1750 may have been a source of CO_2 to the atmosphere. Changing patterns of deforestation mean, however, that the boreal terrestrial ecosystem[9] may now be a sink of CO_2, while the tropical forests[10] may be a recent source. How much terrestrial carbon fluxes to the atmosphere or ocean is debatable[11,12], but recent estimates suggest a present land source of $1\text{–}2\times10^9$ tons C yr^{-1} (Table 2). Part of this carbon loss from land could be stored in the intermediate form of both dissolved organic carbon (DOC) and particulate detrital carbon leached into riverine systems. River systems may release as much as 0.8×10^9 tons DOC yr^{-1} to the shelf while sediment accumulation of terrigenous particulate matter[14] within estuarine systems has been estimated[15] to be 0.2×10^9 tons C yr^{-1}. If the land is a source of CO_2, at least 1.55×10^9 tons C yr^{-1} could be 'missing' in a steady-state global carbon budget (Table 2) that includes fossil fuel and land source terms; atmospheric, DOC, estuarine sediment and deep ocean chemical sinks; but ignores the marine biota as a possible sink.

Table 1 An unbalanced chemical budget of the global CO_2 cycle ($\times10^9$ tons C yr^{-1})

Sources	Fossil fuel emission	5.20
	Equatorial outgassing	?
	Volcanism	0.05
Sinks	Carbonate neutralization	2.00
	Atmospheric storage	2.60
Missing carbon		0.65

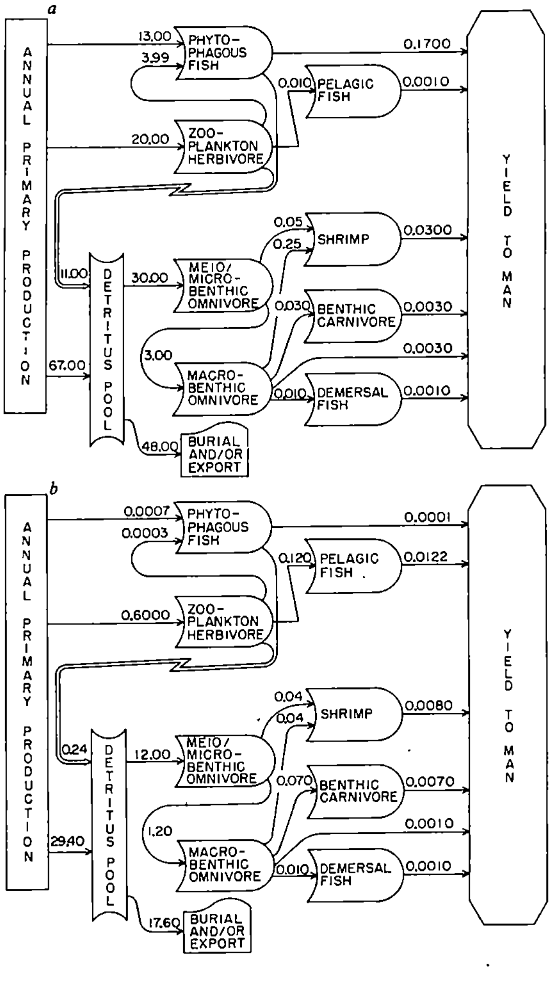

Fig. 1 A carbon budget (g C m^{-2} yr^{-1}) of yield to man derived mainly from riverine input of nitrogen on the: *a*, Louisiana–Texas; and *b*, West Florida shelves of the Gulf of Mexico.

Marine detrital sink

A marine primary production[11,15] of ~26×10^9 tons C yr^{-1} can be partitioned into 20×10^9 tons C yr^{-1} derived from the open ocean (~3×10^8 km^2) and 6×10^9 tons C yr^{-1} from the continental shelves (~3×10^7 km^2). Over 90% of the photosynthetic uptake of CO_2 in the open ocean is grazed within the upper 100 m, however, with most of the phytoplankton carbon and nitrogen recycled by herbivores as CO_2 from respiration and as ammonium from excretion. ^{15}N estimates of the daily nitrogen demand of oceanic primary production suggest[16] that at least 90% is met by the recycled NH_4^+. Those organic detrital particles, which are not grazed and sink out of the euphotic zone (~100 m) of the open ocean, amount to ~2×10^9 tons C yr^{-1} metabolized at depths down to 1,000–2,000 m, where the CO_2 produced is sequestered within the bicarbonate cycle. Heterotrophic metabolism within the O_2 minimum layer poises the diffusion gradient of total CO_2 towards the surface, that is the diffusive flux of CO_2 should be towards the euphotic zone[7]. Because CO_2 returns to the euphotic zone with the 'new' nitrate diffusing upwards to support primary production, the importance of open ocean organic detritus as a net sink for CO_2 is probably small[16]. Of the minute amount (~1% of the open production) of particles that reach 4,000–5,000 m, a fraction of this organic matter with a C/N ratio ≥10 is finally incorporated (Table 2) in bottom sediments of a similar C/N ratio[17].

Phytoplankton populations of the continental shelf, in contrast to those of the open ocean, do not seem to be either nigrogen-limited or grazer-controlled for parts of the year but rather light-limited as evidenced by spatial and temporal outbreaks of algal blooms with C/N ratios ≃5 in coastal waters[14,18,19]. In further contrast to the oligotrophic open ocean, ^{15}N estimates of nitrogen uptake by coastal phytoplankton suggest that at least 50% of the daily nitrogen demand of photosynthesis is met in the form of nitrate off Peru, western Mexico[20], California[21], in the Middle Atlantic Bight[22], in the antarctic[23], and in the south-east Bering Sea[24]. The major sources of nitrate in these systems seem to be river runoff[25] and cross-shelf exchange of subsurface slope water onto the shelf[24,26,27]; the importance of nitrification on the shelf is unknown.

After the decline of the Peruvian anchoveta fishery, removal of fish by man from each shelf amounts to <1% of the annual primary production[28]. Because nitrate supply is considered an estimate of available 'new' production[16,29], because fish yield is not a significant particulate nitrogen loss, and because plankton biomass is not continuously increasing on the continental shelf, ~50% of the 'new' primary production should at times be exported from the shelf water column each year as opposed to the <10% loss derived from 'new' production of the open ocean euphotic zone[16]. Annual carbon budgets for the shelf food web supported by riverine input of nitrogen in the Gulf of Mexico (Fig. 1), from shelf-break input within the Bering Sea (Fig. 2) and the Peru upwelling ecosystem[28], and from the more complex sources of nitrogen in the New York Bight[30], all indicate that 50% of the primary production is apparently not consumed by shelf organisms at 20, 30 or 60° latitudes.

	Carbonate neutralization	2.00
Missing carbon		1.55

A balanced budget of the carbon requirements of the demersal food web on the Scotian shelf[31] was obtained using net production/biomass ratios and transfer efficiencies similar to those above. However, this estimated production, 102 g C m^{-2} yr^{-1}, did not include the spring bloom which amounts to 40–50% of the yearly production within the adjacent Mid-Atlantic Bight. The similarity between the cross-shelf nitrate flux and fish yield of the Nova Scotian and Bering shelves[24] suggests that the annual primary production may be the same. Using an estimate of primary production of at least 200 g C m^{-2} yr^{-1}, we find a budget for the Nova Scotian shelf could not account for 50% of the annual production. Furthermore, a phytoplankton cell, falling to the bottom of the Scotian shelf, might be entrained in the subsurface offshore flow near the shelf-break[32]; sediment chlorophyll content to 800 m on the upper slope is, in fact, 30 times greater than on either the Scotian shelf or the lower slope[31].

Offshore flows of water also occur during upwelling off Peru and on estuarine-type shelves such as the New York Bight and the Bering Sea, suggesting that cross-shelf transport of biogenic particles is a ubiquitous phenomenon, perhaps intensified as a result of winter storms. Deposition of organic carbon in shelf sediments has been suggested[15,31] as a sink in the global carbon

Fig. 2 A carbon budget (g C m^{-2} yr^{-1}) of yield to man derived mainly from the shelf-break input of nitrogen within the outer and central shelf domains of the Bering Sea.

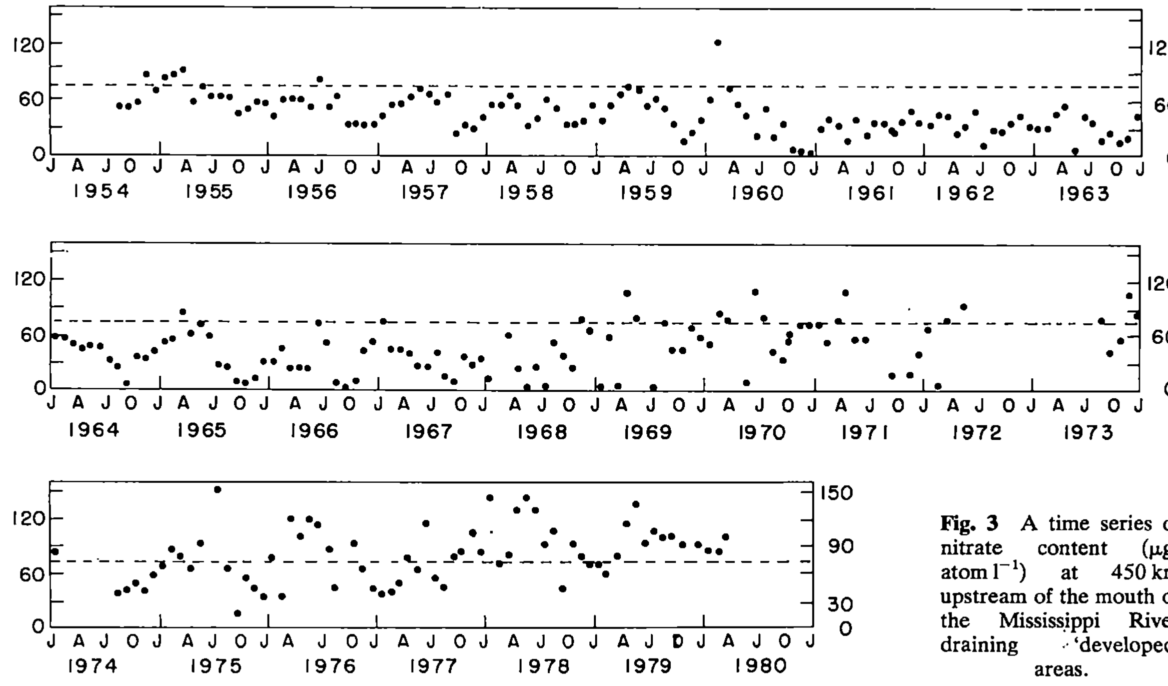

Fig. 3 A time series of nitrate content (μg-atom l^{-1}) at 450 km upstream of the mouth of the Mississippi River draining 'developed' areas.

cycle, but most recent shelves have sediments consisting of relict sands with <0.5% carbon content. However, surficial sediments of the upper slopes, for example, off the US east coast and the Gulf of Mexico, contain low C/N ratios (~5) with organic carbon concentrations >1%, implying marine origin[14]. After early diagenesis, the C/N ratio of particulate matter in these sediments increases to ≥10. That is for every 5 g of carbon and 1 g of nitrogen returned to the slope water column, a maximum of 5 g C could be left behind in the sediments. A carbon export of 3×10^9 tons C yr^{-1} from the total shelf production could now be deposited[1], with perhaps 1.5×10^9 tons C yr^{-1} accumulated[14], within slope depocentres, constituting the sink of missing carbon (Table 2) in the global CO_2 budget. Estimates of the annual detrital nitrogen export from some of these shelves are balanced by independent budgets of shelf nitrogen recycling and of the return flux of nitrate from offshore and riverine sources[24,28,30].

Transients in anthropogenic nitrogen loading

Most of the CO_2 produced by burning fossil fuel has been introduced into the atmosphere within the past two decades[5,6]; before the 1950s most of the emitted CO_2 was thought to have been stored in the ocean[34]. Presumably a transient in one or more of the sinks of CO_2 (Table 2) must have occurred in response to this increase of the fossil fuel source. However, a decline in temperate forest emission[9] of CO_2 from a source of $\sim 3 \times 10^9$ tons C yr^{-1} in 1850 to a net sink after 1950 may have been partially balanced by the increase in fossil fuel emission. For example, ignoring both marine photosynthesis as a sink and the land as a source term, a budget[35] of chemical storage of CO_2 within the deep ocean from 1850 to 1950 may have overestimated[36] the initial carbon content of the pre-industrial atmosphere by $\sim 50 \times 10^9$ tons C. In this case, at least 0.5×10^9 tons C yr^{-1} could have been lost to an unknown biotic sink without considering the changes in deforestation during most of this century.

Other analyses of abiotic storage of CO_2 in the ocean by vertical mixing[37] and/or polar sinking[38] over the past few decades neglect biological fixation of carbon in the sea and cannot account for all the CO_2 recently emitted by fossil fuel burning. The open ocean photosynthetic loss from the water column is unlikely to have increased[16] as a result of either natural or anthropogenic nutrient loading[18]. The shelf ecosystems respond to seasonal nutrient enrichment, however, when light limitation ceases, by formation of spring phytoplankton blooms[18], which seem to be exported to the slope depocentres. In summer stratified conditions of nitrogen depletion, anthropogenic nutrient addition to surface coastal waters would also increase the yield or export from this ecosystem. Poor records of primary production in the ocean on the decadal time scale[39] mean that it is difficult to demonstrate the eutrophication of coastal waters by direct observation. The daily production of the mid-shelf spring bloom in the New York Bight has apparently not changed, for example, over the past 25 yr [27], but spatial sampling was inadequate to determine whether nearshore production had increased. The Baltic[40] and Waddensea are exceptions, where the data base indicates that annual production of the nearshore zone has apparently increased from 80 to 240 g C m^{-2} yr^{-1} over the past 20 yr [41].

The lack of change in nutrient content at midshelf off New York, away from the influence of the Hudson River over the past 25 yr [27], suggests that only coastal anthropogenic sources of nutrients, not shelf-break sources, could have reasonably changed in response to the industrial revolution. The phosphate content[42] of the Rhine River has, in fact, increased 10-fold over the past 50 yr. The nitrogen content of the Rhine[43] almost doubled between 1959 and 1968, while that of the Seine (Y. Monbet, personal communication) increased fourfold to ~400 μg-atom N l^{-1} from 1965 to 1975. The mean winter nitrate content of the North Sea shelf is also at least two- to fourfold higher off the Thames estuary, the Wash and the Rhine estuary than at the edge of the shelf[44]. Indeed, as much as 350 μg-atom NO_3 l^{-1}, ~10-fold the concentration of NO_3 in deep slope water, has been found both in the Scheldt estuary and 10 km off the Belgian coast[45].

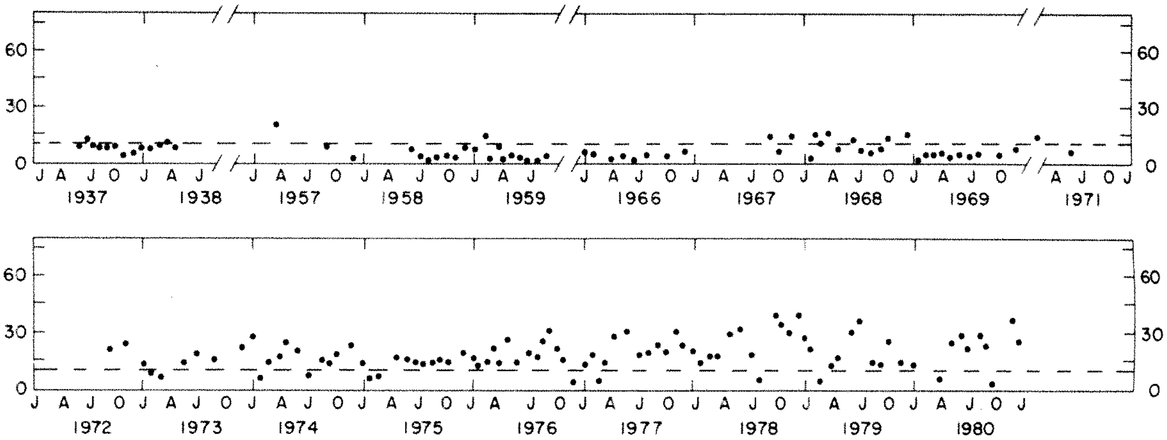

Fig. 4 A time series of the nitrate content (µg-atom l^{-1}) at 50–100 km upstream of the mouth of the Altamaha River draining 'undeveloped' areas.

Within North America, the nitrate content of the Mississippi River (Fig. 3) has at least doubled to $\sim$150 µg-atom NO_3 l^{-1} during spring flood over the past 25 yr, while 30 µg-atom NO_3 l^{-1} can still be found downstream on the otherwise oligotrophic shelf at its mouth[15]. Data[46–49] for US rivers which drain other heavily populated areas suggest that their nitrogen content has also increased over the past 25–50 yr from sewage inputs, agricultural fertilizers and nitrate release to groundwater after deforestation[50]. Similarly, US rivers which drain areas of low populations used to contain 10-fold less inorganic nitrogen ($\sim$7–10 µg-atom N l^{-1}) than the above rivers before 1970, but the nitrate content of the Altamaha (Fig. 4) and Pamlico[52] rivers is now $\geq$30 µg-atom NO_3 l^{-1}.

The location and discharge of the world's 30 largest rivers further suggests that a similar freshwater flux occurs from 'undeveloped' areas ($\sim 286\times 10^3$ m^3 s^{-1}) compared with those from 'developed' areas ($\sim 234\times 10^3$ m^3 s^{-1}) with a sixfold larger human population, that is greater anthropogenic nitrogen sources. If we assume that half the world's total river discharge ($\sim 4\times 10^{16}$ l yr^{-1}) has not yet been affected by deforestation, sewage and fertilizers in these underdeveloped countries, and that the low nitrate contents of the Amazon[53], Congo[54], Orinoco (J. Edmond, personal communication) and Niger[54] Rivers ($\leq$10 µg-atom NO_3 l^{-1}) are typical of these regions (Table 3), nitrate input to the shelves from such drainage systems is $\sim 0.3\times 10^{13}$ g NO_3–N yr^{-1}. If we also assume that the other half of the world's river discharge now has at least 60 µg-atom NO_3 l^{-1} due to population distribution and the industrial revolution (>70 µg-atom NO_3 l^{-1} is found in the Hudson, Potomac, Susquehanna, Delaware, Mekong[55] and Yantze (J. Edmond, personal communication) rivers and recall concentrations of 150–300 µg-atom NO_3 l^{-1} in the Mississippi, Seine, Rhine and Scheldt rivers) the annual nitrate input from these developed terrestrial ecosystems would be $\sim 1.7\times 10^{13}$ g NO_3–N yr^{-1}.

A present input of 2.0×10^{13} g NO_3–N yr^{-1} from river runoff would be at least treble that of 0.6×10^{13} g NO_3–N yr^{-1} estimated more than 25 yr ago[56], from data taken more than 50 yr ago[57]. Using a similar unrevised estimate of 0.8×10^{13} g NO_3–N yr^{-1} in river runoff, it has been suggested[58] that only $\sim$10% of the nitrogen fertilizers previously applied to fields had yet to be released from the soil to streams by 1970. In terms of a seasonal range, the inorganic nitrogen content of rural land runoff in Ohio[59] varies during the year from $\sim$10 to 600 µg-atomic N l^{-1} as reflected in the monthly nitrate content of the downstream Mississippi River (Fig. 3). The long-term trend of this and the Altamaha (Fig. 4) time series over the past 25 yr, however, suggests that NO_3 concentrations of these rivers has doubled within the past decade. If mobilization of nitrogen from soil pools is now increasing, we would expect future increases of primary production in the coastal zone and greater export of this carbon to the slope.

In fact, other estimates[60] of riverine nitrogen loading range as high as 3.5×10^{13} g N yr^{-1} and rivers are not the only source of anthropogenic nitrogen inputs to coastal waters. An analysis[61] of the present annual nitrogen loading from coastal sewage outfalls, waste dumping and river input to the shelves of the New York Bight and the Mediterranean, Seto Inland, Baltic, North and Irish Seas suggest a range of 1–3×10^4 tons N yr^{-1} (10^6 persons)$^{-1}$ for each of these areas. Extrapolating the mean of this estimate to half of the world population of 30×10^8 persons for just coastal communities of North America–Asia–Europe (Table 3), we obtain an estimate of 3×10^7 tons N yr^{-1}, or 3×10^{13} g N yr^{-1} from both rivers and other sources of nitrogen within the developed regions.

Conclusions

With a C/N ratio of 5:1 for primary production/nitrogen uptake, this anthropogenic loading of 'new' nitrogen would allow a coastal export of 0.15×10^9 tons C yr^{-1} without considering the carbon fixed in recycling this nitrogen source. The dissolved nitrogen pool of nearshore shallow waters is recycled $\sim$10 times during the year[62], which is reflected by observations that indicate recycled nitrogen amounts to 90% of the daily ^{15}N uptake of phytoplankton in the Hudson[63] and Chesapeake[64] plumes. These data suggest a primary production of 1.50×10^9 tons C yr^{-1} from this source, that is, $\sim$25% of the present shelf production. After each change of the particulate C/N ratio from 5/1 to 10/1 during the nearshore remineralization cycle, 0.75×10^9 tons C of refractory carbon could be available for export each year as a result of this nitrogen loading. Once produced on the outer and inner shelf, organic matter of a C/N ratio of either 5/1 or 10/1 tend to be transported with those fine-grain sediment particles, which, escaping the sediment traps of the estuaries, transit the continental shelf and are deposited on the upper slopes[65,66].

Our analyses suggest that up to half of the estimated 1.50×10^9 tons C yr^{-1} of the slope carbon sink could result from increased eutrophication since the industrial revolution. A combination of outer shelf ungrazed phytodetritus with a C/N of 5/1 and nearshore reworked detritus with a C/N of 10:1, sequestered together on the slope, would constitute both the missing carbon (Tables 1, 2) and the particle flux required as a sink for ^{210}Pb budgets[67]. The biological export of shelf carbon in transient and steady-state budgets of the global CO_2 cycle could present an important management strategy. Increased eutrophication of a well-flushed coastal zone should lead to both increased primary production (fixation of CO_2) and export, not anoxia[68], such that sewage waste disposal problems might be coupled with averting increases in the CO_2 content of the atmosphere.

This research was mainly sponsored by the Department of Energy (DOE) under contract DE-AC02-76CH00016 as part of our Atlantic Coastal Ecosystem (ACE) programme. Additional support was provided by the NSF as part of the Processes and Resources of the Bering Sea (PROBES) programme. Dr Charles Demas, Melvin Edwards and Dr John Edmond provided data on nitrogen content of the Mississippi, Altamaha, Yantze and Orinoco Rivers, while our colleagues in the ACE and PROBES programmes shared additional data and ideas.

Homology between the primary structure of α-fetoprotein, deduced from a complete cDNA sequence, and serum albumin

Simon W. Law* **& Achilles Dugaiczyk**†

Department of Cell Biology, Baylor College of Medicine, Texas Medical Center, Houston, Texas 77030, USA

The entire DNA complementary to murine α-fetoprotein mRNA has been cloned in the plasmid vector pBR322 and its complete nucleotide sequence determined. The deduced amino acid sequence identifies a hydrophobic prepeptide of 19 amino acids and the complete primary structure of α-fetoprotein. Its structure reveals extensive homology to serum albumin and suggests that there are 15 disulphide bridges in the α-fetoprotein molecule, all at the same positions as those found in albumin. The AFP molecule can be organized into a three-domain structure almost identical to that of serum albumin, suggesting a common ancestral origin of the two proteins.

α-FETROPROTEIN (AFP), a serum protein with an apparent molecular weight[1] of 72,000, is made and secreted by the fetal liver[2] and yolk sac[3] of all mammals so far studied. The serum concentration of AFP decreases rapidly during fetal development to a residual level in adulthood but rises again in individuals with hepatomas or germ-cell tumours[4–6]. Elevation of serum AFP levels is also observed in a variety of pathological conditions[6,7] and in certain human fetal malformations such as neural tube defects[8,9]. The exact function of AFP is unclear, although similar biological and physicochemical properties suggest that it may be the fetal counterpart of adult serum albumin.

Human AFP and albumin have been reported to exhibit some homology in amino acid sequence[10]. However, a comparison of the amino-terminal sequence of human, murine and rat AFP with sequences of the respective albumins showed no sequence homology between the two proteins[11]. Furthermore, cDNA to rat AFP mRNA does not cross-hybridize to rat albumin mRNA in moderately stringent conditions[12,13]. The determination of a partial cDNA sequence of rat AFP[14,15] has recently revealed a partial homology between the rat AFP and serum albumin

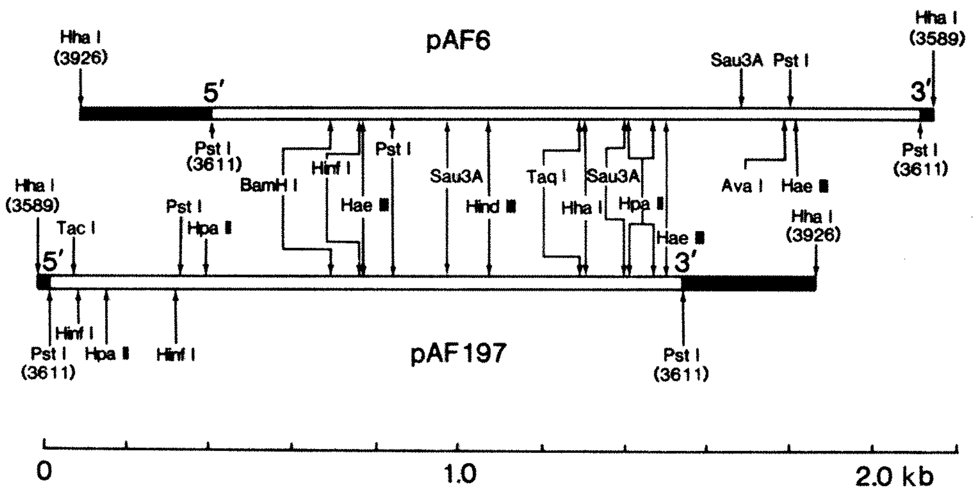

Fig. 1. Restriction endonuclease cleavage sites on the overlapping murine AFP cDNA inserts in the recombinant plasmids pAF6 and pAF197. The map shows the inserted AFP DNA (open bar) and its orientation in the PBR322 plasmid DNA (black bar). The murine-derived DNA is inserted at the *Pst*I site of the plasmid DNA as described in detail previously[16]. The AFP mRNA sequence is presented by the upper DNA strand of the pAF6 and pAF197 map, with the 5′ and 3′ ends as indicated. Numbers on restriction sites within the pBR322 sequence, like *Pst*I (3,611), are taken from available sequence data from Sutcliffe[35] and represent positions on the sequence map of pBR322, counted from the single *Eco*RI site on the circular DNA molecule. kb, Kilobases.

amino acid sequence. We now describe the cloning and nucleotide sequence determination of the entire DNA complementary to murine AFP mRNA and analyse the deduced primary amino acid structure and disulphide bonding pattern of the AFP molecule in the light of its homology to serum albumin.

The recombinant plasmid pAF6

We have previously reported[16] the construction of a cDNA clone containing about 1.65 kilobases of mouse AFP mRNA sequence (Fig. 1). The clone was identified on the basis of a hybrid-arrested *in vitro* translation of mouse yolk sac mRNA, which specifically arrested the translation of the AFP mRNA species. As shown below, nucleotide sequence analysis has revealed that the cDNA sequence in pAF6 corresponds to the 3′ region of the AFP message. This clone does not contain the 5′ sequence corresponding to the known 20 amino acids at the amino terminus of mouse AFP. Comparison of the size of the protein[1] and the size of the cDNA in pAF6 indicates that about 400 nucleotides of additional coding sequence are required to complete the 5′-terminal sequence of the AFP message.

Cloning of cDNA complementary to the 5′ region of AFP mRNA

A *Bam*HI–*Ava*I DNA fragment was isolated from the cDNA clone pAF6 (Fig. 1), annealed to mouse yolk sac mRNA and the resulting RNA/DNA template/primer used in the reverse transcriptase reaction to synthesize a cDNA copy for the 5′ region of the mRNA template. Using the same reverse transcriptase the cDNA was converted to its double-stranded form[16], treated with endonuclease S_1, tailed with about 15 (dC)-residues and annealed with the *Pst*I-linearized plasmid vector pBR322 which had been tailed with 15 (dG)-residues as previously described[17]. Clones of the *Escherichia coli* strain RR1[18] which had been transformed[19] by the annealed recombinant plasmids were identified by their tetracycline resistance and ampicillin sensitivity, the two markers being carried on the plasmid pBR322 genome[18].

Clones containing sequences 5′ upstream of the *Bam*HI–*Ava*I DNA primer were identified by colony hybridization[20]; the probe for this hybridization was obtained by using polynucleotide kinase and [γ-^{32}P]ATP to end label[21] the 5′-terminal *Pst*I–*Bam*HIDNA fragment of pAF6 (Fig. 1), containing the AFP cDNA sequence 5′ upstream of the *Bam*HI–*Ava*I DNA primer. Sequence analysis of one of the positive clones, pAF197, which was found to contain about 400 base pairs 5′ upstream of the last cDNA nucleotide of pAF6 (Fig. 1), revealed that this cDNA codes for the entire amino-terminal region of murine AFP up to amino acid −9 of the AFP prepeptide; a partial amino acid sequence of the prepeptide has recently been reported[22]. As the two cDNA clones share an extensive (1.1 kilobase) segment of homologous DNA in their central portion and pAF6 codes for the 3′-terminal region of AFP mRNA, together they encode the entire sequence of the murine AFP molecule.

DNA sequence analysis of the AFP cDNA

In contrast to serum albumin, where the entire amino acid sequence is known for the human and bovine proteins, very little sequence information is available for AFP, apparently because of hindrance by the carbohydrate moieties of the molecule[11]. What little sequence information is available includes 20 amino acids of the prepetide[22], some 20 residues at the amino terminus and the carboxy-terminal valine[11].

We obtained the amino acid sequence of AFP by determining the entire sequence of the AFP cDNA insert in pAF6 and pAF197 by the chemical method of Maxam and Gilbert[23], mainly using both DNA strands to ensure accuracy. All the restriction sites on the restriction map were accounted for by sequence analysis, and all the restriction sites used to end-label DNA fragments were sequenced across by labelling a neighbouring restriction site. The murine-derived sequence of pAF197 actually starts with the *Mnl*I recognition sequence CCTC and corresponds to leucine −9 of the prepeptide. The sequence 5′ upstream of leucine −9 was determined as described in Fig. 2 legend.

Figure 2 shows entire nucleotide sequence of the cDNA in pAF6, pAF197, of the primer-extended cDNA at the 5′ terminus of the AFP mRNA and of the deduced amino acid sequence. The combined length is 2,064 nucleotides, of which 41 represent the 5′-untranslated region, 57 identify the prepeptide of 19 amino acids, 1,758 code for the 586 amino acids of AFP, 153 make up the 3′-untranslated region and 55 are the poly(A) sequence.

The hydrophobic presequence (Fig. 2) for AFP, which is 19 amino acids long, is processed to generate the mature polypeptide. The length and hydrophobic nature of this presequence are similar to those reported for other secretory proteins (see ref. 24 for a compilation of presequences). Instead of two terminal methionine residues[22] only one is accountable for by direct DNA sequencing. No other ATG codons are observed in any reading frame in the entire DNA sequence 5′ upstream from the amino-terminal methionine. Therefore, our data on the presequence show a length of 19 rather than 20 amino acids as previously reported[22]. The remaining DNA sequence data agree, with few exceptions, with the published amino acid sequence in this region of AFP. The amino-terminal residue in AFP is found to be Ala rather than the previously reported Ser[11]. Considering that our sequence in this region is derived

Fig. 2 Nucleotide sequence of murine AFP mRNA as determined from cloned cDNA. The Maxam and Gilbert[23] method was used throughout this work for sequence determination. The sequence 5′ upstream of leucine −9, which is not contained in pAF197, was determined as follows. A 0.1-kilobase *Hha*I(3,589)–*Hin*fI DNA fragment (Fig. 1) was isolated from pAF197 and 5′ labelled with polynucleotide kinase[21] and [γ-^{32}P]ATP. This fragment was subsequently digested with *Mnl*I, which cuts at the very beginning of the AFP sequence and removes the pBR322 portion of the *Hha*I–*Hin*fI fragment. The resulting *Mnl*I–*Hin*fI murine DNA fragment was labelled only at the *Hin*fI 5′ terminus. This fragment was annealed to mouse yolk sac mRNA and the resulting RNA/DNA template/primer was used in the reverse transcriptase reaction to synthesize a cDNA copy extended into the 5′ terminus of the mRNA template. This cDNA was separated from the deoxyribonucleotide triphosphates on a Sephadex G-50 column and used directly for sequence determination. The amino acid sequence shown is deduced from the nucleotide sequence. Nucleotides are numbered at the end of each row and amino acids above the sequence. In the 3′-untranslated region four potential termination codons are indicated in the amino acid reading frame. There seems to be no propeptide sequence in AFP analogous to that in serum albumin. The molecular weights for the aglycoprotein of AFP and its precursor, as determined from the amino acid composition, are 65,164 and 67,286, respectively.

from sequencing both DNA strands, we reassign the amino acid positions accordingly (Fig. 2).

The 5′-noncoding region of the murine AFP message reveals the presence of a purine-rich sequence in positions 26–38 (Fig. 2). This region exhibits partial sequence homology among the various mammalian mRNAs which have been found to have a purine-rich region with its 3′ end 2–6 nucleotides from the starting AUG codon (for a compilation of 5′-noncoding sequences see refs 25, 26). Nucleotides 6–14 (Fig. 2) are complementary to a 3′-terminal region of eukaryotic 18S

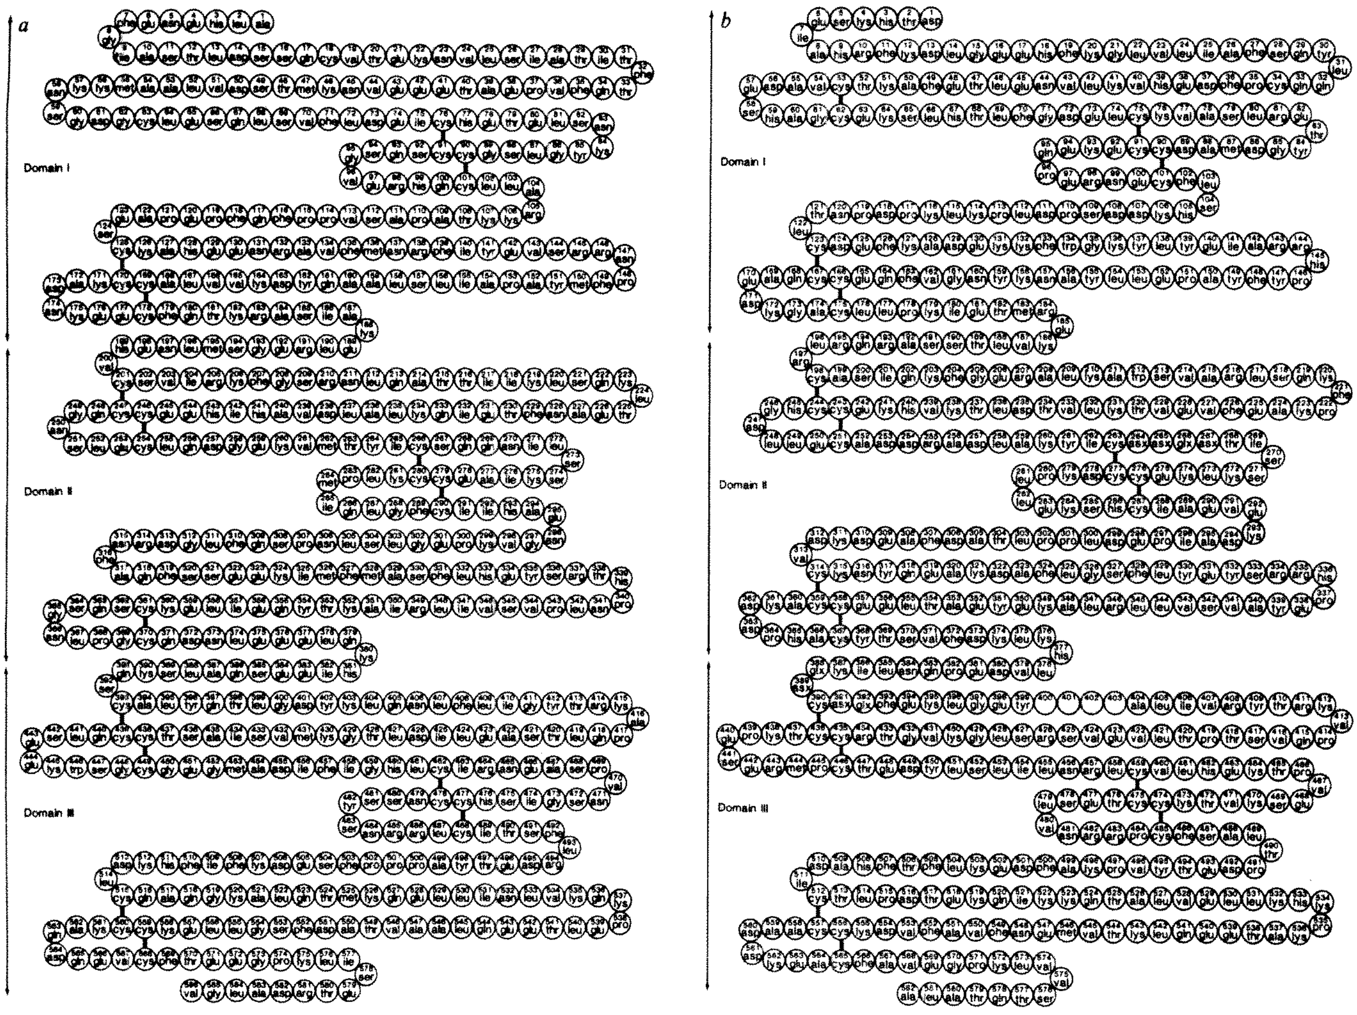

Fig. 3 *a*, Amino acid sequence and disulphide bonding pattern of murine AFP. A triple domain structure is indicated by arrows: I, amino acids 1–193; II, amino acids 194–385; III, amino acids 386–586. The sequence represents our present data, the layout of the sequence follows that of serum albumin, and the disulphide bridges are assigned by analogy with serum albumin. *b*, Amino acid sequence and disulphide bonding pattern of bovine serum albumin. The triple domain structure is indicated by arrows: I, amino acids 1–190; II, amino acids 191–382; III, amino acids 383–582. The sequence and its layout are according to Brown[33].

RNA[27] and thus could represent a ribosome binding site:

(5′)...CUUCC^GCA..............AFP mRNA

(3′)...GAAGGCGUCCm_2^6A m_2^6A...18S RNA

The 3′-noncoding region consists of 153 nucleotides beyond the carboxy-terminal valine. It starts with the translation stop signal UAA and contains four more potential stop codons in the same reading frame. The hexanucleotide AAUAAA, which is conserved in this region of eukaryotic mRNAs[28], is located in the AFP message 15 nucleotides 5′ upstream from the poly(A). Contrary to reports on some human cDNA sequences[29], mouse AFP codons are not biased towards those ending in one or two specific nucleotides, although there is a bias in the use of certain codons.

Structural relationship between α-fetoprotein and albumin

From a detailed amino acid sequence analysis of bovine (BSA) and human (HSA) serum albumin[30–33], Brown discovered a repeating pattern in the structure[32,33]. On the basis of spacing of the cysteine residues in the complete polypeptide chain and the positions of the disulphide bridges, the albumin sequence can be organized to generate three very similar repeat units, called domains (Fig. 3*b*).

To elucidate the structure of AFP, we have translated the entire AFP mRNA coding sequence into a corresponding amino acid sequence and aligned the disulphide bridges of cysteine residues in the same way as has been described for BSA or HSA[32,33]. The resulting structure reveals that the amino acid sequence of AFP can be divided into three domains of sequence homology, analogous to the domains of albumin (Fig. 3*a*, b). A total 15 disulphide bridges can be formed throughout the AFP molecule, two less than found in BSA. The cysteine residues occur within the polypeptide chain of AFP at almost identical sequence positions to those found in albumin, thus allowing for the formation of the same disulphide bridges in the secondary structure of AFP. Note however, the disulphide bridges in AFP are assigned here by analogy with serum albumin only, and we have no experimental evidence for such arrangement.

A comparison of the AFP amino acid sequence with that of human or bovine albumin shows about 40, 30 and 10% homology of identical amino acids between domains III, II and I, respectively. The homology between the two proteins increases further to ~65% for domain III and ~55% for domain II if the amino acids are compared on the basis of their belonging to one of four groups having a characteristic side chain: hydrophobic (Phe, Leu, Ile, Met, Val, Pro, Ala, Tyr, Trp), polar (Ser, Thr, Gln, Asn, Cys, Gly), basic (His, Lys, Arg) or acidic (Glu, Asp). Among the differences between the two proteins there are three potential N-glycosylation sites (Asn-X-Thr; Asn-X-Ser)[34] in the AFP sequence and none in albumin.

It is tempting to analyse the nucleotide sequence of the AFP message in the two regions where, in contrast to the albumin sequence, there are no disulphide bridges in the AFP structure. One such region is the Cys 53–Cys 62 disulphide pair in BSA

(Fig. 3*b*). In AFP, this structure corresponds to the juxtapositioned Ala 54–Cys 63 amino acid pair (Fig. 3*a*) which obviously lost a bridging capacity. There is, however, a cysteine UGC codon and thus a 'hidden' Cys residue in the critical position of Ala 54, if the reading frame is shifted by one nucleotide in this region (Fig. 2). A difference of one nucleotide is thus responsible for the difference of one extra disulphide bridge in the structure of the two proteins. The other region is the Cys 314–Cys 359 pair in BSA (Fig. 3*b*), which is also absent from the AFP structure, where it is replaced by the Ala 317–Ser 362 pair instead (Fig. 3*a*). Examination of the AFP nucleotide sequence (Fig. 2) reveals again that only single nucleotide changes are required to re-establish the missing Cys 317–Cys 362 structure in the AFP molecule. The mRNA sequence seems to carry a more detailed record of ancestral relationship between AFP and serum albumin than is evident from their existing amino acid homology. When DNA sequences for AFP and albumin from the same species become available, their comparison will probably give a better indication of the genetic relationship between the two proteins.

This work was supported by the Baylor Center for Population Research and Reproductive Biology. We thank Olivia Dennison and Serlina Robinson for technical assistance, Dr John Compton and James Hawkins for critical reading of the manuscript and David Scarff for the artwork.

Nucleotide sequence of *Xenopus laevis* 18S ribosomal RNA inferred from gene sequence

Mohammad Salim & B. Edward H. Maden

Department of Biochemistry, University of Glasgow, Glasgow G12 8QQ, UK

18S ribosomal RNA in Xenopus laevis *is 1,825 nucleotides long, as inferred from sequence analysis of an 18S gene. All the 40 rRNA methyl groups can be located in the sequence. Comparison with the yeast* (Saccharomyces cerevisiae) *18S sequence reveals extensive regions of high homology interspersed with tracts having little or no homology. Regions of high homology contain almost all the RNA methyl groups. Major regions of low homology are considerably richer in C + G in* Xenopus *than in yeast.*

KNOWLEDGE of the primary structure of ribosomal RNA (rRNA) in higher organisms should elucidate several aspects of ribosomal function, assembly and phylogeny. Here we report the nucleotide sequence of 18S rRNA in the frog *Xenopus laevis*, as inferred from analysis of an 18S gene. We compare our findings with the recently reported yeast (*Saccharomyces cerevisiae*) 18S sequence[1].

The sequence was determined from the *X. laevis* rDNA clone, pXlr 101, which contains a complete ribosomal transcription unit with its preceding non-transcribed spacer (Fig. 1). The sequencing strategy involved almost complete analysis of both strands of the 18S gene with extensive overlapping (Fig. 1); the inferred RNA sequence is shown in Fig. 2. Considerable evidence indicates that this sequence is representative of 18S rRNA in *X. laevis*. Oligonucleotide data on the 5′ 160 nucleotides[2], the 3′ 230 nucleotides (B.E.H.M., unpublished data), the various oligo(A) tracts[3] and the methylated sequences (below) all agree with the DNA sequence. Limited sequence data from other clones of *X. laevis* rDNA agree with the sequence shown in Fig. 2 (B.E.H.M., unpublished results), and the many restriction sites identified here agree well with those reported previously for an independently cloned rDNA unit from *X. laevis*[4,5].

rRNA methylation

Knowledge of the sequence provides a means of determining the sites of all the rRNA methyl groups (40 in *X. laevis* 18S rRNA). Data on the methylated oligonucleotides in 18S RNA[6–10] and on their approximate locations in the sequence as deduced from 'hybridization mapping'[11] have allowed us to locate all the methylated nucleotides. The methyl group distribution is highly irregular (see Figs 2, 3). There is considerable clustering of 2′-*O*-methyl groups in the 5′ 40% of the sequence and the distribution in this region is also irregular; another cluster of 2′-*O*-methyl groups occurs in the region 1,240–1,400. The remaining 2′-*O*-methyl groups are outliers from the main clusters. All the base methyl groups are in the 3′ 35% of the molecule. The hypermodified nucleotide amψ (1-methyl-3-aminobutyryl pseudouridine[12]) is at position 1,209. m^7G occurs at the point encoded by the *Eco*RI site (nucleotide 1,596). The base-modified A residues are in the last 40 nucleotides.

The numerous pseudouridines in 18S rRNA are also found by hybridization mapping to be widely distributed (unpublished results), but, as few have been precisely located[2], this class of modifications is not included in Fig. 2.

0028-0836/81/210205—04$01.00

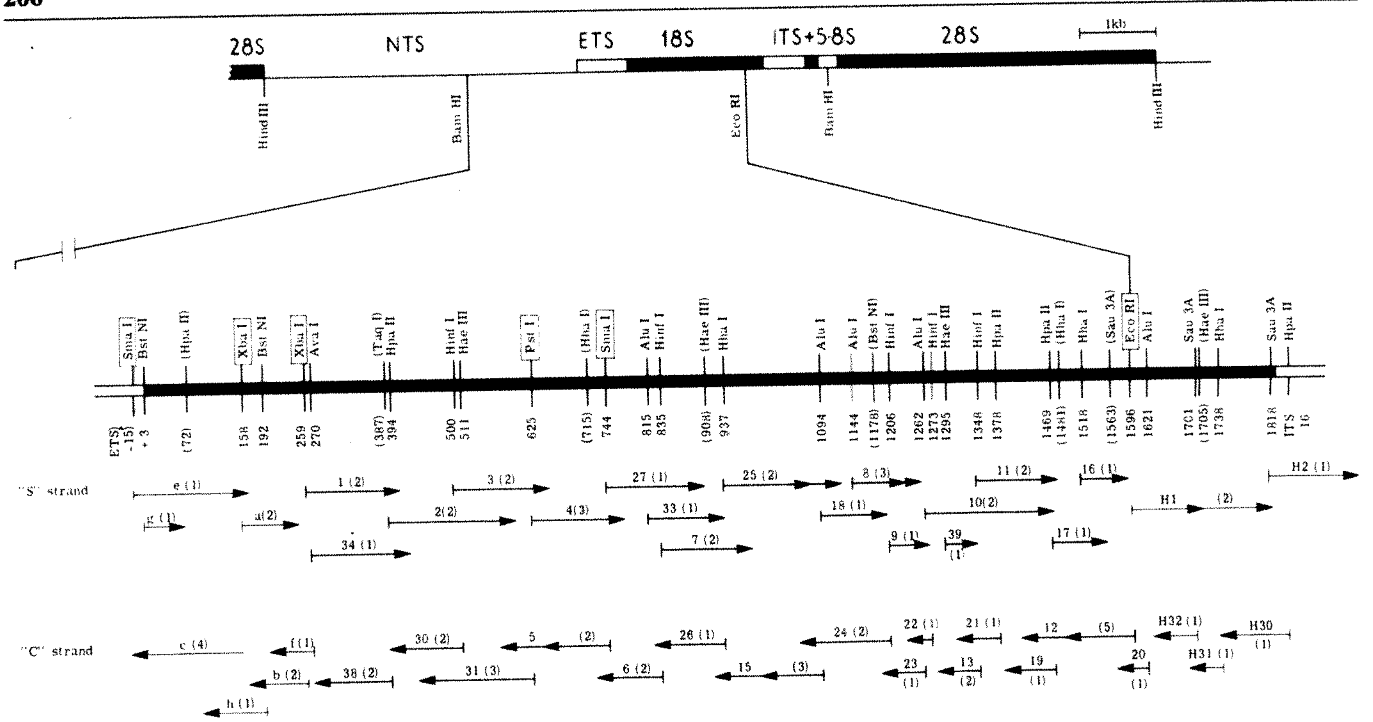

Fig. 1 Top line, repeating structure of rDNA in *X. laevis*. Solid sections represent rRNA coding sequences. NTS, ETS and ITS denote non-transcribed, external and internal transcribed spacers. pX1r 101 consists of a complete rDNA unit bounded by *Hin*dIII sites, cloned in the vector pMB9. Lower part of the figure shows the sequencing strategy. Most of the sequence was determined after subcloning the indicated 3.5-kilobase *Bam*HI/*Eco*RI fragment into pBR322 (ref. 2). The sequence to the right of *Eco*RI sites was determined after subcloning the 1.1-kilobase *Eco*RI/*Bam*HI fragment into pBR322 (ref. 30). The sequence through the *Eco*RI site was determined as indicated below (gel 20). Sequences of the 5′ 275 nucleotides and 3′ 227 nucleotides, including identification of the two ends of the 18S gene, have been reported elsewhere[2,30]; sequencing strategy for these regions is included for completeness. The major part of the sequence was determined by the Maxam and Gilbert method[31] from gels 1–38. Restriction sites used for sequencing are shown on the centre line; numbers denote the first nucleotide in each site counted from the 5′ end of the 18S gene. Boxed sites were used separately or in combination for large-scale digests. Some of the resulting material was labelled at the 5′ termini; the remainder was digested with one or more further enzymes before labelling. Upper arrows denote sequencing gels on the 'S' strand (synonymous to RNA); lower arrows denote gels on the 'C' strand (complementary to RNA). The tips of the arrows indicate the points to which the gels were read. Numbers in parentheses indicate the number of sequencing gels from each 5′-labelled starting point. When the distances that were read differed substantially between experiments (for example due to use of different secondary restriction sites) arrows with two tips are shown. The entire sequence was read on both strands except at the following points: restriction sites *Hin*fI 1,273, *Hpa*II 1,378 and *Alu*I 1,621 were sequenced only on S strand; sites *Xba*I 259 and *Eco*RI 1,596 were sequenced only on C strand. Secondary structure effects interfered with the reading of short segments on S strand at 244–7, 681–4, 1,146–7 and on C strand at 226–9, 666–7, 705–8. Methylated C residues in *Eco*RII sites were evident as gaps or very faint bands as follows: S4, C6; S804, C806; S1,180, C1,182. Gel 9 was unclear at 1,256 but at this and all other points referred to above, the sequence was unambiguously read on the other strand, and the restriction sites just mentioned were all experimentally demonstrated. (*Bst* NI cuts at methylated *Eco*RII sites.) In most cases the purification of fragments was straightforward, and sequencing was carried out after 5′ labelling and secondary restriction. At a few points more complex procedures were needed to allow the necessary overlapping sequences to be obtained. The relevant gels were as follows. S strand—gel 18, partial *Alu*I digest yielded fragment 1,094–1,262. 5′-terminal labelling was followed by secondary restriction at *Hin*fI 1,206. Gel 17, fragment bounded by *Hpa*II 1,469 and *Eco*RI 1,596, was labelled and subjected to partial *Sau*3A digestion to yield fragment terminating at 1,563. (Another *Sau*3A site at 1,497 is not shown.) Gel 8 (*Alu*I fragment 1,144–1,262), gel 9 (*Hin*fI fragment 1,206–1,273) and gel 16 (fragment bounded by *Hha*I 1,518 and *Eco*RI 1,596) were sequenced after strand separation. C strand—Gel 23, *Alu*I fragment 1,144–1,262, was labelled and subjected to secondary restriction at *Bst*NI 1,179; gel 22, *Hin*fI fragment 1,206–1,273, was subjected to secondary restriction with *Hae*III at 1,229 (not shown). Gels 13 (*Hin*fI fragment 1,273–1,348) and 19 (*Hpa*II fragment 1,378–1,469) were subjected to strand separation. (In this and some other experiments only one strand was successfully purified.) Gel 20, this crucial fragment (*Alu*I 1,262–1,621), which allowed sequencing through the *Eco*RI site, was obtained from the parent plasmid pX1r 101 by *Alu*I digestion of a 4.5-kilobase *Bam* HI fragment (these sites are shown in the top line of the figure). The *Alu*I fragment was labelled, subjected to secondary restriction at *Hpa*II 1,469 and the C strand was sequenced. The result confirmed the presence of a single *Eco*RI site and the correctness of the adjacent sequences as previously deduced from the subclones.

Figures 2 and 3 show a comparison of the *X. laevis* and *S. cerevisiae*[1] sequences. There are extensive tracts where the two sequences are almost identical. Most of the two sequences are >70% homologous, but there are also tracts with little or no homology. Almost all the *X. laevis* methylation sites are in regions of high homology with the yeast sequence. Four major regions of low homology are designated *a*, *b*, *c* and *d* in Fig. 3. Table 1 shows that these regions are considerably richer in C+G in *Xenopus* than in yeast.

Evolutionary trends

These findings provide insight into evolutionary trends in eukaryotic rRNA and suggest a general explanation for a well-known paradox: rRNAs from distantly related eukaryotes differ considerably in overall base composition[13,14] but show substantial homology by nucleic acid hybridization[15,16]. Clearly in *Xenopus* and yeast 18S rRNA the nucleic acid hybridization experiments show extensive, highly conserved sequences. The divergence in base composition between the two rRNAs results from cumulative changes in less highly conserved parts of the molecules, and much of this variability is concentrated in clearly circumscribed tracts. These range in size from short runs of a few nucleotides such as tract 65–75 (Fig. 2) to the longer, major variable regions of Table 1. Thus the pattern of sequence homology between *Xenopus* and yeast 18S rRNAs may be described as 'extensive but interrupted'.

How general is this pattern? Sequence analysis of the 3′ regions (rightwards from the *Eco*RI site) of 18S genes in silkworm[17] and fruitfly[18] shows that much of this region has also remained highly conserved in these organisms, but again the tract corresponding to region *d* is more variable. Recent refinements in nucleic acid hybridization experiments, in which heterologous rRNAs are hybridized to specific restriction fragments of rDNA, confirm the general pattern of 'extensive but interrupted' homology for both 18S and 28S rRNA[19,20].

How variable are the variable regions? Table 1 shows that the 18S variable regions in *Xenopus* and yeast differ from each other less widely than do the respective internal transcribed spacers. The regions differ in length only slightly between the two species, and although the *Xenopus* regions are rich in G+C, the corresponding yeast regions are, on average, no more rich in A+U than the rest of the sequence (*a* is rich in A+U but *b* is slightly rich in G+C even in yeast). This suggests that there are constraints on evolution in these 18S regions, but not such stringent ones as in the highly conserved regions. The 18S variable regions possibly play a semi-specific structural role in

Table 1 *X. laevis* and *S. cerevisiae* base composition data

		No. of nucleotides		U	A	C	G	%C+G
Complete 18S:								
X. laevis		1,825		411	432	467	515	53.8

Fig. 2 Nucleotide sequence of *X. laevis* 18S rRNA, with positions of methyl groups indicated by superscripts and comparison with the yeast *S. cerevisiae*[1] sequence indicated by subscripts. Most of the methyl groups were located from T_1 oligonucleotide data[6–9,11], but in several cases additional data from pancreatic ribonuclease fingerprints (B. E. H. M., unpublished results) were also needed—this work will be fully reported elsewhere. The methylation sites are as follows: m superscripts denote 2′-*O*-methyl groups at 27, 99, 116, 121, 163 (not 181 as was reported previously[2]), 393, 401, 427, 433, 449, 474, 477, 482, 541, 555, 566, 592, 609, one of 633–636, 648, 759, 761, 992, 1,249, Um and Gm between 1,280–1,289, 1,344, 1,352 or 1,355, 1,399, 1,447, 1,635, 1,660 and 1,760. Remaining superscripts denote base methyl groups at amψ 1,209, m^7G 1,596 (encoded at first base of *Eco*RI site), m^6A 1,788, m^6_2A 1,806 and 1,807. This list includes all known *X. laevis* 18S methyl groups except for one fractional 2′-*O*-methyl U which occurs at an unidentified location in the 5′ third of the molecule. Also mentioned in the text are oligonucleotides containing oligo(A)tracts[3]. These are: A_4C, 218–222; A_5U, 484–489; $(A_3, AmA)G$, 633–638; $A_6\psi$, 770–776; and A_4G, 1,778–1,782. Differences between the *Xenopus* and yeast sequences are indicated by plain subscripts in the case of substitutions; additional nucleotides in the yeast sequence are shown as subscripts between nucleotides in the *Xenopus* sequence and denoted by a circumflex sign. Crosses indicate deletions. In regions of low homology deletions are arbitrarily placed to allow optimal alignment between regions of good homology. (One apparent deletion from the yeast sequence occurs in a region of otherwise good homology with *Xenopus*, in nucleotides 1,006–1,015 of the latter. This part of the yeast sequence determination used a *Sau*3A site which does not seem to have been overlapped during analysis[1].)

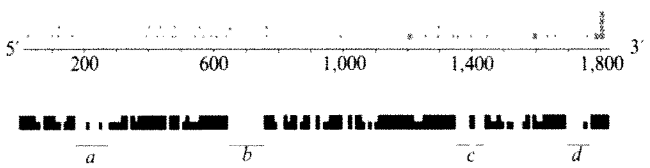

Fig. 3 Location of methylation sites in *X. laevis* 13S rRNA and pattern of homology with *S. cerevisiae*. Upper section: crosses denote 2′-*O*-ribose methyl groups; circled crosses denote base methyl groups. Lower section: high blocks indicate regions of *X. laevis* sequence possessing 85–100% homology with *S. cerevisiae*; low blocks indicate 70–85% homology. *a*, *b*, *c* and *d* denote major variable regions (see text and Table 1).

the ribosome. In 28S rRNA two long, variable regions do differ substantially in length between species[21,22].

What is the significance of localization of methyl groups within the conserved regions? Clearly many sites within these conserved regions provide recognition signals for methylases during ribosome maturation. However, further interpretation is difficult because the conservation of neither sequence nor methyl group numbers is absolute. (Yeast 18S rRNA possesses the same base methyl groups as *Xenopus* but some 15 fewer 2′-*O*-methyl groups[23,24].) Determination of the methylation sites in the yeast sequence should help to clarify the relationship between methylation and primary structure.

In contrast to the readily apparent and extensive tracts of homology between the *X. laevis* and yeast 18S sequences, we can detect little major homology with the *Escherichia coli* (prokaryotic) 16S sequence[25,26] except near the 3′ end. This lack of extensive sequence homology between eukaryotic 18S and prokaryotic 16S rRNA is in agreement with results obtained from nucleic acid hybridization[15,19] and T_1 ribonuclease oligonucleotide data[27]. The relatively high degree of homology between the *Xenopus* and yeast sequences together with the lack of comparable homology between either of these and *E. coli* 16S rRNA further supports the widely held view that the divergence between the eukaryotic and prokaryotic systems for gene expression was a very ancient one[27–29].

Conclusions

Our conclusions and inferences on the structure and evolution of eukaryotic rRNA are as follows. (1) Substantial parts of the sequences have remained highly conserved since the last common ancestor of metazoa and yeasts, a period of probably 10^9 yr. (2) Crucial events in the function or assembly of eukaryotic ribosomes, including rRNA methylation, centre on these conserved regions. (3) Tracts where primary structure is phylogenetically more variable are interspersed among the conserved regions. (4) The most clearly defined variable tracts are rich in C+G in *Xenopus*, and probably in vertebrates generally. (5) Phylogenetic change in these variable regions is less extreme than in the transcribed spacer regions.

We thank R. Reeder for a gift of the clone pX1r 101, Lucinda Hall and W. Darlington for discussion, J. Forbes and Mary Robertson for technical assistance and the MRC for financial support. M.S. was on study leave from the Department of Biology, Quaid-I-Azam University, Islamabad, Pakistan.

RG0044−2958: a peculiar M supergiant at a distance of 2.5 Mpc

Gerard Gilmore

Royal Observatory, Blackford Hill, Edinburgh EH9 3HJ, UK

I. Neill Reid

Department of Astronomy, University of Edinburgh, Blackford Hill, Edinburgh EH9 3HJ, UK

Peculiar M supergiants similar to VX Sgr and VY CMa are characterized by very red visual colours, a flux excess near 9,000 Å (*I* band) and a substantial excess longwards of 2μm (refs 1, 2). HV11417 has recently been reported to be the first similar star discovered in the Small Magellanic Cloud[3]. We report here the discovery of another star of this type, RG0044−2958, which is more unusual in that it is located at a distance of ~2.5 Mpc, and is not associated with a detectable galaxy. It is probably the brightest star in a very low surface brightness dwarf galaxy in the Sculptor group.

We are presently studying the stellar distribution towards the South Galactic Pole to $m \approx 20$ in the B, V, R and I passbands, using UK Schmidt Telescope plates measured on the COSMOS facility at the Royal Observatory, Edinburgh. Our primary aim is the determination of the intrinsically faint end of the stellar luminosity function, and the solar neighbourhood space density of low mass stars. We use as a sensitive absolute magnitude calibrator for main sequence dwarfs the $M_V/V-I$ relationship derived directly from stars of accurately known parallax[4]. The resulting luminosity function can then be compared directly with that derived for the same field using classical kinematic techniques[5]. We are also observing the very red stars in the near IR (*JHK*) to allow luminosity class (dwarf/giant) and population type (halo/disk) discrimination.

One of the more interesting objects we have studied has the broadband energy distribution shown in Fig. 1, which also gives the energy distribution for the similar object HV11417 (from ref. 3), the two very late M dwarfs, VB8 and RG0050−2722 (ref. 6), and a 'typical' giant and supergiant[7]. The ability of *JHK* photometry to provide dwarf–giant classification is evident, while the substantial '*I*' band excess shows the object to be a peculiar M supergiant similar to HV11417 and VX Sgr. This identification has been confirmed from a spectrum obtained with

0028–0836/81/210208—03$01.00

Table 1 Magnitudes for RG0044 − 2958

Passband	Mag
B	22.4 ± 0.4
V	20.5 ± 0.2
R	19.1 ± 0.2
I	17.0 ± 0.2

H	15.86 ± 0.03
K	15.47 ± 0.04

the multichannel scanner on the Palomar 5-m telescope (J.B. Oke and R. D. Cannon, personal communication).

There are two major differences between RG0044 − 2958 and VX Sgr: RG0044-2958 is not associated with a detectable galaxy, at least to the limit of the SRC '*J*' Sky Survey, which has a limiting magnitude near $m_J = 23$, and it has not shown any substantial variability since 1976.7. There is, however, a strong 1-yr selection effect in our data, and any variability with a period near 1 yr would not have been detected. Useful images of RG0044 − 2958 appear on 15 USKT plates, of which five are IIIa-J(B), three are IIIa-F(R), four are V band and three are I band. It is not visible on either POSS print or the ESO 'B' Survey plate. The derived magnitudes are shown in Table 1, together with our IR (*JHK*) data. These were obtained with the 3.9-m Anglo-Australian Telescope on 27 October 1980. One of our deep I plates was obtained the following night, and precludes extreme variability as an explanation of the I/R colours. If RG0044 − 2958 does prove to be non-variable, the suggestion[3] that stars of this type are extreme long-period variables rather than peculiar supergiants would be disproved. The variable nature of the first three known stars of this type is readily explained as a selection effect, as the visual colours are fairly normal (for such late-type stars) and would not excite spectroscopic interest, whereas variability might. As seen in Fig. 1, either visual spectroscopy or both I band and near IR photometry are necessary to discover the peculiar nature of these stars.

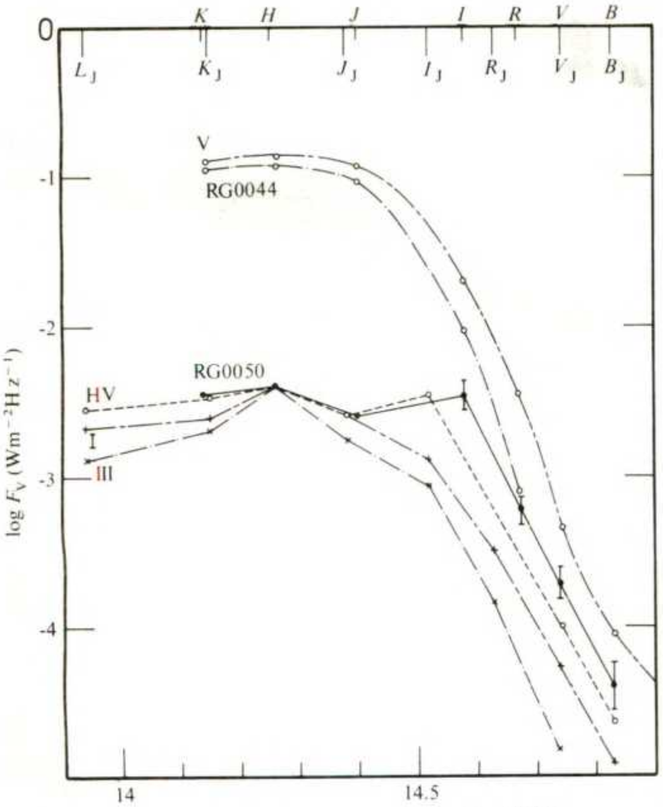

Fig. 1 Spectral energy distributions for the peculiar M supergiants RG0044 − 2958 (—), HV11417 (ref. 3) (HV, – – –), and two late-type M dwarfs, VB8 (ref. 6) (V, - - - -) and RG0050 − 2722 (ref. 6) (— · — ·). A typical M5 giant (III) and supergiant (I) from the data of Lee[7] are also shown. (The zero points are arbitrary.) The effective wavelengths of our filter passbands (*BVRIJHK*) are marked at the top of the figure and are appropriate for our observations (RG0044, RG0050 and VB8). Those of the Johnson photometric system are marked with a subscript J (*BVRIJKL*) and apply to the observations of curves HV, I and III.

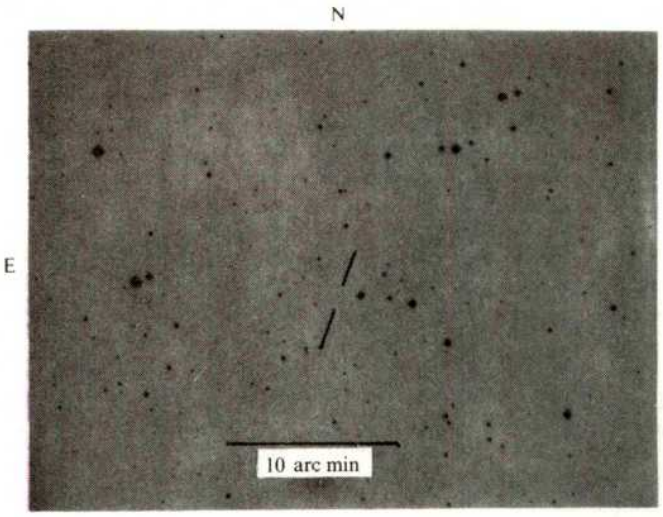

Fig. 2 A finding chart for RG0044 − 2958 reproduced from an I band UKST plate. North-east is at the top left corner, and the scale is marked. (Reproduced with permission from the UK Schmidt Telescope Unit, Royal Observatory, Edinburgh.)

The absolute magnitude of RG0044 − 2958 cannot be directly determined from our available data. Elias *et al.*[3] derive a visual absolute magnitude $M_V = -5.1$ for HV11417, and note that the corresponding value for VX Sgr is only poorly known. Humphreys (Fig. 3 of ref. 8) shows the late M supergiants in M33 to have typically $M_V = -6.8$, with some as bright as $M_V = -8$. If RG0044 − 2958 is similar to these stars, it must have a distance modulus of some 27 mag, although this value may be uncertain by several magnitudes. Significantly, the Sculptor group of galaxies lies in the same direction in the sky, and has distance modulus 27.2 ± 0.2 mag with little if any reddening[9]. If this star is, in fact, associated with this group, its absolute magnitude becomes $M_V = -6.6 \pm 0.5$, consistent with the expected value. However, no associated galaxy is visible. The nearest Sculptor group galaxy is NGC253 (ref. 10), which is some 4.25° away. At a distance of 2.5 Mpc, this corresponds to a spatial separation of ~200 kpc. A velocity of $\sim 0.02c$ is then required for this star to have escaped from NGC253 in the lifetime of the precursor of an M supergiant. It is more likely that RG0044 − 2958 is the brightest star in a dwarf galaxy of low surface brightness, which is associated with the Sculptor group and possibly with NGC253 itself.

The position of RG0044 − 2958, determined relative to a grid of 76 SAO stars from the COSMOS measurements, is RA00 h 44 min 26.2 s, dec −29°58′49″ (1950.0) and a finding chart is provided in Fig. 2.

As Fig. 1 shows there is no detectable difference between an extreme M supergiant and a very late M dwarf from broadband visual colours. The true number of objects similar to RG0044 − 2958 therefore cannot be determined until we have completed *JHK* photometry of our sample of very red stars.

We thank J. B. Oke and R. D. Cannon for obtaining the spectrum with the 5-m Hale Telescope on Palomar Mountain, and the UKST and COSMOS groups at the Royal Observatory, Edinburgh, for assistance.

Solar radio blips and X-ray kernels

Hudson[1] proposed that the primary flare energy release goes into fast electrons. Others[2,3] found the flare soft X-ray emission to consist of bright, small kernels (knots and loops) embedded in a more diffuse halo. These kernels with a typical size of 5′ arc s and a temperature of 6–12 × 10⁶K emit in radio waves at 3.7 and 11 cm (ref. 4). The discovery of a radio brightness temperature equal to the temperature derived from the X rays and the radio size larger than in X rays shows that the observed radio emission is thermal (free–free) and the source optically thick at λ > 3.7 cm. Therefore, Kundu *et al.*[4] did not observe the fast electrons expected to heat the kernels. Here we present high time resolution measurements at 2.8 cm from the Effelsberg 100-m telescope and at decimetric and metric wavelengths with the ETH Zurich spectrometers. Both instruments have detected signatures of non-thermal particles.

We observed the microwave flux of McMath region 15856 on 2 March 1979. The Effelsberg telescope at 10.69 GHz yields a half-power beam width of 1.25 arc min. Simultaneous observations in the metric band by the Nançay heliograph and the Zurich digital spectrometer did not receive any signal in the 2-h observing period. However, decimetric registrations with the Zurich analogue spectrograph showed four groups of short, narrow-band spikes which coincided with the four largest microwave peaks of the observing period. This activity was also associated with four weak soft X-ray bursts as observed with the GOES 2 satellite. Figure 1 summarizes the data for one example. Note the following prominent properties of the radio emissions: (1) The time constant in decimetric and high-frequency microwaves is very small (2–3 s). (2) The radio bursts occur mainly in the rise phase of the soft X-ray emission (delay time of X-ray maximum 3–30 s). (3) The correlation between microwaves and decimetric radiation is excellent. (4) The amplitude of the microwave bursts is of the order of 2 SFU, much smaller than the bursts commonly observed by small telescopes monitoring the full solar disk and routinely reported in the flare bulletins.

These properties apply to all observed events and seem to be typical. All these events look very similar in microwave and X rays, but their shapes in the decimetric frequency–time plane show considerable variation. The flux ratio between single associated peaks in decimetre and microwaves fluctuates in a large range. The microwave emission has unusually short time scales and a very small amplitude. The bandwidth in decimetre waves is much smaller than commonly observed for type III bursts. These differences have led us to coin the the name 'blip' for the radio emission.

No other activity has occurred in the decimetric and soft X-ray bands during that period. A chance coincidence is out of question. In microwaves, however, many smaller peaks have been observed with similar characteristics. Of the four blips to be described here, three coincided with the maxima of subflares in McMath 15856.

A temperature of 10×10^6 K is derived for the plasma of the soft X-ray source from the ratio of the 1–8 Å and 0.5–4 Å intensities (correcting for line emission). The emission measure is 1.2×10^{48} cm^{-3}. X-ray kernels have the tendency to avoid flares with non-thermal radio bursts[2,3]. However, because the observed radio emission does not resemble impulsive radio bursts of conventional types and fluxes, we consider it very likely that the X-ray emission originates in kernels. This is supported by the fact that the observed temperature, emission measure and the correlation with subflares is exactly as in soft X-ray kernels[2]. Thus we adopt a source size of 5 × 10 arc s and a volume of 10^{26} cm^3. This yields a density of $\sim 10^{11}$cm^{-3}.

The optical depth of the kernel at 10.7 GHz is 0.19, and the thermal radiation amounts to 0.67 SFU. Because the observed peaks are a factor of 2 or 3 higher and do not correlate with the X-ray burst, we conclude that the thermal radiation is absorbed in the vicinity of the source. A non-thermal origin for the microwave blips is also suggested from their correlation with their decimetric counterpart which, by its spectrum, is certainly not thermal. Thus we consider non-thermal electrons with velocities β (in units of the speed of light) estimated from the collisional loss time t_c, where

$$t_c = 3.3 \times 10^{12} \frac{(1-\sqrt{1-\beta^2})^2}{n\beta\,(1-\beta^2)} \approx 3\text{s}$$

with the ion density n in cm^{-3}. From the observed decay time of ~3 s one derives $\beta = 0.4$ corresponding to 50-keV electrons. The observed energy input of 2.76×10^{28} erg observed in X rays requires a total number of 4×10^{35} fast electrons. If the X-ray source is heated by the collisional energy loss of these electrons, a total number, N_T, of 4×10^{35} is required.

To estimate the gyrosynchrotron radiation of these electrons in a magnetic field B we applied the emission formula given by

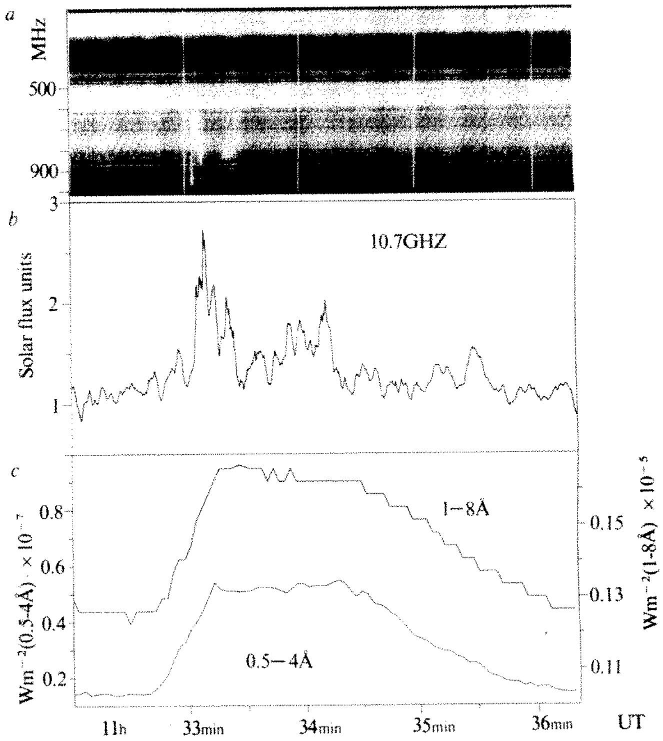

Fig. 1 Solar blip on 2 March 1979 in different wave bands. *a*, Spectrogram of the Zurich analogue spectrometer showing flux (bright) versus frequency (down) and time (right). Horizontal straight lines are all instrumental. The vertical lines are minute marks. The threshold is ~30 SFU. *b*, Total flux versus time observed by the 100-m telescope in Effelsberg (MPIfR, Bonn) of McMath region 15856. *c*, GOES 2 soft X-ray measurements in the bands 0.5–4 Å (left scale) and 1–8 Å (right scale).

0028-0836/81/210210—02$01.00

Bekefi[5] (formula 6.14). The number N of fast electrons present at any one time is their total number, N_T, times the ratio of the decay time and the total blip activity duration ($N=6\times10^{34}$). From the observed average flux of about 0.5 SFU and from the estimated free–free absorption (source $\tau=0.19$; foreground $\tau=1.5$, as required from the lack of thermal radiation) we arrive at $B=250$–300 G for low pitch angles and large angles (>60°) between the line of sight and magnetic field direction.

In the total number of electrons estimated above we have not included fast particles that avoid energy loss in the X-ray source by escape to regions of lower density. Only a small fraction, however, is needed to produce the observed decimetric blip presumably by some plasma emission process.

In conclusion, according to the above discussion the microwave signal of non-thermal electrons is not to be expected at frequencies below 10 GHz. Therefore the previous observations by Kundu *et al.*[4] probably refer to thermal emission of the hot plasma and not to fast particles. The discovery of decimetric signatures proves the presence of non-thermal particles in at least the larger microwave blips. Two important questions remain: first, is the observed rate of one blip (above 1 SFU at 10.7 GHz) in 25 min typical? Second, are the smaller fluctuations[6,7], which occur all the time, of the same nature? An extensive study involving major radio telescopes and the SMM satellite is in progress.

We acknowledge observational support by the Nançay group (M. Pick) and the financial support of the Swiss NSF for the construction of the Zurich radio spectrometers. E. F. and W. H. were supported by the Deutsche Forschungsgemeinschaft.

New positive ion species in the stratosphere

G. Henschen & F. Arnold
Max-Planck-Institut für Kernphysik, 6900 Heidelberg, FRG

Our understanding of atmospheric ions in the ionospheric region is far better than of those in the denser regions, the stratosphere and the troposphere. Mass spectrometric measurements conducted on rockets[1] and balloons[2–4] at altitudes above ~35 km recently revealed that the major ions are proton hydrates $(H^+(H_2O)_n$ and heteromolecular cluster ions identified as $H^+X_L(H_2O)_M$ (refs 2, 5) (X-ions), which probably are formed from proton hydrates by reactions involving a stratospheric trace gas X (ref. 2). The most likely candidate for X seems to be acetonitrile (CH_3CN) (refs 2, 6). The abundance ratio of X ions and proton hydrates increases with decreasing altitude from ~0.02 around 50 km to ~2 around 35 km. It has only been possible to detect ion species with number densities larger than about 6 cm^{-3}, corresponding to a fractional ion abundance of 3% around 35 km. We report here new balloon-borne positive-ion composition measurements around 34 km using improved mass spectrometers which allowed for an ion detection limit of ~0.02 cm^{-3} or 0.1%.

The instruments used have been discussed in detail elsewhere[2,5]. Improving the ion injection into the quadrupole mass filter and the efficiency of ion detection by the channeltron has increased the sensitivity. Thus, the overall ion transmission of the instrument was increased to ~20% depending on the mass resolution setting. Usually, an increase of mass resolution causes a decrease of ion transmission, particularly at higher masses. Decreasing the dark count rate of the channeltron from ~0.02 to 0.001 s^{-1} contributed to an increase of the signal-to-noise ratio and thereby to the sensitivity for ion detection, as the channeltron is operated in a saturated pulse counting mode. For a sufficiently large integration time (~10^5 s) a minimum detection limit of ~0.002 ions cm^{-3} or 0.0001% can be reached for average mass resolution. Considering a more realistic integration time of only 10^3 s the detection limit becomes ~0.2 ions cm^{-3} or 0.01%. If a more realistic minimum number of ion counts per mass peak of 10 rather than 1 were considered, the detection limit becomes ~2 ions cm^{-3} corresponding to a fractional ion abundance of 0.1%. When compared with detection limits reached in stratospheric ion composition measurements reported previously, this value is lower by a factor of ~30.

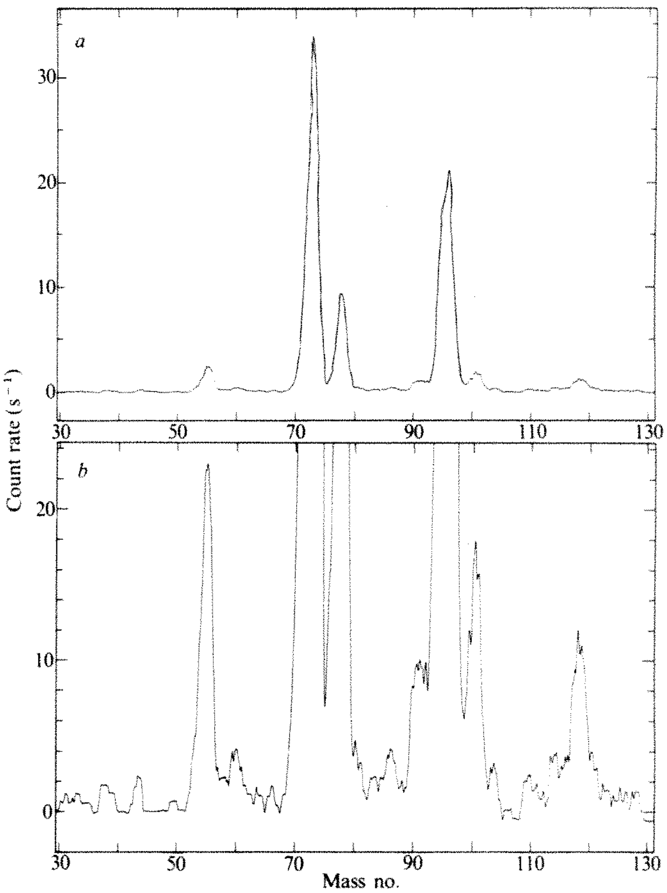

Fig. 1 *a*, Positive ion mass spectrum obtained at an altitude of 34 km (flight B 14). *b*, The same spectrum at an expanded scale for relative count rates. A relatively low mass resolution was used to reach higher sensitivity.

Three balloon-borne positive ion composition measurements were made around 34 km. Characteristic data of the experiments are given in Table 1. The mass range of the instruments which extended from 0 to 280 AMU was scanned in ~11 s to allow for a high time resolution. Data measured at the same altitude were integrated during the data reduction by superimposition of a large number of individual mass scans.

The observed mass peaks may be divided into three groups having fractional count rates in the ranges: (1) 10–100%; (2) 1–10%; and (3) 0.1–1%. Group (1) includes the peaks 73, 78 and 96 AMU for all three flights; of these, either 73 or 78 dominate. Group (2) includes 55, 60, 91, 101 and 119 AMU. Among these, peaks 60 and 91 do not exceed the 1% level in all flights. All ions belonging to group (1) and (2) have already been detected previously and were identified as members of the ion families $H^+(H_2O)_n$ (55, 73, 91), $H^+X(H_2O)_l$ (60, 78, 96), and $H^+X_2(H_2O)_l$ (101, 119) (refs 1, 2, 5).

Table 1 Measured minor ion species having fractional count rates <1% and not belonging to the major ion families $H^+(H_2O)_n$ and $H^+X(H_2O)_n$

Ion	B9	B10	B14	$A^+(H_2O)$	$A^+(H_2O)_2$	$A^+(H_2O)_3$	$A^+X(H_2O)$	$A^+X(H_2O)_2$	A^+
45	+	+		$\underline{27}$	9	—	—	—	27

110	+	+	+	92	$\underline{74}$	56	51	$\underline{33}$	33
117			+	99	81	$\underline{63}$	58	40	63
122	+		+	104	86	$\underline{68}$	$\underline{63}$	$\underline{45}$	63
125			+	107	89	71	68	$\underline{48}$	48
128		+		110	92	$\underline{74}$	69	51	74

Mass numbers for ion cores A^+ are also given assuming that the ions have the form $A^+(H_2O)_n$ or $A^+X(H_2O)_n$ with X having mass 41. The most probable core ions A^+ are underlined. All mass numbers given have an uncertainty of ±1 AMU. The balloon flights B9, B10 and B14 took place over southern France on 30 April, 21 June and 26 September 1980 and reached float altitudes of 33, 34 and 34 km.

Several smaller peaks falling into group (3) can also easily be identified. They include 37 ± 1, 42 ± 1, 45 ± 1, 49 ± 1, 58 ± 1, 83 ± 1, 86 ± 1, 104 ± 1, 110 ± 1 and 114 ± 1. The mass identification for these peaks is less certain as their shapes are not always well defined due to a small number of total ion counts contained in the peak. In other cases, small peaks are located besides large peaks and therefore appear only as shoulders. An example for a mass spectrum (flight B 14) it shown in Fig. 1. A mass uncertainty of ±1 AMU must therefore be allowed for. Besides these 10 ions more members of group (3) were apparently detected in particular in the mass regions 60–73, 78–91 and 110–130. These peaks are only poorly defined and therefore uncertain. The count rates in these regions, however, are significantly above the background signal. Table 1 lists some peaks belonging to group (3) (out of 16) and indicates the flights in which the peaks were observed. Figure 2 shows the measured fractional ion count rates for the major families: (1) $H^+(H_2O)_n$; (2) $H^+X(H_2O)_n$; and (3) $H^+X_2(H_2O)_n$. The average numbers of ligand molecules are 2.7, 2.1, and 1.9. Evidently, incorporating X into the cluster ions decreases the average ligand number a result consistent with previous stratospheric measurements[5] and laboratory studies[6,7].

The total fractional count rates for the above ion families are 48.2, 42.0 and 5.9%. Considering that families (2) and (3) are formed by incorporation of X into ions of families (1) and (2), the incorporation of a second X seems much less efficient than that of the first X. This contrasts with our previous measurement[2,5] which revealed that the efficiency for incorporation of one and two X molecules is about the same while that for the third X is much lower. The latter was interpreted in terms of backswitching of $H^+X_3(H_2O)_n$ ions with H_2O or of thermal detachment of an X from these ions[5,6]. The present finding may suggest that due to the higher stratospheric temperature (240 K) during the B14 flight these processes even affected $H^+X_2(H_2O)_n$ ions.

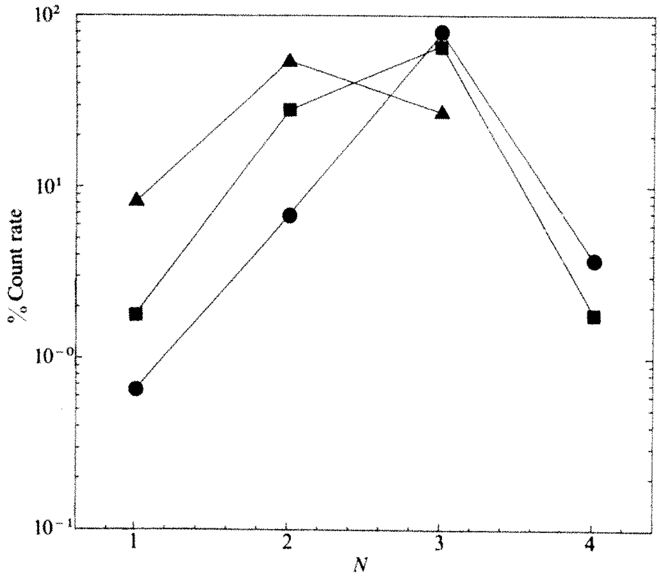

Fig. 2 Per cent count rates measured in flight B 14 for members of the ion families $H_3O^+(H_2O)_n$ (●), $H^+X(H_2O)_n$ (■) and $H^+X_2(H_2O)_n$ (▲) as function of the total number of ligands N.

Three out of the minor ions 37 ± 1, 42 ± 1, 83 ± 1 and 114 ± 1 may be readily identified according to their masses as H^+H_2O, $H^+X_1H^+X_2$ and $H^+X(H_2O)_4$ which are members of the main ion families. For 37 ± 1, 83 ± 1 and 114 ± 1 this is supported by chemical arguments as the abundances of these ions fit very well the distributions shown in Fig. 2. The other minor ions (Table 1) do not belong to the major ion families. Like the X ions they are probably formed from proton hydrates by reactions involving trace molecules Y. They may be formed from X-ions if Y molecules have sufficiently large proton affinities. Thus, the reactions involving Y

$$H^+(H_2O)_n + Y \rightarrow H^+Y(H_2O)_{n-1} + H_2O \qquad (1)$$

$$H^+X(H_2O)_i + Y \rightarrow H^+YX(H_2O)_{i-1} + H_2O \qquad (2a)$$

$$\rightarrow H^+Y(H_2O)_i + X \qquad (2b)$$

and the subsequent reaction involving X

$$H^+Y(H_2O)_{n-1} + X \rightarrow H^+YX(H_2O)_{n-2} + H_2O \qquad (3)$$

would give rise to the formation of ions having the general form $H^+Y(H_2O)_n$ and $H^+YX(H_2O)_n$. On their formation the product ions containing Y and possibly also X undergo rapid hydration and individual equilibrium distributions should be established for each ion family.

For ions of the types $H^+Y(H_2O)_n$ and $H^+YX(H_2O)_n$ the distributions should be similar to those for $H^+X(H_2O)_n$ and $H^+X_2(H_2O)_n$ ions (Fig. 2). This is also suggested by our laboratory measurements of cluster ion distributions which involved X and Y molecules as, for example, CH_3CN and CH_3OH (ref. 6). Consequently, if the minor ions listed in Table 2 have the form $H^+Y(H_2O)_n$ or $H^+YX(H_2O)_n$ they would be expected to contain two or three ligands. Species containing one and four ligands should be much less abundant and therefore were probably not detectable.

The total fractional abundances for the families $H^+Y(H_2O)_n$ and $H^+YX(H_2O)_n$ depend on the abundance of Y. A steady-state treatment of the formation of ions containing Y by processes (1) and (2) and of their loss by ion–ion recombination (rate coefficient α) yields

$$\{n(H^+(H_2O)_n + n(H^+X(H_2O)_n)\}kn(Y) = \{n(H^+Y(H_2O)_n) + n(H^+YX(H_2O)_n)\}\alpha n_- \qquad (4)$$

where $n(\ )$ denotes the number density of the species inside the bracket and n_- is the total negative ion concentration. Assuming that the minor ions are of the type $H^+Y(H_2O)_n$ or $H^+YX(H_2O)_n$

and considering that their total fractional abundance is of the order of 0.01, expression (4) yields $n(\mathrm{Y})$ of the order of 1,000 cm^{-3}. Here, k, α and n_- were taken as 2×10^{-9} $cm^3\,s^{-1}$, 10^{-7} $cm^3\,s^{-1}$ and 2,000 cm^{-3} (ref. 5). Thus, Y molecules seem to be ~100 times less abundant than X whose concentration is of the order of 10^5 cm^{-3} (refs 2, 5). Therefore, it is unlikely that ions containing more than one Y were detected. The total abundance of the $H^+YX(H_2O)_n$ family should not exceed that of the $H^+Y(H_2O)_n$ family by much more than a factor 2. Considering an X concentration of the order of 10^5 cm^{-3}, as inferred previously, the time scale for process (3) may be as small as the ion recombination lifetime.

By analogy to the X-ions the Y-ions might be expected to have the form $HY^+(H_2O)_2$ and $HY^+(H_2O)_3$. Mixed ligand clusters having the form $HY^+X(H_2O)_n$ with n being mostly 1 or 2 may also be present in lower fractional abundances. It is also conceivable that instead of a protonated core H^+Y cluster ions contain an atomic core A^+ which has a low ionization potential as, for example, a metal atom. Assuming that the minor ions listed in Table 1 contain two or three ligands which may be H_2O or an X molecule and H_2O molecules mass numbers for the ion cores may be inferred (see Table 1). As the same core may be contained in more than one of the detected ion species the identification of a particular core becomes increasingly likely the more ion species that can be related to it. Unfortunately, however, because some of the minor ions are also sufficiently abundant to be detectable they may be masked by large adjacent mass peaks which complicates the grouping of ion species into families.

Table 2 Tentative identifications for core ions, and proton affinities for protonated molecules

Mass	Core ion	Mass	Proton affinities (kcal mol^{-1})
23 ± 1	Na^+	23	—
27 ± 1	Al^+	27	—
	H^+HCN	28	178.9 ~ 179
32 ± 1	H^+CH_3OH	33	182
	$H^+CH_3NH_2$	32	217
48 ± 1	$H^+CH_2O_2$	47	178
	H^+CH_4S	49	186
	$H^+C_2H_6O$	47	187
63 ± 1	H^+CH_3NO2	62	188
74 ± 1	$H^+C_2H_3NS$	74	187

The minimum number of cores that the 14 minor ion species listed in Table 1 may be related to is 6, including the core masses 23 ± 1, 27 ± 1, 32 ± 1, 48 ± 1, 63 ± 1 and 74 ± 1. However, because there are alternative mass identifications of cores the core masses inferred above are not unique. For example, ions 63 ± 1 and 81 ± 1 which may be hydrates of a core 27 ± 1 and contain two and three water ligands were found in flight B14 to have fractional count rates (relative to the total count rate of this family) of ~25 and 75%. These values are almost the same as those of the corresponding hydrates of H^+X (see Fig. 2) which supports the above identification for 63 ± 1 and 81 ± 1.

The ion composition data previously obtained by rocket-borne mass spectrometers were affected by strong collision-induced cluster ion dissociation and had revealed the presence of an ion 29 ± 2 which has not yet been satisfactorily explained. This ion species may, in fact, be identical to the above ion core 27 ± 1.

Tentative identifications for the above ion cores are given in Table 2. No gaseous compound from which the cores may have formed has so far been detected in the stratosphere. Although CH_3OH and CH_3NO_2 have been considered as stratospheric trace gases[9]. The core ion 27 ± 1 may also be Al^+. However, Al^+ reacts efficiently with O_3 to give AlO^+ (F. Fehsenfeld, personal communication) which makes it an unlikely candidate.

Contaminant gases desorbing from the balloon or the payload may reside for a relatively long period of time in the vicinity of the payload as this moves only at low speed (1–10 cm s^{-1}) relative to the atmospheric gas. Thus, the payload may, in fact, be surrounded by a cloud of contaminant gases containing compounds which have the potential to react with atmospheric ions approaching the payload. In this respect, balloon-borne ion composition measurements differ greatly from rocket-borne measurements in the stratosphere which should not be affected by contamination as relative velocities are of the order of 1 km s^{-1} and thus contaminants should be carried away from the mass spectrometer by the gas flow. Therefore, ions detected in rocket-borne measurements should at least contain the same ion cores as the ambient stratospheric ions. As mentioned before, they may, however, have lost ligand molecules due to collisional dissociation.

The ions 42 ± 2 and 29 ± 2 detected by the rocket measurements should, therefore, represent cores of stratospheric ions. Whether other core ions inferred from the present measurements are also unaffected by contamination cannot be decided.

Future balloon-borne ion composition measurements should therefore be carried out in conditions of rapid motion of the probe relative to the atmospheric gas which reduces the chance that atmospheric ions collide with contaminants. Technically, this can be achieved by using a balloon which descends at a controlled speed of about 1 m s^{-1} which still allows for sufficient integration time.

We thank E. Ferguson and P. Crutzen for helpful discussions and F. Fehsenfeld for information on recent unpublished measurements of Al^+ reactions. Part of this project was funded by the Bundesministerium für Forschung und Technologie, through Gesellschaft für Strahlen-und-Umweltforschung.

Carbon dioxide, ammonia and the origin of life

T. M. L. Wigley* & P. Brimblecombe†

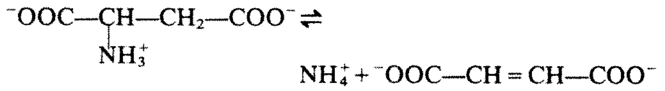
Climatic Research Unit*, and School of Environmental Sciences†,
University of East Anglia, Norwich NR4 7TJ, UK

Stellar evolution theory predicts that the luminosity of the Sun has increased by ~30% over the past 4,000 Myr. Yet geological and biological evidence indicates that the climate of the Earth between 3,000 and 4,000 Myr ago was as warm as, or warmer than, today. This apparent contradiction, the 'faint Sun paradox', has been resolved by invoking the greenhouse effect of radiatively active gases in the early Earth atmosphere. Sagan and Mullen[1] first suggested that the concentration of ammonia in the early atmosphere was around 10–100 p.p.m., sufficiently high to counteract the reduced luminosity. However, because ammonia photodissociates readily and has a short atmospheric residence time[2,3], such a concentration could be maintained only by a large continuous ammonia source. For this reason, carbon dioxide is now considered to have been the radiatively active gas[4–7]. Some atmospheric ammonia is, nevertheless, required to provide conditions conducive to the origin of life[8]. We now show that, if the early Earth's atmosphere contained high concentrations of CO_2, as suggested above, then the chemical conditions required for life to begin can be maintained by very low ammonia partial pressures, rather similar to those observed today.

0028–0836/81/210213—03$01.00

The conditions believed necessary for life to have evolved on Earth are: the existence of liquid water; and aqueous chemical conditions which permit a stable solution of simple amino acids, the chemical precursors of life. Organic molecules may form in the absence of ammonia, but ammonia is probably essential to ensure the stability of amino acids. Amino acid stability depends on temperature, pH and the concentration of dissolved NH_3 (ref. 8). The early evolution of life, therefore, places constraints on the chemistry of early aqueous environments, and hence on the atmospheric concentration of ammonia. To quantify these constraints, we will consider two end-member aqueous systems, a seawater and a freshwater, as possible life-origin environments. First, however, we will determine a general lower bound to aqueous ammonium ion activity as a function of pH and P_{NH_3}.

A minimum ammonium ion activity is required to prevent the decomposition by reversible deamination of amino acids to the corresponding hydroxy acids. Bada and Miller[8] consider the deamination of aspartic acid to fumaric acid



$$^{-}OOC{-}\underset{NH_3^+}{CH}{-}CH_2{-}COO^{-} \rightleftharpoons NH_4^+ + {}^{-}OOC{-}CH{=}CH{-}COO^{-}$$

$$pK = -8.22 + 2.276/T + 0.0106T;\ pX \equiv -\log_{10} X,\ T \text{ in K} \quad (1)$$

and suggest that a necessary condition for life to begin is that the ratio of total aspartate to total fumarate should not fall much below one. At near-neutral pH the aspartate-fumarate ratio sets a lower limit to the ammonium ion activity of around $10^{-2.6}$ (at 25 °C). At lower pH values, higher ammonium ion concentrations are required to offset the higher stability of fumarate to protonation. From equation (1) and the acidity constants for aspartic and fumaric acids we have

$$\text{Asp}^{\text{TOT}}/\text{Fum}^{\text{TOT}} \approx a\text{NH}_4^+\, 10^{-pK}\alpha_a/\alpha_f \quad (2)$$

Here

$$\alpha_a = \frac{K_a'''}{a\text{H}^+} + 1 + \frac{a\text{H}^+}{K_a''} + \frac{(a\text{H}^+)^2}{K_a'} \quad \text{and} \quad \alpha_f = 1 + \frac{a\text{H}^+}{K_f''} + \frac{(a\text{H}^+)^2}{K_f'}$$

where K_a''', K_a'' and K_a' are the dissociation constants for aspartic acid, K_f'' and K_f' those for fumaric acid, and $a\text{H}^+$ ($\equiv 10^{-pH}$) is the hydrogen ion activity. At 25 °C, $pK_a''' \approx 9.9$, $pK_a'' \approx 3.8$, $pK_a' \approx 1.8$, $pK_f'' \approx 4.4$ and $pK_f' \approx 7.4$. Equation (2) is obtained from the acidity reactions of aspartic and fumaric acids neglecting the effect of ionic strength on the activities of the organic acid species. The stability constants quoted are from ref. 10. For $5.3 \leqslant pH \leqslant 8.4$, $\alpha_a \approx 1$, and for $pH \geqslant 5.4$, $\alpha_f \approx 1$. The isopleth $\text{Asp}^{\text{TOT}}/\text{Fum}^{\text{TOT}} = 1$ (at 25 °C), curve (1) on Fig. 1, places an approximate lower limit on the ammonium ion activity for life to evolve.

Equation (2) and the constraint $\text{Asp}^{\text{TOT}}/\text{Fum}^{\text{TOT}} = 1$ determine a minimum ammonium ion activity as a function of pH. The corresponding ammonia partial pressures are determined by the dissociation reaction of NH_4^+. From the mass action equation for this reaction we have

$$pP_{NH_3} = pK_a - pK_{H,a} + p(a\text{NH}_4^+) - p\text{H} \quad (3)$$

where $K_{H,a}$ is the Henry's law constant for ammonia ($pK_{H,a} = -1.785 - 34.85(298.15 - T)/5.7118\ T$, based on free energy and enthalpy data in ref. 11) and K_a is the dissociation constant for NH_4^+ ($pK_a = 0.6322 - 0.001225\ T - 2835.76/T$; ref. 12). Lines of constant ammonia partial pressure at 25 °C based on this equation are shown in Fig. 1.

We now consider the case where life began in a seawater environment in which chemical conditions were controlled by large-scale factors. In these circumstances, an extreme upper limit to the ammonium ion concentration may be set by dissolving all the available atmospheric nitrogen in the oceans as ammonia[8] (curve (2) in Fig. 1). A more realistic upper limit has been suggested[8] based on the cation exchange properties of clay minerals (curve (3) in Fig. 1). The zone between curves (1) and (3) in Fig. 1 defines the range of suitable ammonia partial pressures for life to evolve. pH is the main controlling factor. As the early oceans were probably much more acidic than today[13], extremely low ammonia partial pressures (as low as 10^{-8} atm at pH 5.6, see Fig. 1) would be sufficient to ensure a ratio of aspartate to fumarate in excess of 1. Present-day values, while subject to some uncertainty due to measurement difficulties, are of the order of $2\text{–}6 \times 10^{-8}$ atm over ocean areas[14,15].

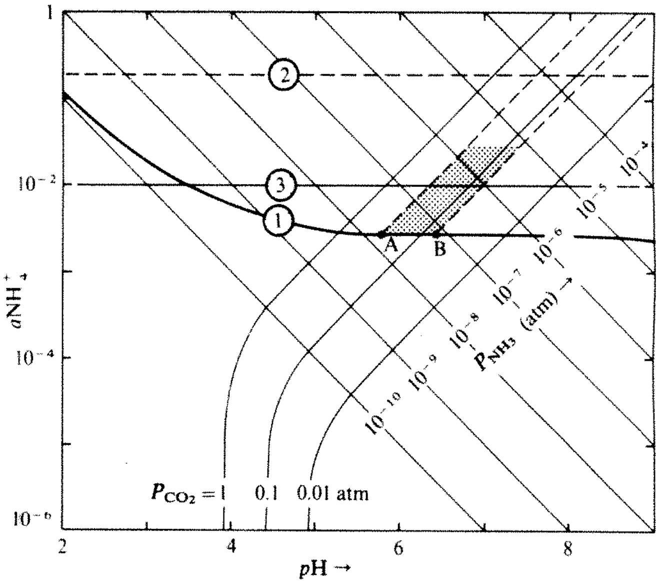


Fig. 1 Curve (1) and lines (2) and (3) define approximate lower (1) and upper (2 or 3) boundaries for ammonium ion activity as a function of pH for the amino acid stability required to allow life to evolve. The ordinate gives ammonium ion activity on a log scale. Isopleths of constant P_{NH_3} are shown as diagonal lines sloping from left to right calculated using equation (3). The zone between curves (1) and (3) is that which would be suitable for life to begin in an oceanic environment. At moderate pH ($\leqslant 6$), suitable conditions would prevail even for low P_{NH_3} ($\leqslant 10^{-8}$ atm). In a freshwater environment, chemical conditions are additionally influenced by P_{CO_2}. Curves of constant P_{CO_2} are also shown (based on equation (8)). These relate the four variables, P_{CO_2}, P_{NH_3}, $a\text{NH}_4^+$ and pH in freshwater environments. A 'life zone' (stippled region) is defined by the range of P_{CO_2} partial pressures thought to have prevailed between 3,500 and 4,250 Myr BP (ref. 20), and by the amino acid stability curve (1). This figure is based on thermodynamic data for 25 °C.

There is, however, no *a priori* reason to assume that life originated in the early oceans. We must, therefore, consider the small-scale end-member possibility, a local 'fresh' water environment. Here the high atmospheric carbon dioxide partial pressures thought to have prevailed at the time are likely to have controlled pH values. To evaluate the effect of high P_{CO_2} on pH we consider a simple model in which only ammonium and carbonate species are present. Charge balance necessitates that

$$m\text{NH}_4^+ + m\text{H}^+ = m\text{OH}^- + m\text{HCO}_3^- + 2m\text{CO}_3^= \quad (4)$$

where m denotes molality. For $P_{CO_2} \geqslant 10^{-5}$ atm, $pH \leqslant 9$ and $P_{NH_3} \geqslant 10^{-10}$ atm, ammonium and bicarbonate ions are the dominant species and the charge balance equation becomes

$$m\text{NH}_4^+ = m\text{HCO}_3^- \quad (5)$$

Within the accuracy of this result molalities may be replaced by activities, as the activity coefficients of NH_4^+ and HCO_3^-, as determined by the extended Debye-Hückel formulation, are approximately equal. Hence

$$a\text{NH}_4^+ = P_{CO_2} K_{H,c} K_c / a\text{H}^+ \quad (6)$$

This result comes directly from equation (5) using $a\text{H}_2\text{CO}_3^* = K_{H,c} P_{CO_2}$ where $pK_{H,c} = 14.0184 - 0.015264\ T - 2385.73/T$ is the Henry's Law constant for carbon dioxide[16], and the mass

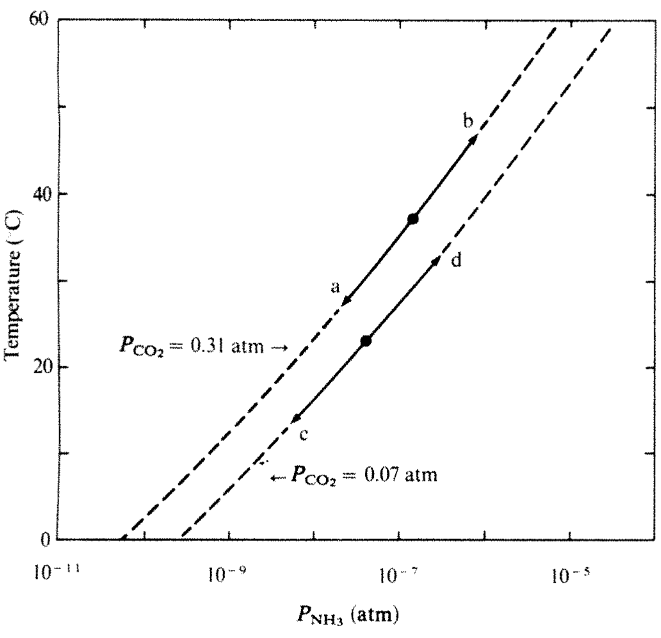

Fig. 2 The effect of changing temperature and P_{CO_2} on the minimum ammonia partial pressure needed for life to evolve. The points a and b span conditions which are thought to have prevailed around 4,250 Myr BP, while c and d span conditions for 3,500 Myr BP. If temperature is lower, then lower P_{NH_3} values are sufficient. The coupling of temperature and P_{CO_2} through the greenhouse effect means that life could have originated at lower P_{NH_3} for lower P_{CO_2} (see points a and c), in spite of the fact that the direct influence of P_{CO_2} is in the opposite direction.

action equation for the dissociation of $H_2CO_3^*$, $aHCO_3^- \, aH^+ = K_c \, aH_2CO_3^*$ where $pK_c = -14.8435 + 0.032786\,T + 3404.71/T$ (ref. 16). $H_2CO_3^*$ is the sum of dissolved carbon dioxide and carbonic acid. Equation (6) can be written in logarithmic form as

$$pP_{CO_2} = -pK_c - pK_{H,c} + p(aNH_4^+) + pH \quad (7)$$

which allows isopleths of constant carbon dioxide partial pressure to be constructed on Fig. 1. Strictly this linear relationship is only valid for $P_{NH_3} \geqslant 10^{-10}$ atm. Although lower ammonia partial pressures are not relevant here the more general relationship, obtainable from equation (4),

$$10^{-pH} + aNH_4^+ \approx 10^{pH}[10^{-14} + 10^{-7.8} P_{CO_2}(1 + 10^{-10+pH})] \quad (8)$$

has also been used in constructing Fig. 1. In deriving equation (8) activity coefficients have been neglected (compare with derivation of equation (7)), but this results in no significant loss of accuracy.

Life is believed to have originated within the Earth's first billion years, possibly earlier than 3,000 Myr ago (ref. 17; but see also refs 18 and 19). Hart[20] estimates that the atmospheric P_{CO_2} was 0.07 atm at 3,500 Myr BP and 0.31 atm at 4,250 Myr BP, and values of this magnitude are required to give a sufficient greenhouse effect to compensate for reduced solar luminosity[4–7]. The range 0.07–0.31 atm P_{CO_2} therefore determines the range of pH values in early freshwater environments. Combined with the lower limit to aNH_4^+ derived earlier this range defines a 'life zone' in Fig. 1 (stippled region) within which chemical conditions would have been conducive to the origin of life. Note that the upper limit imposed by cation exchange considerations (curve (3) in Fig. 1) need not apply to the freshwater environment.

Figure 1 shows immediately that for life to evolve the local P_{NH_3} pressure must exceed 10^{-8} atm. Present-day values in non-oceanic areas are usually less than this value, but may exceed it. Values quoted recently range between 0.1 and 1.2 10^{-8} atm. (refs 14 and 21), and even higher values have been reported[22]. All these data may reflect local organic processes and so are not strictly relevant to conditions which might have prevailed before the origin of life. However, similar levels could easily be attained by the catalytic photochemical reduction of atmospheric nitrogen by TiO_2 in desert sands. Henderson-Sellers and Schwartz[23] postulate a 100-fold increase above present productivity by this mechanism to estimate a total atmospheric ammonia loading of 10^{13} kg, which corresponds to a partial pressure of around 1.9×10^{-6} atm. Using their figures, and present productivity levels, gives an estimated global atmospheric ammonia mass of 7×10^{10}–7×10^{12} kg, equivalent to a partial pressure between 1.3×10^{-8} and 1.3×10^{-6} atm. While these values may be a little high compared with present-day measurements[14,21] the lower end seems reasonable for local environments.

Figure 1 only shows the results for 25 °C, but we have performed the same calculations at other temperatures. The effect of temperature is shown in Fig. 2 where the ammonia partial pressure minimum spanned by the freshwater 'life zone' in Fig. 1 (points A and B) is plotted as a function of temperature. As temperature decreases the minimum ammonia partial pressure decreases. Mean global temperature estimates corresponding to the limiting P_{CO_2} values of 0.31 and 0.07 atm assumed above have been given by Owen *et al.*[6]. Assuming a global temperature range of ± 10 °C we can define regions in Fig. 2 which correspond to the range of P_{CO_2} and temperature values likely for the early Earth. If life began in a low salinity aqueous environment (such as might exist where local conditions today are conducive to the inorganic production of ammonia) then local P_{NH_3} values around 10^{-7} atm and possibly as low as 10^{-8} would would have been sufficient to have maintained a suitable ratio of amino to hydroxy acids. Global mean P_{NH_3} may well have been even smaller.

Life may have been originated in highly saline conditions; the seawater case considered initially. In this case low ammonia partial pressures ($\leqslant 10^{-8}$ atm) are still sufficient, provided the pH is relatively low ($p\text{H} \leqslant 6$) compared with modern oceanic environments. Thus, high partial pressures of ammonia are not essential precursors for the origin of life in either of the systems considered here. Although our P_{NH_3} estimates are substantially less than some other estimates ($\sim 10^{-4.5}$ atm, see refs 1, 20, 24), and much less than the limit ($\sim 10^{-5}$ atm) for which a noticeable greenhouse effect might occur[3,23], such values seem unlikely because of the rapidity with which ammonia is photodissociated[2,3]. Our values are similar to values which occur locally today. A strongly reducing atmosphere does not seem to be necessary for the origin of life.

Archaeomagnetic secular variation record of Mount Vesuvius

G. S. Hoye

Institute of Earth and Planetary Physics, University of Alberta, Edmonton, Alberta, Canada T6G 2J1

The lavas produced by historically recorded eruptions of Mt Vesuvius, and the Herculaneum mudflow resulting from the AD 79 eruption have been investigated archaeomagnetically. The mudflow carries a magnetically hard remanence, the direction of which is significantly different from that of the present-day field, suggesting that the remanence is primary. The secular variation curve for Vesuvius agrees well with the Rome record and with other curves from Italy and London. A model for westward drift which accounts for certain features of secular variation in Europe over the past 200 yr requires a mean deceleration rate of 0.004 deg yr^{-2}. This is less than the current rate, suggesting that the deceleration rate was smaller 200 yr ago than it is today.

The historical lava-producing eruptions of Mt Vesuvius between AD 1631 and 1944 have recently been mapped in detail[1]. Earlier events are poorly documented except the Plinian eruption of AD 79 which produced no significant lava. The period covered by the flows and the proximity of the volcano to Rome, where direct compass observations have been recorded since the sixteenth century, make an archaeomagnetic investigation particularly attractive because it is possible to compare the observatory with the archaeomagnetic records.

Eleven dated lava flows were sampled: where exposure permitted, flows were sampled at two or more sites (Table 1) located to obtain the greatest possible coverage of each flow. Five orientated 25-mm cores were collected at each site using routine techniques. Twenty orientated specimens of the mudflow which engulfed Herculaneum during the AD 79 eruption were collected from inside two adjacent rooms that had been filled completely by the mud. The finest silty material exposed was sampled by pressing small plastic boxes into prepared vertical surfaces.

Routine alternating field demagnetization indicated that the remanence at all sites was essentially single-component and stable. Angular shifts between demagnetization steps were small and random, and the mean median destructive field was close to 200 Oe. The natural remanent magnetization (NRM) and the cleaned flow mean directions are not significantly different (Table 1), but in all cases the precision is improved (average α_{95} is 2.7° and 1.9° respectively) and consequently the cleaned results are preferred.

The cleaned directions are plotted in Fig. 1*a*. The early part of the curve (excluding the point for AD 79) is indicated by a dashed line because this 330-yr span is defined by only two points. The general features of the curve are: a shift from shallower inclinations between the fourteenth and seventeenth centuries, and an incomplete clockwise elliptical loop in the subsequent period up to the present.

Observations during the past few centuries show that the curve of secular variation in Europe has been proceeding in a near-elliptical clockwise loop; Fig. 1*b* shows the curve for Rome. The shapes of the curves in Fig. 1*a* and *b* agree, bearing in mind that the 95% confidence limits on the Vesuvian directions are typically 1° or 2°. Inclinations at Vesuvius are expected to be ~1° shallower due to the latitude difference, but even after allowing for this, the Vesuvian curve remains 2° or 3° too shallow. A similar discrepancy was noted in the lavas of Mt Etna by Tanguy[2] who suggested that it was caused by magnetic refraction. Tanguy's results are replotted in Fig. 1*c*. The latitude difference requires that this curve be shifted ~3° to steeper inclinations for comparison with the Vesuvian results, and when this is done the elliptical portions of the two curves show good agreement. There is, however, a significant difference in the early parts of the curves: Tanguy's curve seems to describe part of a counterclockwise loop with no indication of movement from shallower inclinations. Mt Etna is only 300 km south of Ischia and it seems unlikely that the difference is due to real variations in the non-dipole field. The discrepancy does depend to a large extent on the point for the lava flow of 1329. If this flow were wrongly identified (the incompleteness of early records makes this a possibility) the point may be disregarded, and this brings the two curves into better agreement over a longer interval. Tanguy expressed doubt about the reliability of the date.

It is interesting to compare the present observations with the record for London[3] which displays a large shift from shallower inclinations between AD 1300 and 1600 followed by the well-documented clockwise elliptical loop. The corresponding movement in Italy is not so large, but identical angular displacements are not to be expected because the two localities are

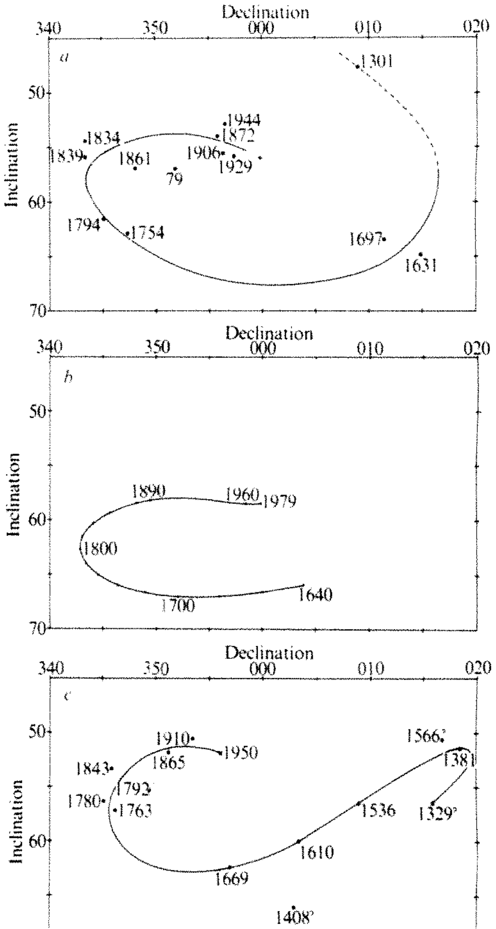

Fig. 1 *a*, The secular variation record for Mt Vesuvius. The dated points show the cleaned flow mean directions in Table 1. The present field direction is indicated by the cross. The direction for AD 1301 is from the lava del' Arso, Ischia[6] which is only 40 km to the west of Vesuvius. The point for AD 79 is obtained from the mudflow at Herculaneum. *b*, The secular variation record for Rome derived from observatory records. 1979–60 supplied by F. Molina (personal communication); 1890–1640 taken from ref. 7. Bauer's reconstruction for the period 1640–1508 should be disregarded although the easterly declination is not in doubt. Bauer describes an observation of declination 005° for 1436, and there is a record of declination 007° for the eastern Mediterranean in the mid-sixteenth century[8]. *c*, The secular variation record for Mt Etna from Tanguy[2]. A question mark by a point indicates that he doubted the date of the flow sampled. The point for 1950 is from ref. 9.

Entries in normal type refer to sites. Those in bold type give flow mean data. The first line of each entry (site or flow) refers to the NRM, the second to the partially demagnetized remanence. In cases where there is only one site per flow, site and flow means are the same. *J*, site or flow mean intensity of magnetization in 10^{-3} e.m.u. cm^{-3}; Dec, declination; Inc, inclination; α_{95}, Fisherian 95% confidence cone about the mean; *k*, Fisherian precision parameter; *N*, number of individually orientated specimens used for the statistics. One core from a site in the flow of 1754 was misorientated and its direction rejected.

* Taken from ref. 6. † Dates are all AD and are taken from the map of Principe[1]. Flows shown on the available topographical maps are not always reliably identified. ‡ Mudflow.

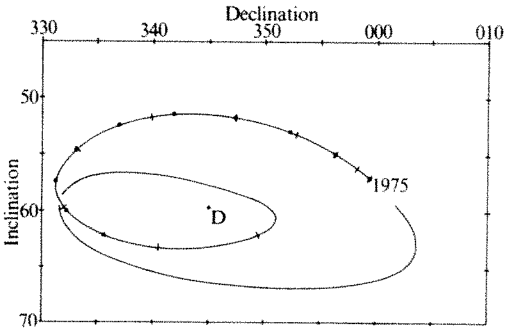

Fig. 2 Two models for the secular variation curve at Vesuvius, based on the IGRF75 representation of the main field. The dots show the predicted direction at 100-yr intervals from 1975, for a uniform drift rate of 0.1 deg yr^{-1}. The transverse bars give the direction at 25-yr intervals from 1975, for a deceleration rate of 0.004 deg yr^{-2} to a velocity of 0.1 deg yr^{-1} in 1975. Point D indicates the dipole field direction.

far enough apart to be affected in different amounts by the same non-dipole anomalies.

It is not possible to extend the secular variation curve to include the point for Herculaneum because of the interval of 1,200 yr between this point and that for Ischia. The direction for Herculaneum, which lies within the recent ellipse, is not unreasonable, however. In the London record, the direction for AD 79 lies just outside the ellipse. This similarity in position, and the stability of the remanence, suggest that the mudflow did indeed record the ambient field direction at the time of emplacement. The mechanism of magnetization remains uninvestigated but it may be a shear-induced remanence[4] acquired when the mud came to rest.

A theoretical secular variation curve for Vesuvius based on the 1975 International Geomagnetic Reference Field (IGRF75) is illustrated in Fig. 2. The direction of the dipole component of the main field, which is defined by the first three spherical harmonic coefficients, has remained effectively constant since 1829 whereas the dipole moment has decreased by 6%. In the model the dipole contribution is taken as fixed, and the non-dipole field, which is given by the higher-order coefficients, is driven westwards at the rate of 0.1 deg yr^{-1}. This rate is a reasonable estimate for 1975 and is taken from ref. 5. The secular variation curve for this model consists of a double clockwise loop about the dipole direction (Fig. 2). Although the whole curve is shifted to the west because of the orientation of the stationary dipole, the ranges of declination and inclination and the general elliptical shape are comparable with observation (Fig. 1). However, the time scale, which is determined by the rate of westward drift, is not suitable. For example, the time of maximum westward declination which was ~1810 occurs in the model ~1250. In fact the model is in fair agreement with observation only in the present century. Better agreement over the past two centuries can be obtained if the westward drift is allowed to decelerate. A first-order calculation for a uniform deceleration which brings the time of maximum westward declination to ~1810 (Fig. 2) yields a mean deceleration of 0.004 deg yr^{-2}. This is about half the observed rate, averaged over the past three decades of 0.01 deg yr^{-2} (derived from Fig. 2 of ref. 5). The same calculation for London yields the same mean deceleration, which suggests that westward deceleration of the non-dipole field has been occurring on a continental scale in Europe over the past two centuries. The absence of a double loop in the record implies that the model breaks down after a few centuries, and this is in accordance with the recognized transient behaviour of non-dipole features.

This work was supported by the Natural Sciences and Engineering Research Council of Canada and by the President's Fund of the University of Alberta. The samples from Herculaneum were collected under permit No. 4239 issued by the

Soprintendenza Archeologica di Napoli e Caserta. I thank M. E. Evans for fruitful discussions and R. Scandone for assistance in the field.

Stromatolites at ~3,500 Myr and a greenstone–granite unconformity in the Zimbabwean Archaean

J. L. Orpen & J. F. Wilson

Geology Department, University of Zimbabwe, PO Box MP 167,
Mount Pleasant, Salisbury, Zimbabwe

Two controversial areas of geological endeavour are the establishment of the antiquity of life and the tectonic setting of greenstone sequences. We record here the recent discoveries in the Fort Victoria greenstone belt of stromatolites in limestones assigned to ~3,500 Myr (minimum age) Sebakwian Group rocks of the Rhodesian Archaean Craton within Zimbabwe, and a nearby outcrop of a thin sedimentary formation, basal to a thick ~2,700 Myr volcanic pile, resting with definite unconformity on ~3,500 Myr Mushandike Granite.

Granite–greenstone terranes of different ages are now known to exist in the Rhodesian Craton[1–3]. The oldest greenstone belt remnants constitute the Sebakwian Group dated at ~3,500 Myr minimum on the evidence from various granites and gneisses; the more extensive main greenstone belts comprise the Bulawayan and Shamvaian Groups (Table 1). An unconformity in the Bulawayan Group allows its subdivision into the Lower Greenstones (?~2,900 Myr) and the Upper Greenstones, which together with the overlying Shamvaian are ~2,700 Myr old. Two suites of late granite post-date greenstone belts. These are the largely tonalitic Sesombi Suite at ~2,700 Myr, and the dominantly adamellitic Chilimanzi Suite at ~2,600 Myr. Archaean stromatolites in Zimbabwe have been recorded only from ~2,700 Myr Upper Greenstones[4]; further the only recorded and clearly demonstrable occurrence of greenstone belt rocks deposited unconformably on granitic basement is from the eastern margin of the Belingwe belt[5].

Table 1 Simplified stratigraphic table of the Zimbabwean Archaean

		Age (Myr)
Chilimanzi Suite (Adamellite)		~2,600
Sesombi Suite (Tonalite)		~2,700
Shamvaian Group		~2,700
Bulawayan Group	Upper Greenstones	~2,700
	Lower Greenstones	?~2,900
Mushandike Granite		~3,500
Sebakwian Group		~3,500

The newly discovered stromatolites occur in limestones some 9 km east of Mushandike Dam wall, in the northern margin of the Fort Victoria greenstone belt, and within the Mushandike National Park (Fig. 1). These limestones are confined to the vicinity of the lake and to the east. They are part of a sedimentary unit that has its greatest development west of Mushandike Dam. This unit was originally regarded by Wilson[6] as belonging to the Bulawayan succession. Later, as part of a craton-wide reassessment, Wilson[2] assigned the bulk of this sedimentary unit and some associated metavolcanic rocks to the ~3,500 Myr Sebakwian Group of the area. He was undecided, however, on the status of the sedimentary rocks east of the Dam because of the effects of later (? ~2,700 Myr) tectonism.

Our recent fieldwork has indicated the presence of two greenstone belt successions in this area (Fig. 1)—one clearly younger, and one which we regard as older than the Mushandike Granite dated at $3{,}445 \pm 260$ Myr ($\lambda\,^{87}\mathrm{Rb} = 1.42 \times 10^{-11}\ \mathrm{yr}^{-1}$; errors at 2σ)[7], equating with the Upper Greenstones and Sebakwian Group respectively.

We propose to call the basal sediments of the Upper Greenstones the Gwenya formation, after Gwenya hill on the western flanks of which an 80-m thick sequence of ferruginous siltstones, with minor arkose and quartzite lenses, lies directly on the Mushandike Granite (Fig. 2). The sediments all dip at 50° SE and young to the south, away from the granite. The unconformity contact is essentially planar with minor undulatory features which may be wash-out channels. It is not faulted.

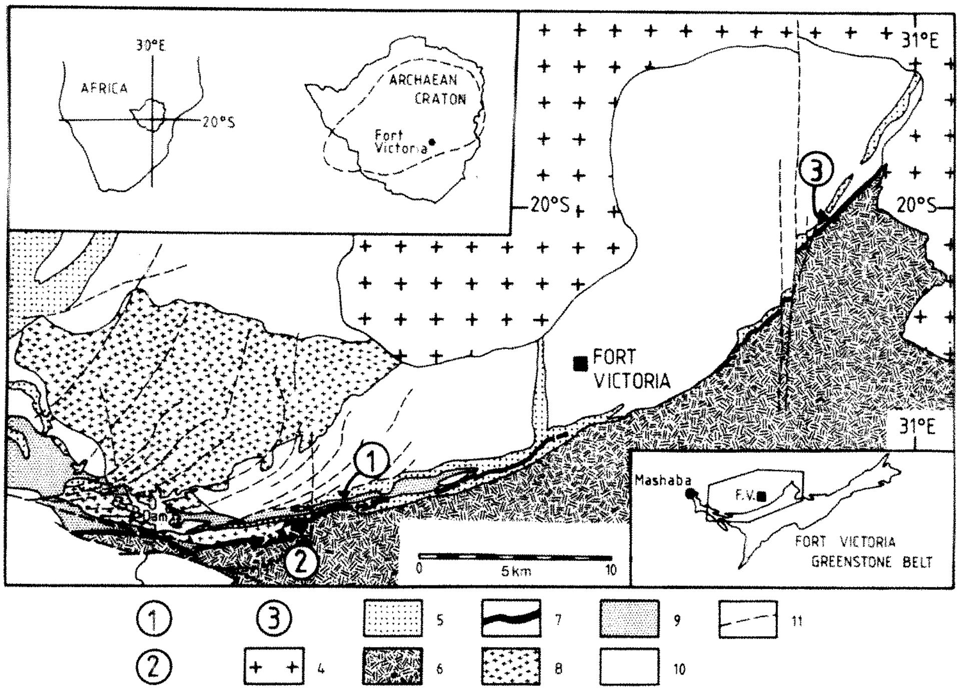

Fig. 1 Simplified geological map of the northern margin of the Fort Victoria greenstone belt. 1, Mushandike stromatolite locality; 2, Gwenya hill unconformity exposure; 3, Rockwood farm unconformity exposure; 4, Chilimanzi granite (~2,600 Myr); 5, Mashaba Igneous Complex; 6, Upper Greenstones volcanic rocks; 7, Gwenya formation (~2,700 Myr); 8, Mushandike Granite (~3,500 Myr); 9, Sebakwian Group; 10, various gneisses; 11, shear zones.

0028-0836/81/210218—03$01.00

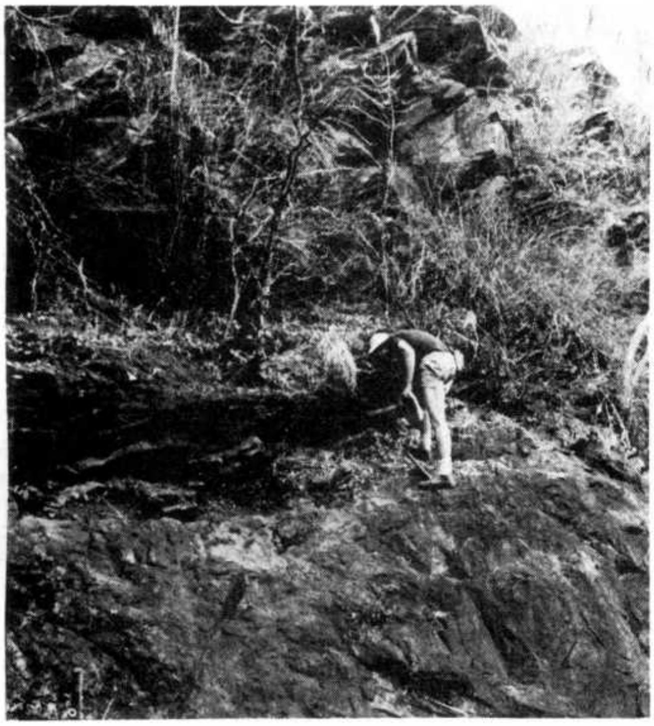

Fig. 2 Gwenya hill unconformity exposure. Left shoe straddles contact between weathered Mushandike Granite regolith and well-cleaved siltstones of Gwenya formation. A shallow depression in the centre of the picture forms a possible wash-out channel now filled with bedded siliceous siltstone.

West of the hill, the Gwenya formation is displayed by minor north–south faults, but seems traceable to south of the Mushandike Dam wall. Dips steepen westwards to 70°–80° and as the wall is approached intense east–west shearing, slightly discordant to strike, has so disrupted the geology that we cannot establish field relationships between granite and sediments. However, Coward and Shackleton[8] claim to have located an unconformity exposure, apparently from this region.

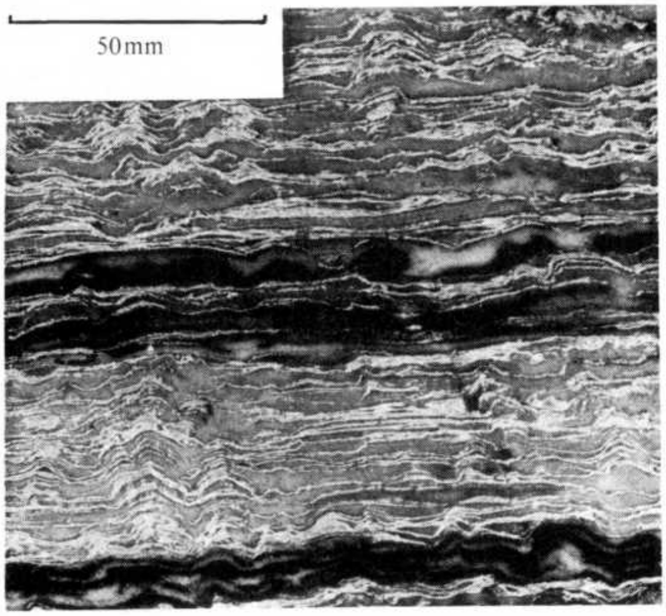

Fig. 3 Cut and etched surface of Mushandike stromatolitic limestone. Dark layers are of metasiltstone. Note preponderance of convex upward structures, moderate inheritance of domed laminae forming pseudocolumns in which successively younger laminae often develop a second order of curvature and thickening of laminae over the crests of flexures.

To the east of Gwenya hill, the sediments can be traced intermittently for some 40 km along the northern margin of the greenstone belt. For the most part the formation consists of ferrguinous, argillaceous sediments, banded iron-formation and a few small limestone pods. For much of this sector of the northern margin, the Gwenya formation is bounded below, and in places above, by the peridotitic eastern arm of the intrusive Mashaba Igneous Complex[6]. Approximately 20-km north-east of Fort Victoria, the Upper Greenstones and Mashaba Igneous Complex are cut by ~2,600 Myr Chilimanzi granite. On the Rockwood farm road, 4 km south-west of this contact, the Gwenya formation sediments are poorly exposed in unconformable contact with the underlying gneisses.

The older sedimentary rocks, of which the limestones are an integral infolded part, are an eastwards continuation of the Mashaba Sebakwian Group. Unlike the Gwenya formation rocks, which together with the overlying volcanic rocks of the Upper Greenstones have suffered only low-grade metamorphism, these sediments show widespread evidence of a medium grade, contact metamorphic event. Para-amphibolites, containing cordierite, show stellate clusters of anthophyllite, up to 100 mm across, cutting an earlier tectonic fabric. Relict, but occasionally fresh, andalusite has developed in metapelites adjacent to the limestones and in pelitic inclusions both within the Mushandike Granite and the surrounding gneisses[6]. When unaffected by the shearing (?~2,700 Myr), these andalusites have a random orientation. We attribute the development of these minerals to the thermal effects of the Mushandike Granite intrusion.

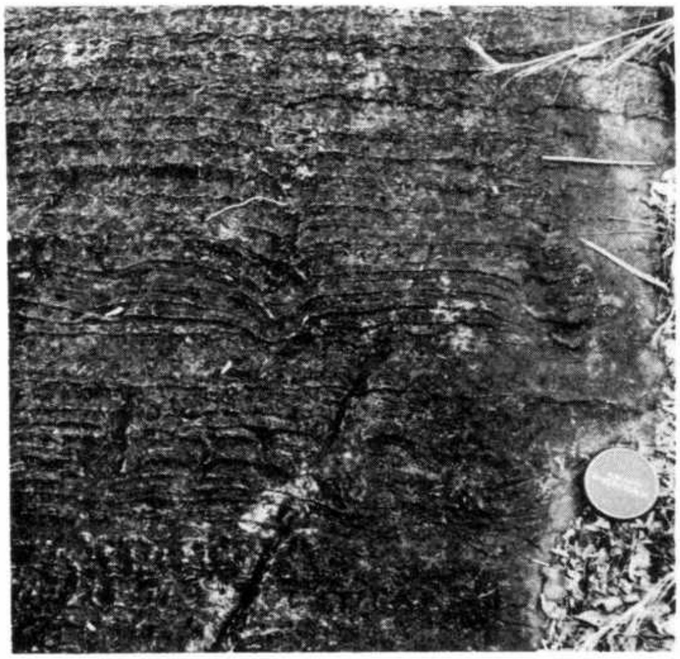

Fig. 4 Outcrop of Mushandike stromatolites showing large oblate domes with high laminae inheritance characteristics. Lens cap is 5 cm in diameter.

The limestone has a complex mineral assemblage, but commonly all specimens studied from widely spaced localities along strike contain the following: calcite, clinochlore, talc, tremolite, zoisite, grossularite and calcic plagioclase, which is compatible with the medium grade of the other Sebakwian rocks.

The stromatolites occur in a limestone unit that crops out over a 7-km strike, and has an average 200-m outcrop width (Fig. 1). Centimetre-thick, intercalations of metasiltstone are common. The limestone is in places massive, but is mostly finely laminated on a millimetre/centimetre scale, although the body has been tightly folded so that much of the lamination may be transposed foliation.

The stromatolite locality has escaped this intense deformation hence the biogenic structures have been fortuitously preserved.

The exposure is small and consists of a few scattered outcrops over an area of some 20 m^2. In these the millimetre-thick laminae are distinct, and following Hofmann[9] and Buick *et al.*[10], they are stratiform and corrugate, with a preponderance of convex-upwards structures in close to open spacing between laterally linked domes that have moderate inheritance. These form pseudocolumns, some of which develop a second order of curvature having the appearance of incipient dendroid branching (Fig. 3). Some of the larger domes are oblate and are formed from laminae with high inheritance characteristics (Fig. 4). In thin section the limestone has undergone extensive recrystallization, making recognition of microfossil structures hazardous. The morphology of the laminae, which characteristically thicken over the crests of flexures, does not resemble the plicated structure of stylolites, nor is it explicable as either a deformational or sedimentary structure.

The maximum height of any pseudocolumn is 3 cm, with the total relief of any lamina varying between 2 and 10 mm. The angle of inclination of a column axis to bedding is generally 90°, but may lean at 60°–70°. Hemispheroid radii are commonly up to 1 cm, but can be as much as 4 cm. The vertical increase in radius of successive hemispheroids is usually <0.1 mm, whereas the upward displacement of the centre of successive domes is 2 mm giving a growth factor of 0.2.

The relationship of the morphology described to named stromatolitic groups is uncertain, but the forms bear affinity to *Stratifera* and/or *Irregularia*.

The Mushandike stromatolite discovery is one of the most significant yet in the search for early life forms. To our knowledge they are the best example of ~3,500 Myr biogenic structures known and add to the growing body of evidence[11–14] that life was manifest as early as ~1,000 Myr after the formation of the Earth.

We thank A. Martin, M. J. Bickle and E. G. Nisbet for constructive criticism.

Syn-sedimentary gravity slides (growth faults) in the Coal Measures of South Wales

T. Elliott & K. O. Ladipo

Department of Geology, University College of Swansea,
Singleton Park, Swansea SA2 8PP, UK

Growth faults are an important class of syn-sedimentary fault which have been widely recognized in sub-surface studies of hydrocarbon-bearing clastic basin successions[1–4]. They are listric normal faults which are active for a limited period during sediment deposition and therefore affect a discrete sedimentary interval. Whilst active, the faults substantially influence sedimentation and a thicker, generally sand-dominated succession accumulates on the downthrown side which is consistently towards the basin. The faults are not directly related to basement tectonics, and instead are thought to originate principally by gravity sliding within the sediment pile[5]. Overpressured/undercompacted conditions in buried muds aid development of the faults by reducing the slope required to initiate sliding[5], and in some cases associated mud diapirism also contributes by creating steeper slopes[6]. Despite their widespread recognition in sub-surface studies, relatively few examples have been described from exposed successions[7–10], and none from the economically important Upper Carboniferous Coal Measures of Europe. Here we describe examples of growth faults recently discovered in an opencast site of the Coal Measures in South Wales and comment on their possible significance.

The faults occur in the Middle Coal Measures (Westphalian B–C) which is the principal coal-bearing interval of the South Wales coalfield. They are exposed in the National Coal Board opencast site at Llanilid, north-west of Cardiff (NGR SS975813) in which the succession from the Five Foot-Gellideg Seam to the Bottom Abergorki Seam can be examined. This succession comprises 222 m of mudstones, siltstones and sandstones in which 14 workable coal seams occur. Growth faults have been detected at two levels in the upper part of this succession between the Gorllwyn and Bottom Abergorki Seams.

The lower set of faults affects an 8-m interval, and both underlying and overlying strata can be seen to be unaffected by the faulting (Fig. 1). The succession at this level comprises a series of small-scale coarsening-upwards sequences, two of which are affected by the faulting. The sequences commence with black, plant-rich shales which contain horizonated sideritic ironstone nodules. This facies coarsens upwards into siltstones with occasional thin (1–2 cm) sharp-based beds of fine-grained sandstone. The sandstones increase in thickness and frequency upwards and grade into a fine- to medium-grained sandstone unit. These uppermost sandstones contain abundant plant rootlets and ironstone nodules, and have a light-grey leached and mottled appearance typical of Upper Carboniferous sandy palaeosols. A coal seam overlies the fault-affected interval and is abruptly overlain by mudstones at the base of the next sequence. These coarsening-upward sequences reflect the repeated infilling of shallow-water environments, initially by the deposition of fine-grained sediment from suspension and subsequently by sand-laden currents. Rapid infilling of the area culminated in soil formation, plant colonization and peat/coal accumulation. The sequences may have accumulated in the interdistributary bays of a delta[11], or in shallow lakes or barrier-sheltered lagoons as small-scale deltas prograded into the area[12–15]. The lack of afficiated large-scale coarsening-upward sequences of delta front or beach-barrier origin at this stratigraphic level favours a lacustrine setting, perhaps analogous to the Atchafalaya area west of the present Mississippi delta[12].

Six faults are exposed within this interval in a horizontal distance of 165 m (Fig. 1). Each fault plane dips to the east and the strata are downthrown in this direction. The faults have a curved cross-sectional profile which is steep at the top (50°) and flattens progressively into a bedding plane fault in the shales at the base of the lower sequence and the underlying coal. The downthrown strata dip at angles up to 20° from the regional dip in the mid-depth region of the fault planes and terminate abruptly against the planes. The faults are thin zones only a few centimetres wide with minimal brecciation and only a weak foliation. In one example the distal portion of a fault steepens slightly from a bedding plane fault into a low angle thrust. Minor, westerly-dipping antithetic faults occur in the down-faulted mass and are typically steeper and straighter than the major faults. At the top of the faulted interval the dipping, faulted beds are truncated in the distal parts of each fault block and some of the material eroded from these sites appears to have been redeposited in depressions immediately adjacent to the fault on the downthrown side. The upper part of the fault-affected interval is overprinted by the leached palaeosol horizon at the top of the second sequence. These faults are clearly syn-sedimentary as both underlying and overlying strata are

0028–0836/81/210220—03$01.00

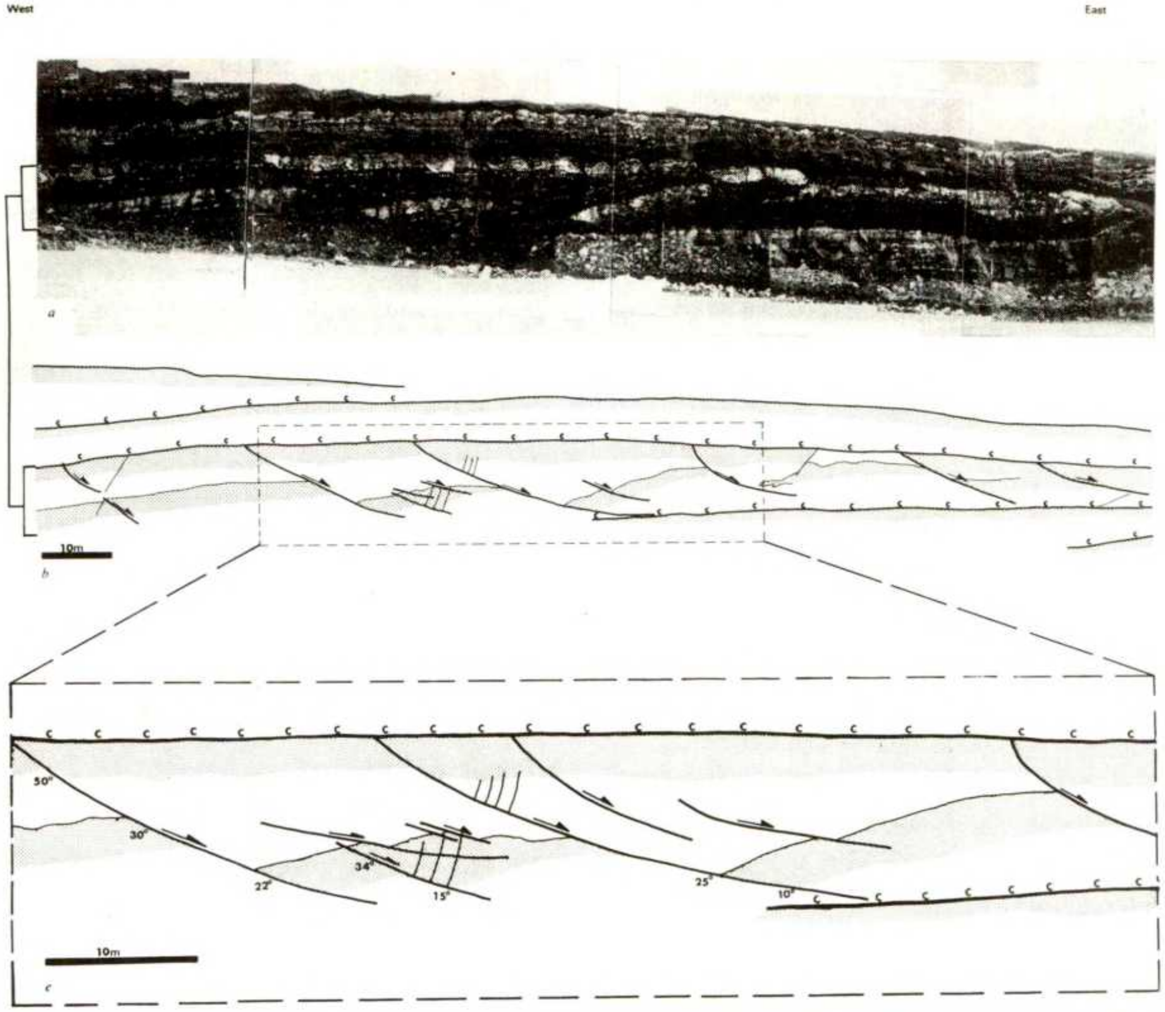

Fig. 1 *a*, Panorama of the lower set of growth faults in centre of photograph; *b*, line drawing of *a* showing the principal listric normal growth faults, occasional minor antithetic faults, the sandstones (stippled) and coal seams (c); note that both underlying and overlying strata are unaffected by the faults; *c*, detail of central part of *b* including dip angles of the faults.

unaffected, and the faulted strata were locally eroded before deposition of the next sequence. The major faults are listric normal faults reflecting easterly-directed gravity sliding. The orientation of the faults to the overall sediment transport direction is not known as the sedimentary structures have been obliterated by rootlets and palaeosol processes. The amount of deposition during faulting seems minimal, but is difficult to estimate in view of the small scale of the fault blocks and the extent of penecontemporaneous erosion in the distal parts of the fault blocks which has removed crucial evidence. However, it is clear that (? surface) relief created by the faulting was gradually obliterated by mass wasting processes possibly assisted by local wind-driven waves, resulting at least in re-sedimentation of this material. Following the planation of the area a period of soil formation and plant colonization ensued, overprinting the levelled surface of the fault blocks.

The upper set of faults affects the succession immediately below the Bottom Abergorki Seam. At this level the succession comprises thinly bedded, current ripple-laminated sandstones with interlaminated siltstones and mudstones which are cut by a series of lenticular, channelized, fine- to medium-grained sandstones. These facies possibly represent the upper parts of river mouth bar systems cut by the fluvial channels which supplied them[16], although research into this problem is still in progress. Three normal faults dipping generally eastwards are exposed in a horizontal distance of 45 m (Fig. 2). The principal fault has

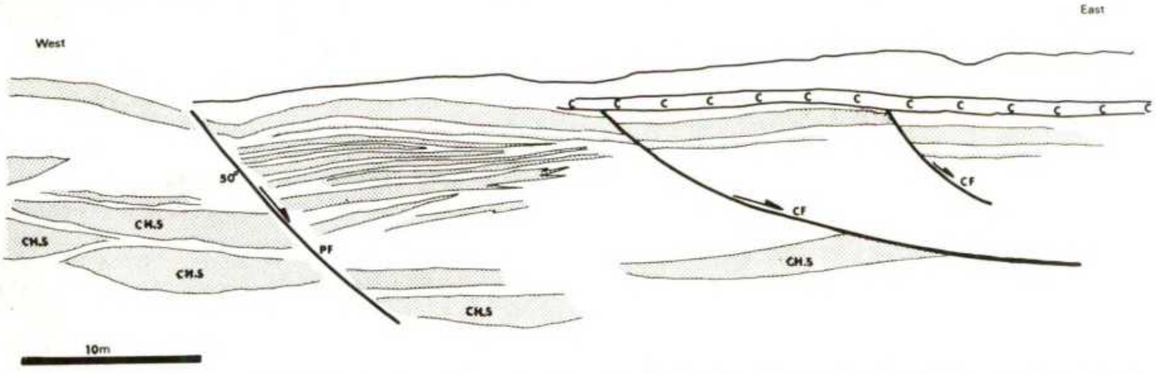

Fig. 2 The upper set of faults immediately below the Bottom Abergorki coal seam. The principal fault (PF) has only its upper part exposed, whereas the smaller scale, (?) crestal faults (CF) are completely exposed. Note the localized sandstone-dominated succession adjacent to the upper part of the principal fault which diminishes away from the fault. Sandstones are stippled. CH.S, channel sandstones; c, coal seam.

only its upper part exposed, dipping at 50° and flattening slightly with depth in the limits of exposure, suggesting a listric profile. This fault affects at least 18 m of succession and has a thicker, sandstone-dominated succession adjacent to the fault on the downthrown side. Numerous sandstone beds become thinner and finer grained when traced away from the fault plane, and eventually grade into siltstones and mudstones. These beds dip into the fault plane and are 'unconformably' overlain by the succeeding sandstone unit in the distal part of the fault block. Exposure of the fault plane permits the strike to be measured accurately at 072°/252°, indicating downthrow to the SSE. The preserved channel shape of numerous (inaccessible) sandstone units implies that the overall sediment transport direction was at a high angle to the strike of the faults. The localized sandstone-dominated facies on the downthrown side of the principal fault suggests that movements along this fault created a localized depression in the depositional area which became a prime site for the accumulation of sand-grade sediment. Differential sedimentation of this nature may have perpetuated the fault movements for some time causing the fault to grow until the locus of sedimentation shifted away from this area. On the downthrown side of the principal fault are two fully exposed, smaller scale faults with listric profiles. These faults parallel the principal fault and are downthrown slightly in the same direction, but do not exhibit a facies contrast between upthrown and downthrown sides. These smaller scale faults are clearly subordinate to the principal fault and are interpreted as minor, synthetic faults, possibly akin to the crestal faults of Evamy *et al.*[4] in the growth-faulted Tertiary depocentre of the Niger delta.

The described faults are therefore syn-sedimentary, listric normal faults which are interpreted as growth faults and are considered to have been produced by gravity sliding directed generally east or south-southeast. Evidence for sedimentation during faulting is limited for the lower small-scale faults, but is clearer for the upper, larger scale faults. Formation of the faults may have involved overpressured/undercompacted conditions in the mudstones which reduced the slope required to initiate sliding. Previously it was felt that relatively deep burial was required to produce overpressured conditions, but *in-situ* measurements of pore pressures in delta plain and delta front muds of the Mississippi delta have recently detected overpressured conditions at very shallow depths below the sediment surface[17,18]. In these conditions mass movement of sediment has occurred in the Mississippi delta on slopes as low as 0.14° (ref. 19), and Crans *et al.*[5] consider that the slope required to initiate gravity sliding diminishes to $<3°$. Slopes towards the lower end of this range of values may have existed on the small- to moderate-scale deltas in which the faults occur. As in the Mississippi delta, excess pore-water pressures may have been supplemented by methane gas (as a bubble phase?) in the richly organic muds of the Coal Measures.

The recognition of growth faults in the Coal Measures has considerable potential significance because if they prove to be common, particularly on a larger scale, they may influence the location, lateral extent, frequency, thickness and disposition of coal seams. Although the described faults are small by comparison with many of the sub-surface examples described from hydrocarbon provinces, they clearly influenced sedimentation and the resultant facies patterns (particularly the upper, larger scale example). The scale of the observed faults is in proportion with the scale of the exposures and larger scale examples may be recognizable in seam-correlated cross-sections through coalfields. A series of larger scale listric normal faults known collectively as the Jubilee Slide has been described in sub-surface studies of the South Wales coal basin in the Pontypridd area[20]. This structure comprises numerous slightly arcuate listric normal faults arranged *en echelon* in a fault zone traceable for 20 km along strike. The fault system affects the Lower, Middle and Upper Coal Measures and has a maximum throw of 90 m. The structure pre-dates later tectonic structures, but cannot be regarded as a syn-sedimentary growth fault as there is neither evidence that the faults influenced sedimentation, nor that they are overlain by beds not affected by the faulting. In view of the growth faults described herein the Jubilee Slide should be re-examined to determine whether or not it is a large-scale syn-sedimentary growth fault.

We thank the National Coal Board for access to opencast sites, and A. R. Gardiner and A. J. Pulham for comments on an earlier version of the manuscript. K.O.L. acknowledges a reasearch grant from the University of Ilorin, Nigeria.

Visual observations of the Red Sea hot brines

A. S. Monin, E. A. Plakhin, A. M. Podrazhansky, A. M. Sagalevich & O. G. Sorokhtin

P. P. Shirshov Institute of Oceanology, USSR Academy of Sciences, 117218 Moscow, USSR

The research vessel Akademik Kurchatov has investigated the Red Sea rift zone with the aid of a manned submersible Pisces XI in the winter of 1979–80, as the value of such investigations is now well established[1,2]. Our research involved a comprehensive programme of hydrophysical studies in deeps containing thermal brines of the sea axial rift—Atlantis II, Discovery and Valdivia (see Fig. 1). Measurements were made with standard hydrographic stations, the AIST temperature and salinity meter with specially selected temperature and electric conductivity scales on board a towed vehicle Zvouk-4m, and Pisces XI. The present data on water stratification in the Atlantis II, Chain and Valdivia deeps have in general confirmed previously known data[3–9] but have also revealed some new facts. For example, we have recorded an increase of temperature of the hot brine of up to 62 °C in the southwestern basin of the Atlantis II deep since studies aboard the R/V Sonne in 1977. Using data from this expedition, Hartmann[9] gives a curve of temperature growth in the lower brine constructed from the data of different expeditions since 1965. A multilayer temperature structure of the upper brine and horizontal inhomogeneities have also been found[8–10]. Steps in the upper brine of the Atlantis II deep were first described [6,9] from the surveys of the R/V Valdivia (1971–72) and Sonne (1977). Our observations reveal stratification of the deep brine (Table 1) in temperature and electrical conductivity (salinity) and enable their rate of change of thickness to be estimated[10].

Water in the area of the deeps and on the relief saddle between the Chain and the Discovery deeps was sampled using a 15-l water bottle designed to function at 5–10 m depths above the sea floor. The samples were analysed hydrochemically (Table 2) as well as in a spectrohydronephelometer which measured spectral transparency curves.

A comparison of these curves for the bottom water shows that in the Atlantis II deep a sharp decrease in transparency is

0028-0836/81/210222—04$01.00

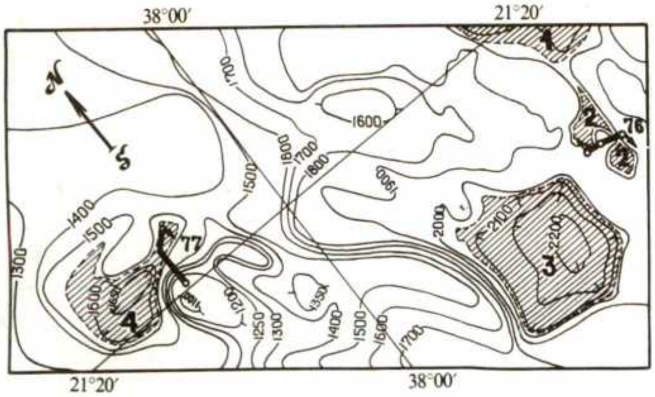

Fig. 1 A scheme of the "Pisces XI" dives into the Chain (76) and Valdivia (77) deeps: 1, Atlantis II deep; 2, Chain deep; 3, Discovery deep; 4, Valdivia deep.

observed at ~11 m above the bottom (for $\lambda_{ef} = 546$ nm): a 10-m thick turbid bottom layer seems to exist. The transparency curve of the Valdivia deep resembles the curve from the Atlantis II deep; however, in the Discovery deep the bottom water differs appreciably. On the saddle between the Chain and the Discovery deeps the optical properties of the water are intermediate between those of the Valdivia and the Discovery deeps. Note that the Discovery and the Atlantis II waters differ considerably in their chemical composition (Table 2). Our analyses indicate that the nature of the brines changes within the deeps.

Taking into consideration the large amount of data available for this region, our expedition aimed to verify the hypothesis of a common source of thermal water in the Atlantis II, Chain and Discovery deeps[4,7,8] and to investigate the Valdivia deep for which only scanty data have been published[5].

The hypothesis of the formation of high-salinity thermal water in the Chain and the Discovery deeps assumes an overflow of this water through bottom depressions from the southwestern basin of the Atlantis II deep.

Table 1 Thermohaline characteristics of water in brine steps within the Atlantis II deep

No. of steps	Thickness (m)	Temperature (°C)	Salinity (%)
1	4	40.9	67.6
2	8	47.1	113.6
3	16	51.5	144.3
4	10	52.2	145.1
5	From 2,049m depth to the bottom	62.3	275.0

The Pisces XI submersible was equipped with hydrophysical sensors and a dive was made to the supposed place of contact of thermal waters between the Chain and the Discovery deeps (see Fig. 1, route 76). Meridional towing of the Zvouk-4m vehicle across the saddle had already yielded 14 photographs of the saddle bottom (see, for example, Fig. 2). The photographs show a highly dissected topography with rock outcrops and numerous fragments of apparently basaltic rocks powdered with sediment often white and showing ripple marks in some areas. Figure 2 *a*, *b* indicates a complicated bottom topography within the saddle. Steep step-like scarps of a 3–4 m amplitude have been fixed (Fig. 2*a*). In the vertical walls, bedrock crops out, flat areas are powdered with loose sedimentary material. Judging by the bedrock fragments, we have observed, not effusive formations encountered in the axial rift zone, but carbonate strata (marls) or iron–manganese consolidated sediments the fragments of which were found in the submersible's ski (dive 76). A tectonic origin of the scarps is most probable. Ripples are seen on the scarp to the right of the rock in Fig. 2*a*, on the left-hand part of the photograph in Fig. 2*b* and on the whole of Fig. 2*c* which reveals mysterious decimetre-scale ripples (possibly, on the brine surface).

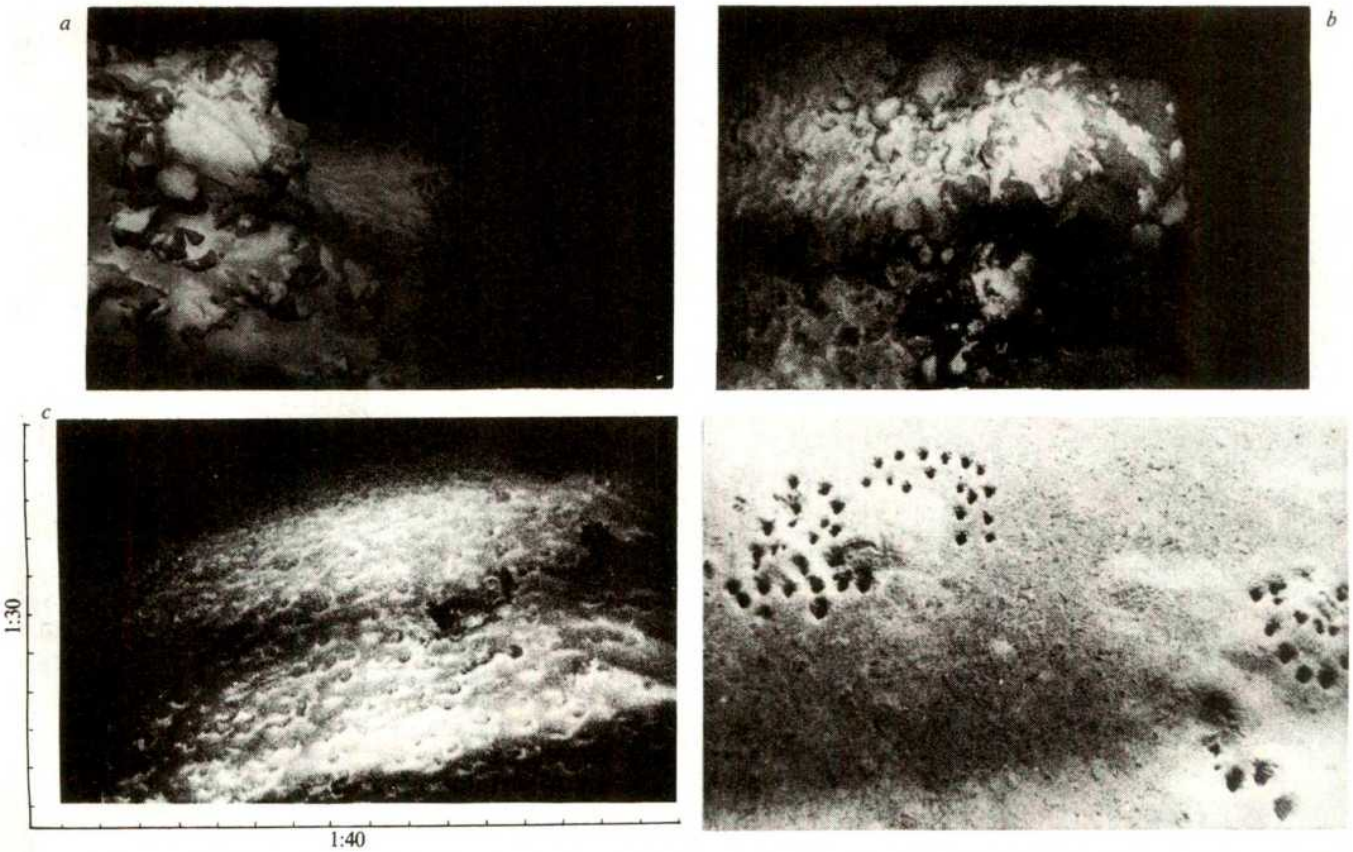

Fig. 2 Bottom and brine surface photographs made in the diving area with the aid of the towed vehicle Zvouk-4m: *a*, bottom area covered with ripples (to the right of the rock); *b*, bottom area with ripples (in the left-hand part of the photograph); *c*, decimetre-scale ripples (possibly, on the brine surface); *d*, a group of bottom holes.

Table 2 Hydrochemical characteristics of deep brines and surface water in the Red Sea

Red Sea	—	—	0	27	38.9	4.5	11	0.21	51

The Pisces XI dive (76) onto the Chain–Discovery saddle on 12 February 1980 showed that the water changed its transparent-blue colour to dull yellow (due to a high concentration of suspended matter in the upper part of the sharp pycnocline layer) at a depth of 1,995 m, as the bottom was approached. The water temperature increased from 21 to 25 °C and the sound velocity from 1,560 to 1,572 m s^{-1}. The sea floor at a depth of 2,005 m was covered with light-yellow sediment with easily turbidable black coating, straight parallel sand bars 1.5–2 m apart and with separate white spots, decimetres in diameter, and centimetre-high knolls (possibly, evaporite outcrops). Although there were no traces of life on the bottom a dead fish found there may be indicative of the conditions preserving organic matter, that is the absence of oxygen and bacteria.

The submersible moved towards the Discovery deep, just above the apparent bottom which looked to the observers like mud covered with waves. However, in their attempts at touching-down on this bottom the observers made sure that they saw (and the echosounder of the Pisces recorded) the brine surface.

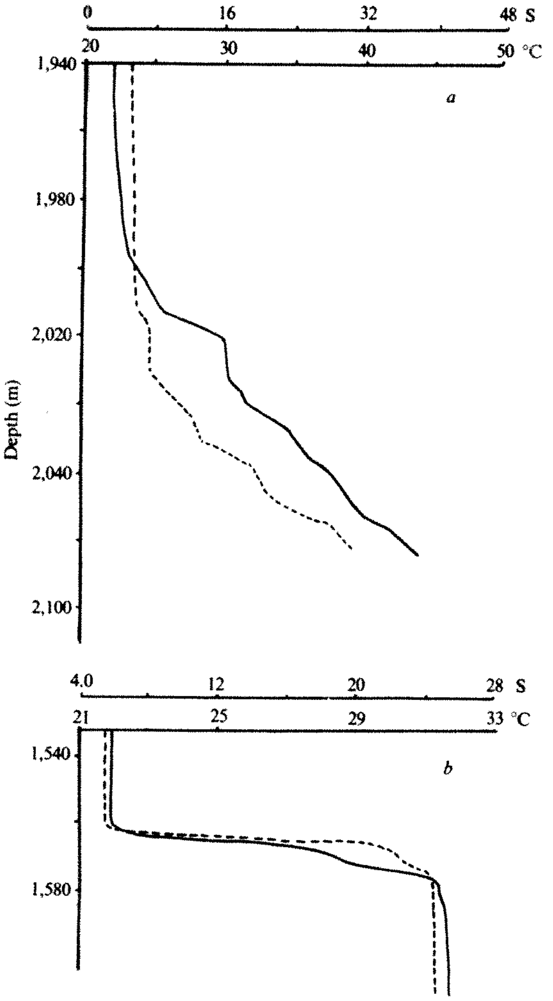

Fig. 3 Curves showing vertical distribution of temperature (solid line) and conductivity (dashed line) in the thermal brine layer of the Chain (*a*) and Valdivia (*b*) deeps.

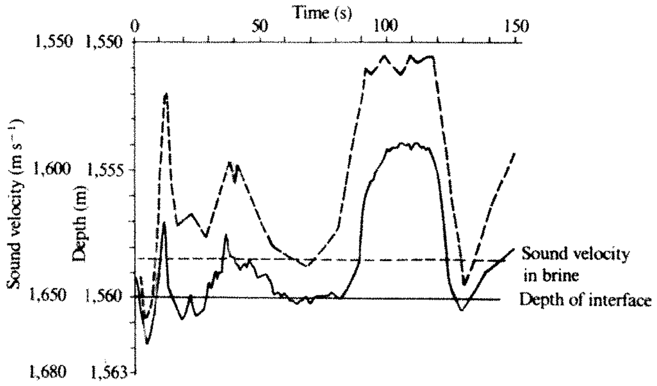

Fig. 4 Graphic recordings of sound velocity and depth during the Pisces XI manoeuvres in its dives into the Valdivia deep (a sample of the recordings of the submersible's sensors during 150 s).

Going deeper into the brine the water became sharply turbid, a streaming yellowish haze could be seen through the portholes, overboard temperature increased to 33 °C and sound velocity to 1,625 m s^{-1} (the Chain deep). At the maximum depth of 2,030 m the buoyancy force of the pycnocline balanced the forces of the thrusters and stopped the descent of the submersible.

The analysis of the hydrophysical and echosounder recordings made during the crossing of the saddle shows no evidence of brine overflows from the Chain to the Discovery deeps. Contact between the deeps takes place, evidently, only at the depth of the transition layer between the normal Red Sea deep waters and the brine layer (1,980–2,010 m layer, Fig. 3*a*).

Hydrophysical studies of the Valdivia deep (Fig. 1, route 77) were also undertaken. Preliminary standard hydrographic casts and soundings with the AIST had revealed a sharp pycnocline with a very thin transition layer (Fig. 3*b*). During the dive into the Valdivia deep, on 14 February, 1980 the submersible reached the bottom at a depth of brine of 1,530 m east of the deep. On setting course for the west, at a depth of 1,555 m the Pisces entered the transition layer which was immediately noted by the observers as a streaming viscous haze. A pycnocline layer as a turbid surface covered with ripples was clearly seen 3–5 m below the submersible. As in the dive to the saddle described above, no penetration through the pycnocline was possible, and after attempting to go deeper with the aid of its thrusters the submersible headed eastwards above the brine surface. The manoeuvres of the submersible during its attempts to go deeper into the brine are shown in Fig. 4 together with the results of continuous sound velocity measurements in the brine (a sample taken over 2.5 min is presented).

Moving above the brine surface the submersible reached its underwater 'shore' covered with yellowish mud and descended at 30–40° into the underwater salt 'lake'. Against the background of the slope the brine level was distinct, resembling a whitish mist surface, and the observers noted underwater waves at a depth of 1,560 m (internal waves on the brine surface which was disturbed by the Pisces thrusters) which were rolling on the shore of the salt lake and then were rolling down in streams.

Furthermore the Pisces started ascending along the bottom rise slope covered with sediments with light-yellow and brown crests of thin-layered sedimentary rocks usually inclined towards the slope and covered with carbonate crusts with a dark yet thin manganese 'tarnish' on the surface. The inclined bedding of sedimentary rocks is most likely to be due to slide phenomena on the salt-bearing slopes of the Red Sea main trough.

According to M. S. Barash (personal communication) the samples taken during the dives from laminated sedimentary rocks contain abundant well-preserved late Quaternary planktonic foraminifers (*Orbulina universa* d'Orb; *Globigerinita glutinata* Egger; *Globigerinoides sacculifer* Brady; *Globigerinoides ruber* d'Orb; *Globigerinella aquilateralis* Brady; *Globigerina rubescens* Hofker; *Globigerinoides tenellus* Parker).

Ushakova studied the same samples and determined Pleistocene (*Emiliania huxleyi* Lohman; *Unibilicosphaera mirabilis* Lohman; *Geophyroacapsa oceanica* Kamptner; *Coccolithus atlanticus* Cohen) redeposited Cretaceous (*Lucianorh abdus cayeuxi* Deflandre; *Microrhabdulus decoratus* Deflandre; *Lithraphidites quadratus* Bramlette, Riedel) and Palaeogene calcareous nannoplankton (*Helicopontosphaera intermedia* Martini, Hay, Mohler; *Discoaster multiradiatus* Bramlette, Riedel; *Pseudozygrhablithus latus* Hag; *Marcalius inversus* Deflandre, Bramlette, Martini).

The carbonate crusts covering thin-laminated sedimentary rocks are identical in composition to those studied in detail in the Red Sea rift zone at 18 °N where their formation is associated with the climate cooling stages in Pleistocene. These crusts are most likely to be dated as Würmian. Their origin could be accounted for by a partial bridging of the Bab-el-Mandeb strait due to a general lowering of the World Ocean level during Würmian glaciation. Several metres above the lake level, separate pink shrimps and numerous groups of holes (1–3 cm in diameter and ~1 dm apart) were noted in the sedimentary cover, the latter being found almost everywhere on the Red Sea bottom (see, for example, Fig. 2*d*). No such groups of holes were encountered in the vicinity of the brine surface or on the bottoms of the thermal deeps. This may be evidence for their biological origin.

Atlantic-type carbonate stratigraphy in the late Miocene Pacific

Dean A. Dunn, T. C. Moore Jr
& Lloyd D. Keigwin Jr*

Graduate School of Oceanography, University of Rhode Island,
Kingston, Rhode Island 02881, USA

In previous attempts to correlate fluctuations of climate with the carbonate content of deep-sea sediments, using the ratio ^{18}O/^{16}O as an indicator of palaeotemperature, conflicting patterns have emerged between Pacific and Atlantic deep-sea cores. Although there is controversy about the relative importance of the primary productivity of calcareous microorganisms[1-3] and their dissolution at depth[4-10], in Pacific Pleistocene cores high-carbonate sediments correlate with glacial episodes and low-carbonate sediments with interglacials[1-4,7-10]. In Atlantic Pleistocene cores, on the other hand, the correlation seems to be reversed[4,5,7,10-12]. We report here that a late Miocene (6.14–6.53 Myr) deep-sea sediment core from the eastern equatorial Pacific (DSDP Site 158) shows a negative correlation between carbonate content and benthic oxygen isotopes which is similar to that found in Quaternary records of the Atlantic rather than the Pacific. The explanation may be that Atlantic and Pacific waters differed in HCO$_3^-$ concentration at depth as they do today, and that in the late Miocene, Atlantic water flowed over the submarine sill at the Isthmus of Panama and at least periodically, reached the location of Site 158.

Stable isotope and carbonate analyses were performed on 44 sediment samples from DSDP Site 158 (Cocos Ridge, eastern equatorial Pacific Ocean, 06°37.36′ N, 85°14.16′ W, 1,953 m water depth). Samples were taken from cores 15 and 16 at intervals of 20 cm across the late Miocene ^{13}C depletion in benthic foraminifera[13,14], and thus, our samples span an interval of 390 kyr between ~6.14 and 6.53 Myr, based on the estimated age of 6.3 Myr for the carbon shift[15]. The sample spacing represents an interval of ~10 kyr between samples, based on the estimated sedimentation rate of 2.0 cm kyr^{-1} for the late Miocene[16]. Stable carbon and oxygen isotopic ratios of the benthic foraminifera[14] *Globocassidulina subglobosa*, and benthic/planktonic (B/P) foraminiferal ratios were determined for each sample. Carbonate percentages for each sample were determined by the revised carbonate bomb techniques[17].

Our results for Site 158 show that the highest percentages of carbonate correlate with lighter benthic oxygen isotopic ratios (Fig. 1*a*), indicating warmer palaeotemperatures and/or less continental ice volume. The maximum correlation occurs with an offset of one sample interval, suggesting that changes in the carbonate content lead changes in the oxygen isotopic content by ~10 kyr. This conflicts with previous studies of Pleistocene equatorial Pacific cores[18-21] which estimated that carbonate oscillations lagged behind oxygen isotope variations by 5–10 kyr. The pattern of Site 158 is that of an Atlantic-type carbonate stratigraphy (high-carbonate interglacials); although the maximum magnitude of the correlation coefficient (0.42 at one sample lag) is low, it is of approximately equal magnitude with the maximum oxygen isotopic–carbonate correlations of Pleistocene cores V19–29 ($r = 0.52$) and V28–238 ($r = 0.35$) from the equatorial Pacific[21], despite the fact that cores V19–29 and V28–238 show the opposite Pacific-type pattern.

Our data also show that higher B/P values correlate with lower carbonate percentages (Fig. 1*b*). The maximum correlation coefficient ($r = 0.54$) occurs at one sample lag, indicating that changes in carbonate content lead corresponding changes in B/P ratio by ~10 kyr, and that B/P ratio and oxygen isotope records are in phase. Because dissolution preferentially removes planktic foraminifera, higher B/P ratios indicate increased dissolution. The lag between these two indicators of dissolution is perplexing. Total carbonate content (both coccoliths and foraminifera) may respond more rapidly to changes in bottom water chemistry than do changes in foraminiferal faunas alone. The correlation of B/P ratios with per cent carbonate suggests that in the late Miocene (6.14–6.53 Myr) samples from DSDP Site 158, carbonate percentage is controlled primarily by dissolution. Furthermore, it indicates that times of greater δ^{18}O ('glacials') are times of greater carbonate dissolution, the pattern found in Pleistocene Atlantic deep-sea cores[4,5,7,10-12].

Spectral analysis of such short time series, especially those for which the time-spacing of samples is only approximate, cannot

---

0028-0836/81/210225—03$01.00

be expected to give very accurate estimates of the variance distribution as a function of frequency; however, such an analysis can give a general idea of how the variance is partitioned between the low and high frequency parts of the spectrum. More important, cross-spectral analysis[21,22] of the carbonate and oxygen isotope paired time-series can provide a useful indication of the frequencies over which the two records are most highly correlated. The age model for our spectral analyses is based on the shift in benthic ^{13}C isotopes at 136.50-m depth in this site, which has been dated[15] at 6.3 Myr, and the estimated sedimentation rate[16] of 2.0 cm kyr^{-1}.

The oxygen isotope spectrum shows broad spectral peaks centred at frequencies corresponding to periods of 167 kyr, 53 kyr, and 22.7 kyr (Fig. 2). The carbonate spectrum shows broad peaks at 235 kyr and 29.4 kyr, with only a shoulder in the spectrum near the frequency corresponding to a period of ~60 kyr. These results agree with a study of the carbonate record[23] from the entire late Miocene of Site 158 which showed that most of the variance in the record is associated with periods of oscillation longer than 150 kyr. The presence of spectral peaks in both records near the periods associated with the changes in obliquity and precession of the Earth's orbit[24] may be only fortuitous.

A high degree of correlation (coherency) occurs between the oxygen isotopic and the carbonate signals of Site 158 at low frequencies (periods longer than 111 kyr, with a coherency peak at a period of 182 kyr). A second region of high coherency is centred about a period of 30 kyr. The coherence between the two curves at long periods of oscillation may be due to matching a few peaks and valleys in a relatively short section of the carbonate record. However, the length of record (~390 kyr) is comparable with many of those which have been used to establish the relationship between carbonate and isotope stratigraphies in the Pleistocene[18–21]. Moreover, the coherency between the oxygen isotopic record and the carbonate record even at higher frequencies lends credence to the proposed relationship between the two records.

The discovery of an 'Atlantic-type' carbonate stratigraphy in the late Miocene eastern equatorial Pacific Ocean and the eventual development of the 'Pacific-type' stratigraphy may be related to the tectonic evolution of the Isthmus of Panama. The carbonate variations seen in the late Miocene at Site 158 are primarily due to dissolution, as shown by the B/P foraminifera ratios, with less dissolution occurring during the warmer (isotopically lighter) intervals. This pattern may have been caused by the exchange of water between the Atlantic and Pacific through the open seaway of Panama. Thus, before the middle Pliocene closure of the Isthmus of Panama[25,26], periods of warming (lower $\delta^{18}O$) may have been associated with increased flow of Atlantic waters across the Panama Seaway and into the Pacific basin. This water would be less corrosive to calcite because it would be younger and contain less dissolved CO_2 than

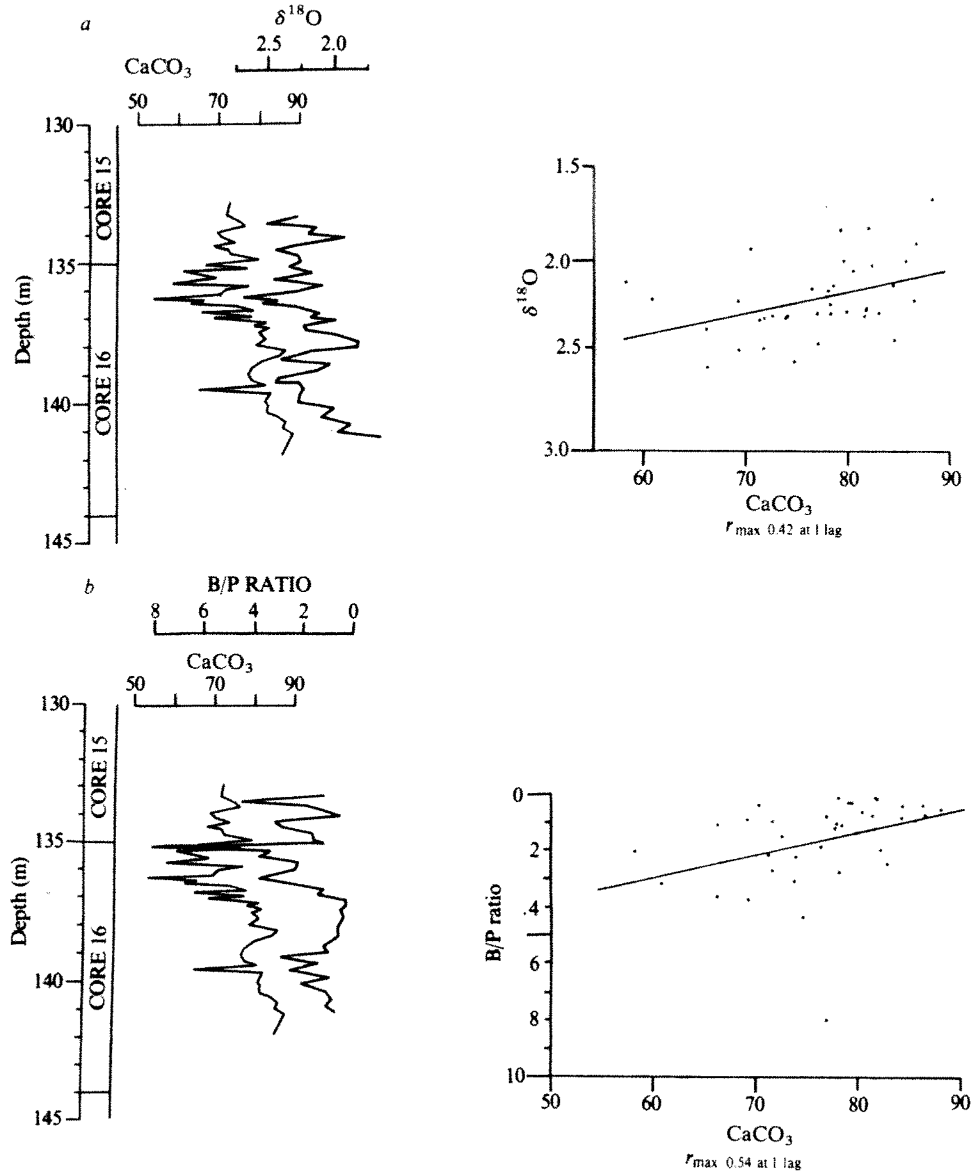

Fig. 1 *a*, Carbonate percentages and stable oxygen isotopic ratios of the benthic foraminiferan *Globocassidulina subglobosa* (relative to the B-1 powder standard) for 44 paired samples in DSDP Site 158. Per cent carbonate and $\delta^{18}O$ are negatively correlated, implying that there are high-carbonate warm intervals (an 'Atlantic-type' carbonate stratigraphy) in this sediment from the late Miocene eastern equatorial Pacific. The *y*-axis ($\delta^{18}O$) has been inverted in this figure to make the Atlantic-type correlation more obvious. The maximum correlation coefficient ($r = 0.42$) occurs at one sample lag, indicating that changes in benthic oxygen isotopic content lag behind changes in carbonate percentage by ~10 kyr. *b*, Carbonate percentages and B/P foraminiferal ratios for DSDP Site 158 samples. Per cent carbonate and B/P ratios are negatively correlated, implying that variations in carbonate percentage are primarily due to dissolution, as shown by high B/P ratios correlating to low carbonate percentages. Maximum correlation coefficient ($r = 0.54$) occurs at one sample lag, indicating that changes in the B/P ratio lag behind corresponding changes in carbonate percentage by ~10 kyr.

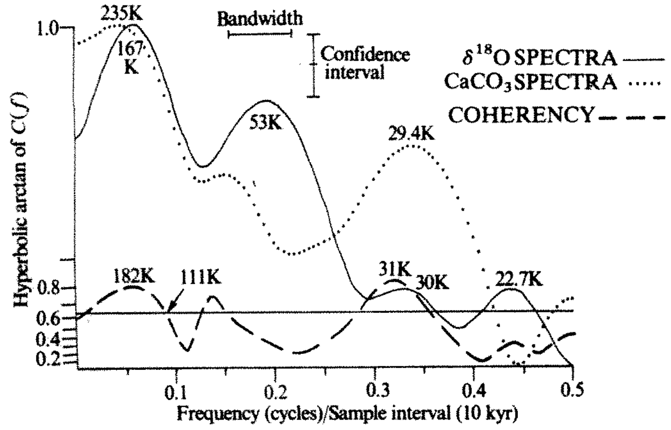

Fig. 2 Spectral analysis of stable oxygen isotopic ratios of *Globocassidulina subglobosa* and carbonate percentage, and coherency between these two signals. Horizontal axis is cycles per 10 kyr. Log spectra of both time series are plotted on the vertical axis as power (equal to mean variance squared) versus frequency. Spectral estimates for δ^{18}O and CaCO$_3$ have been scaled by a constant, so that the area under each curve equals one. Vertical axis for coherency (hyperbolic arctangent of coherency for each frequency) was chosen so that the confidence interval is constant for all frequency bands.

the Pacific waters. During cool intervals, Pacific water masses (which have been away from the surface longer and thus are higher in dissolved CO$_2$ and more corrosive to calcite) could have replaced those derived from the Atlantic. The exact mechanism which might drive this oscillation in the source of deep waters for the eastern tropical Pacific is uncertain, but it may be associated with differing rates of production of deep waters in the Northern and Southern Hemispheres.

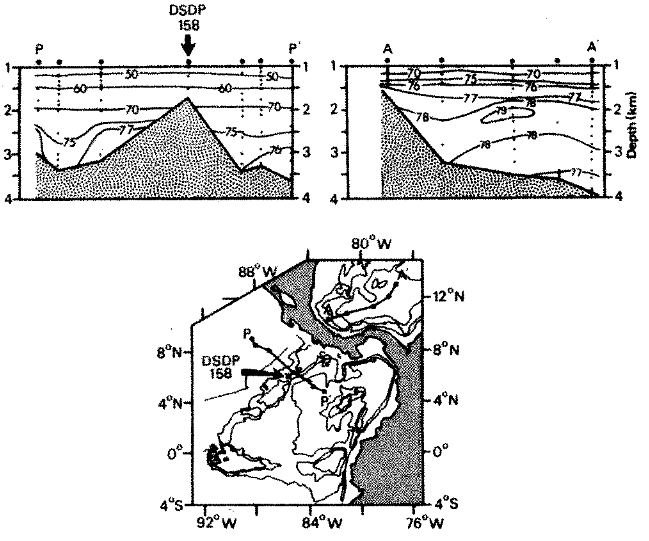

Fig. 3 Modern hydrographical sections for the Colombian Basin and the eastern equatorial Pacific. Density contours are plotted as values of $(\sigma_\theta - 27) \times 100$; a σ_θ value of 27.70 would be represented by 70. The estimated late Miocene palaeodepth of Site 158 is 1,700–1,800 m (ref. 31). Assuming that late Miocene density stratification of these basins was similar to the modern situation, then water masses passing over a minimum sill depth of 1,000–1,200 m would sink to the depth of Site 158.

At present, surface waters on opposite sides of the Panama Isthmus have similar surface temperatures (26–28 °C), but Atlantic waters have higher salinities. Flow of warm, saline Caribbean water from the Atlantic North Equatorial Current into the eastern equatorial Pacific has been proposed as a contributing factor to accumulation of Pliocene carbonate-rich sediments in the equatorial Pacific[27]. Also, passage of shallow Caribbean waters across Panama in the Pliocene has been implied as the mechanism for migration of a shallow-water benthic foraminiferan (*Amphistegina gibbosa*), normally restricted to the Atlantic–Caribbean province, into sediments off the California Continental Borderland[28]. Examination of modern hydrographic data[29,30] from the western Colombian Basin and the eastern equatorial Pacific Ocean (Fig. 3) indicates that Atlantic water masses passing across the Panama sill would sink to greater depths in the eastern Pacific, due to high densities found at shallower depths in the Atlantic. (Additional hydrographic data for the Colombian Basin and the eastern equatorial Pacific was made available by the National Oceanographic Data Center.) Thus, flow of Atlantic waters westward into the Pacific is theoretically possible, with circulation being driven by sinking of Atlantic water masses along isopycnal surfaces to greater depths in the Pacific.

Based on an estimated back-tracked depth of 1,700–1,800 m for Site 158 during the late Miocene[31], and assuming that density stratification of late Miocene ocean basins was similar to the modern situation, we estimate that the minimum depth for the late Miocene Panama sill was 1,000–1,200 m. This sill depth would allow Atlantic intermediate water masses to be transported through the Central American seaway. In the eastern Pacific, the Atlantic water masses could sink to the estimated depth of Site 158, causing the reduced carbonate dissolution at this site and producing the 'Atlantic-type' carbonate stratigraphy. If this proposed hypothesis is valid, then the shoaling of the Panama Seaway should mark the end of the negative correlation between the oxygen isotope and carbonate records.

Evidence for the absence of biological methylation of lead in the environment

K. Reisinger, M. Stoeppler & H. W. Nürnberg

Institute of Chemistry, Institute 4 Applied Physical Chemistry,
Nuclear Research Centre (KFA), Jülich PO Box 1913,
D-5170 Jülich, FRG

Biological methylation of arsenic and mercury by pure cultures of microorganisms such as moulds[1] and bacteria[2], and by 'mixed cultures of environmental systems', such as sediments[3], sludges or canal mud[4], seem to be well known processes, although there is no unequivocal evidence of the proposed pathways[5–7]. In contrast, the biomethylation of inorganic or ionic organic lead compounds has been a topic of controversy, with no conclusive explanation of the mechanism of the reactions that might lead to the corresponding alkyl lead compounds[8–13]. We report here attempts to produce leadalkyls in anaerobic and aerobic conditions. Our study was greatly helped by our use of labelled and unlabelled substrates as methyl donors and labelled and unlabelled lead compounds as acceptors. In none of numerous experiments have we found leadalkyls to be the products of biomethylation. Experiments with organic lead salts resulted in lead tetraalkyls but only as the products of chemical reactions.

We started with the assumption that if microorganisms could really convert inorganic Pb(II) compounds and organic Pb(IV) salts, such as PbMe$_3$OAc, PbEt$_3$OAc and PbEt$_3$Cl, into the corresponding leadalkyls, a biochemical carbanion transfer reaction should occur in the bacterial cell[14–16]. We therefore used mixed cultures and an enrichment culture of methanogenic bacteria for the anaerobic experiments, and a mixed culture of aerobic bacteria and the *Escherichia coli* auxotroph 113–3 for the aerobic experiments. The enzymatically bound CH$_3$-cobalamin (Fig. 1) formed from various substrates by these organisms could act as a carbonium donor in the formation of methane and methionine, respectively, or possibly as a biological 'Grignard intermediate', transferring a carbanion (CH$_3^-$) to lead compounds, with leadalkyls as the final products. The criterion for the metabolic activity was the formation of CH$_4$/CO$_2$ and CO$_2$ by the anaerobic and aerobic bacteria, respectively. The criterion for the metabolic activity of *E. coli* 113–3 was methionine formation.

Experiments were carried out in bioreactors attached to leadalkyl collectors for trapping the alkyls blown out with the CH$_4$/CO$_2$ gas mixture produced by methanogenic bacteria, or with the air stream fed into the reactor during incubation of aerobic bacteria. The bottom of the collector was equipped with a rubber septum for sampling using syringes. Three analytical methods were applied (Fig. 2). In tracer-free experiments a gas chromatograph in combination with an atomic spectrophotometer (GC–AAS) served as the leadalkyl detector system. Samples from the collector were analysed daily by direct injection of the liquid from the collector into the gas chromatograph. Leadalkyls possibly adsorbed on the reactor wall, the bacterial mass or the sediments were also extracted after incubation and analysed by GC–AAS. Sediments and nutrient solutions were analysed for non-volatile partially biomethylated intermediates such as PbMe$_3^+$ and PbMe$_2^{2+}$ by TLC[17].

The incubation experiments with ^{14}C-labelled substrates and ^{210}Pb enabled us to use two further detection procedures. After refluxing the collector liquid to blow out ^{14}CH$_4$ and ^{14}CO$_2$ absorbed in the cooled liquid, one sample was analysed by GC–AAS and another by liquid scintillation counting. If lead had been methylated there would have been a relationship between the count rate remaining after refluxing and the peak height found by GC–AAS. In the ^{210}Pb-tracer experiments with unlabelled substrates, a multi-channel analyser was used as leadalkyl detector, and in the ^{210}Pb-tracer experiments with the labelled substrates we used the multi-channel analyser and liquid scintillation counting as detector systems. Here, too, a relationship between the ^{210}Pb and ^{14}C radioactivity would have to be found if lead compounds were methylated.

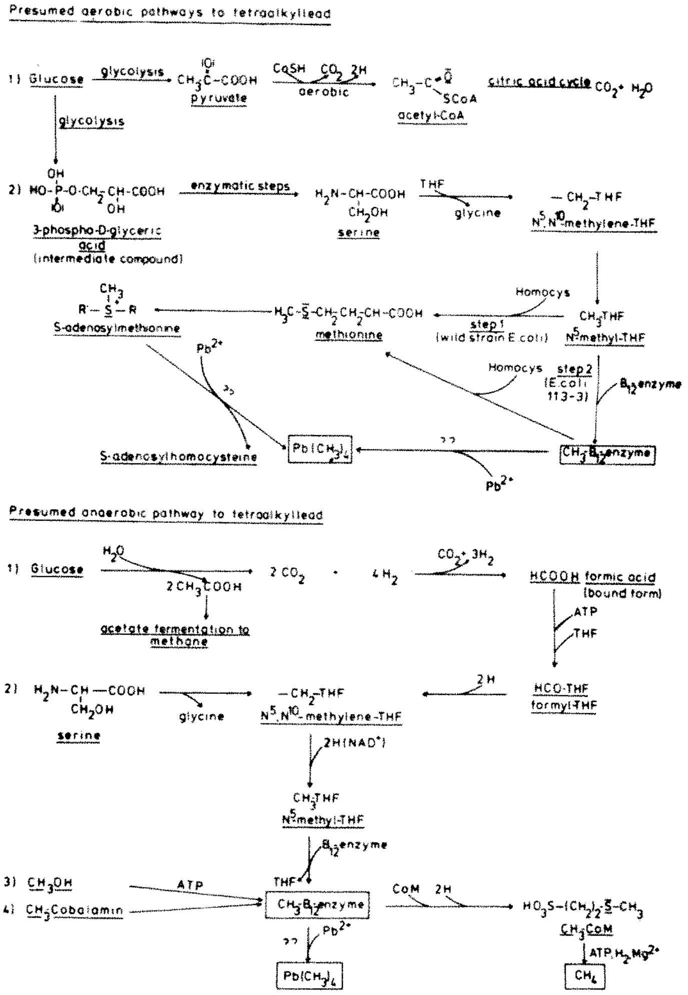

Fig. 1 The biosynthesis of the CH$_3$-B$_{12}$-enzyme from various substrates and the hypothetic methyl group transfer to lead in anaerobic and aerobic conditions.

In none of our experiments were leadalkyls or partially methylated intermediates detected as the products of biomethylation. Analysis of the collector liquid in the incubation experiments with inorganic lead and the ^{14}C-labelled substrates after refluxing revealed no Pb^{14}Me$_4$ peak, but there was a residual count rate, possibly representing a trace of Pb^{14}Me too low to be detectable by the GC–AAS. However, experiments with ^{210}Pb^{2+} as the methyl group acceptor and ^{14}C-serine and ^{14}C-methanol, as the methyl group donors, respectively, proved conclusively that this residual count rate was not due to Pb^{14}Me. As before, there was a residual ^{14}C-count rate, but no corresponding ^{210}Pb radioactivity was detectable. The incubation experiments with ^{210}Pb^{2+} and the unlabelled substrates have verified these results. At no time did the analysis of the leadalkyl trap with the multi-channel analyser exceed 135 counts per h. This count rate represented the 10^{-8} part of the count rate produced by 100 μCi ^{210}Pb radioactivity added to the culture initially.

However, incubation with PbMe$_3$OAc, PbEt$_3$OAc and the substrates summarized in Table 1 yielded PbMe$_4$ and PbEt$_4$ (Fig. 3*a*). However, as no PbMe$_3{}^{14}$Me or PbEt$_3{}^{14}$Me was found,

Incubation mixtures were 200g sediment or sludge, 50 ml enrichment culture or 5 ml pure *E.coli* culture, 60 mg unlabelled Pb compounds or 100 μCi $^{210}Pb(NO_3)_2$ (specific activity 1 mCi per 0.016 mg Pb), the substrates and 800 ml nutrient medium. Nutrient medium A (per 1): K_2HPO_4 (1 M), 3.7 ml; NH_4Cl (10%), 4 ml; $MgCl_2 \cdot 6\,H_2O$ (16.6%), 1 ml; $FeCl_2 \cdot 4\,H_2O$ (0.72%), 2 ml; Wolfe's minerals, 20 ml; Wolfe's vitamins, 20 ml; $NaOOCH_3 \cdot 3\,H_2O$, 1.7 g; NaOOCH, 2 g; $NaHCO_3$, 2 g; cysteine-HCl·H_2O, 0.5 g. *p*H of final mixture 7.0. Nutrient medium B (per 1): K_2HPO_4, 7 g; KH_2PO_4, 3 g; Na-citrate·(5.5 H_2O), 0.55 g; $(NH_4)_2SO_4$, 2 g; D,L-aspartic acid, 1 g; D-glucose, 5 g; $MgSO_4$, 0.05 g; NaCl, 1 g. *p*H of final mixture 7.4. Nutrient medium C (per 1): as medium B, but with vitamin B_{12}, 1 μg; D,L-homocysteine, 0.3 g.

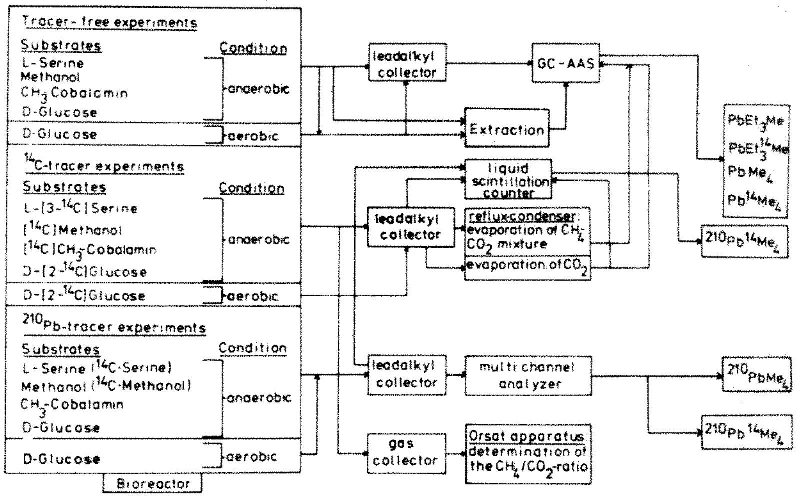

Fig. 2 Analytical methods for the determination of leadalkyls possibly formed by anaerobic or aerobic incubation in the presence of various substrates and lead compounds. During the incubation experiments leadalkyl collector used 4 ml ethanol as absorbent liquid, −30 °C; extraction of the incubation mixture was with 20 ml ligroin (b.p. 60–80 °C): GC–AAS 10 μl; detection limit 0.09 μg Pb per ml extract. Liquid scintillation counting used 0.5 ml extract and 15 ml scintillation gel; background count rate was 13 c.p.m.

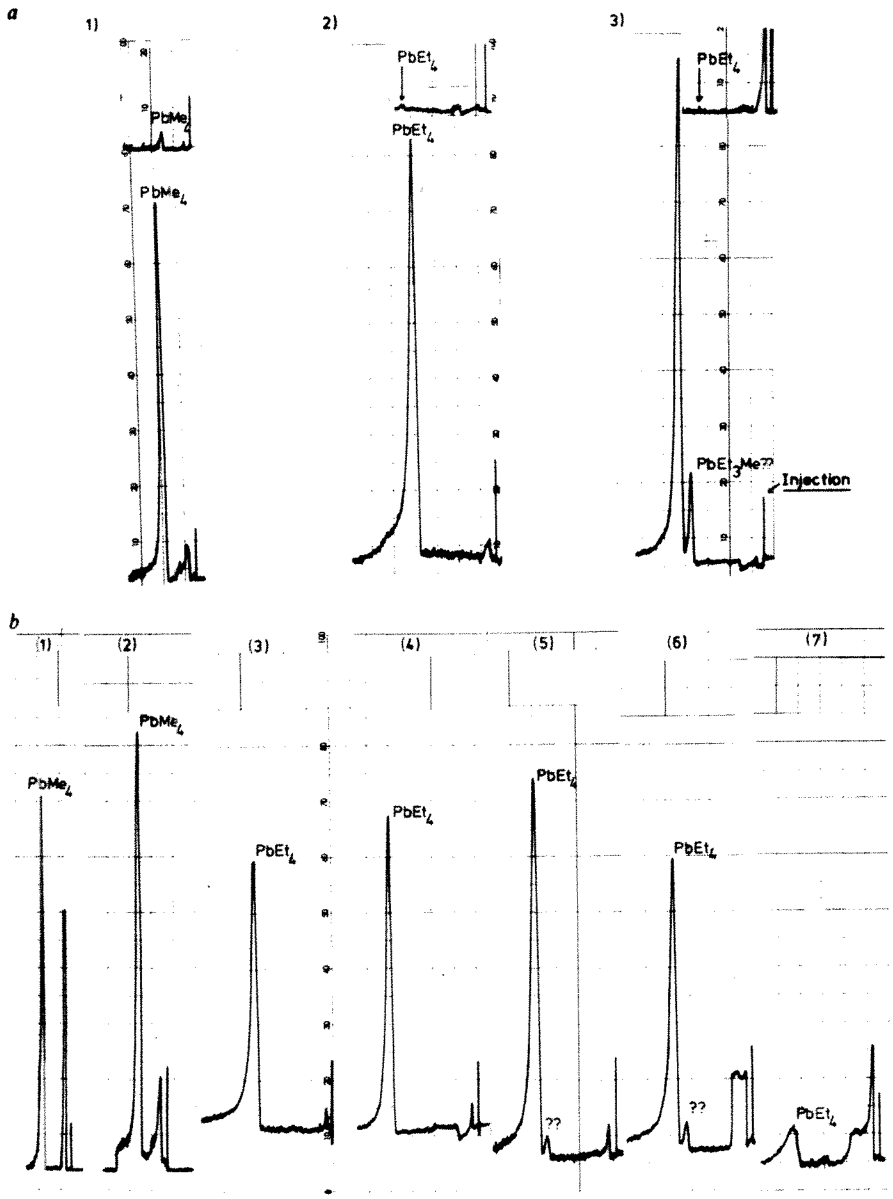

Fig. 3 The conversion of $PbMe_3OAc$, $PbEt_3OAc$ and $PbEt_3Cl$ in *in vivo* and *in vitro* conditions. *a*, Results of *in vivo* incubation of organic Pb(IV) salts with sewage sludge and L-serine substrates for 24 h. (1) Sludge + $PbMe_3OAc$; (2) sludge + $PbEt_3OAc$; (3) sludge + $PbEt_3Cl$. For comparison, blanks due to chemical side reactions in distilled water are given at the top. *b*, Results after the *in vitro* reaction (37 °C) between organic Pb(IV) salts and sulphur-containing compounds such as Na_2S, cysteine and methionine for 24 h (7: 96 h). Reaction mixture was 200 ml tridistilled water (de-aerated by boiling and gasing with N_2), 10 mg Pb compound, 10 mg sulphur compound. (1) $PbMe_3OAc$ + sulphide; (2) $PbMe_3OAc$ + cysteine; (3) $PbEt_3OAc$ + sulphide; (4) $PbEt_3OAc$ + cysteine; (5) $PbEt_3Cl$ + sulphide; (6) $PbEt_3Cl$ + cysteine; (7) $PbEt_3Cl$ + methionine.

the incubation products could not be the result of biological methyl transfer from the substrates to the corresponding ionic organic lead compounds. Moreover, tests with sulphur-containing substances have unambiguously verified the results of the important finding of Jarvie *et al.*[12] that $PbMe_4$ and naturally $PbEt_4$ are the result only of a chemical conversion induced by sulphide. Nevertheless, not only is 'free sulphide' involved in the reaction but also amino acids containing 'bound sulphide', such as cysteine and glutathione (Fig. 3*b*). On the other hand, sulphur-free amino acids, amino acids with blocked S-functions (methionine; Fig. 3*b*, chromatogram 7) or compounds with S-functions, such as thiourea, had no effect on the chemical conversion of the organic lead salts.

Incubation with $PbEt_3Cl$ (Fig. 3*a*) and $PbEt_4$ seemed to produce $PbEt_3Me$ which could be considered a product of biomethylation. However, the appearance of the presumed $PbEt_3Me$ compound even in the absence of any methylating agent, with only sulphide present (Fig. 3*b*, chromatograms 5 and 6), proved that the peak presumed $PbEt_3Me$ in Fig. 3*a* was not the result of biological methyl transfer but corresponds to an impurity. Tracer experiments have unambigiously supported these findings.

We therefore conclude that there is no basis for the assumption that biological methylation of Pb(II) occurs in the environment, whereas sulphide-induced chemical conversion of organic Pb(IV) salts into leadalkyls is possible.

We thank Dr S. Schoberth for microbiological advice and particularly K. May for support in the tracer experiments.

Glycosaminoglycan synthesis by the apical ectodermal ridge of chick limb bud

Robert A. Kosher & Mary P. Savage

Department of Anatomy, University of Connecticut Health Center, Farmington, Connecticut 06032, USA

The apical ectodermal ridge (AER) along the distal periphery of the embryonic chick limb bud seems to have a decisive influence on the development of subjacent mesenchymal cells, preventing cartilage differentiation but ensuring the outgrowth and formation of distal limb structures[1–5]. It has been suggested that when mesenchymal cells leave the AER's influence, they undergo an intimate cell–cell interaction that triggers chondrogenic differentiation by elevating cyclic AMP levels[6–8]. Moreover, the AER may inhibit the differentiation of subjacent mesenchymal cells by causing them to secrete a considerable quantity of hyaluronate which by accumulating extracellularly may prevent the cell–cell interaction necessary to trigger differentiation[9]. Here, we have examined the synthesis of hyaluronate and other glycosaminoglycans by the AER and by limb and non-limb ectodermal tissues that do not promote limb bud outgrowth[1,5,10,11]. We find that there is a selective and substantial increase in the amount of hyaluronate produced by the AER compared with the non-inductive ectodermal tissues.

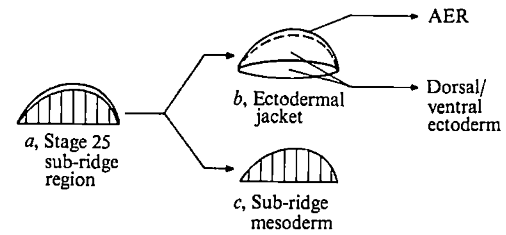

Fig. 1 Diagram of the method used to obtain AERs and dorsal/ventral limb ectoderm from the sub-ridge region of a stage 25 limb bud. Ectodermal jackets (*b*) were separated intact from the sub-ridge mesoderm (*c*) following a brief treatment with trypsin[4], and the AER was then surgically separated from the dorsal/ventral limb ectoderm by cutting with fine knives along the dotted line indicated in *b*.

Distal wing bud tips composed of the sub-ridge mesoderm capped by the AER and surrounded dorsally and ventrally by ectoderm were cut away from stage 25 embryos[12] of White Leghorn chicks (see Fig. 1*a* and ref. 4), and the ectodermal jackets (Fig. 1*b*) were separated intact from the sub-ridge mesoderm (Fig. 1*c*) following brief treatment with trypsin[4]. The AER was then surgically separated from the dorsal/ventral limb ectoderm by cutting with fine knives along the dotted line indicated in Fig. 1*b*. These procedures cleanly separate the ectodermal tissues from the sub-ridge mesoderm, and no adherence of mesodermal tissue to the isolated AERs and dorsal/ventral ectoderm is detectable with the dissecting microscope. In addition, non-limb ectodermal tissue surrounding the flank region of stage 25 embryos was removed with the aid of trypsin. The isolated AERs, the pieces of dorsal/ventral limb ectoderm and the non-limb flank ectoderm were incubated separately at 37 °C for 90 min, 17 h or 24 h in F12X medium containing 10% fetal calf serum and 100 μCi ml^{-1} of ^{3}H-glucosamine. For the 90-min incubation 150–200 AERs were used, and 30–50 AERs for the longer incubations. After incubation, glycosaminoglycans (GAGs) were extracted from the tissues and medium and the types of GAGs synthesized were determined as described in Table 1 legend.

Table 1 shows the relative amounts of the various ^{3}H-glucosamine-labelled GAGs accumulated by the AER, dorsal/ventral limb ectoderm and flank ectoderm after the three labelling periods. The only major difference in the pattern of GAG accumulation between the AER and dorsal/ventral limb ectoderm after each labelling period is in the relative amount of hyaluronate; the hyaluronate accumulated by the AER (~8%) is about twice that accumulated by the dorsal/ventral ectoderm (~4%). In contrast, there is little, if any, difference in the

Table 1. Relative amounts of the various ^{3}H-glucosamine-labelled components accumulated by the AER, dorsal/ventral limb ectoderm and flank ectoderm after various labelling periods

		Hyaluronate		Chondroitin sulphate		Other GAGs		Glycoprotein	
Labelling period	Tissue	%	Relative to AER*	%	Relative to AER*	%	Relative to AER*	%	Relative to AER*

24 h	AER	8.1±0.9	—	15.9±1.7	—	17.8±0.4	—	58.2±2.9	—
	Dorsal/ventral limb ectoderm	3.9±0.8	0.48	15.5±2.1	0.97	16.7±0.6	0.94	63.9±2.3	1.10
	Flank ectoderm	6.6±1.8	0.81	10.6±1.6	0.67	19.8±0.4	1.11	63.2±3.9	1.09

After the appropriate labelling period, GAGs were extracted from the tissue and medium as previously described[15]. Briefly, the tissue and medium were sonicated, and an aliquot of the sonicate removed for DNA determination[16]. The sonicates were boiled, digested with Pronase (Calbiochem), treated with ice-cold trichloroacetic acid, and the acid-soluble material was extensively dialysed to remove unincorporated isotope. The dialysates were lyophilized or evaporated to dryness, and dissolved in distilled water. The effectiveness of the isolation procedure in removing unincorporated isotope was monitored in each experiment by subjecting ^{3}H-glucosamine-containing medium which was incubated in the absence of tissue to the extraction procedure. The amount of ^{3}H-glucosamine-labelled hyaluronate was determined as previously described[17] using leech hyaluronidase (hyaluronic acid-B1, 3 hydrolase; Biometrics), an enzyme which specifically degrades hyaluronate[18,19]. Briefly, after treatment of an aliquot of the ^{3}H-glucosamine-labelled samples with the enzyme, the amount of radioactivity associated with leech hyaluronidase-sensitive and -resistant material was determined after precipitation of undegraded GAGs with cetylpyridinium chloride (CPC)[17]. Data were corrected for no enzyme control values, that is, the amount of untreated ^{3}H-glucosamine-labelled material soluble in CPC. The amount of untreated ^{3}H-glucosamine-labelled material soluble in CPC was taken to represent labelled polysaccharide chains of glycoproteins (see ref. 17). The amount of ^{3}H-glucosamine-labelled chondroitin sulphate was determined as previously described[17] using chondroitinase ABC (Miles), an enzyme which degrades the isomeric chondroitin sulphates as well as hyaluronate[20]. Aliquots of the GAG samples were treated with the enzyme, and the amount of radioactivity associated with chondroitinase-sensitive and -resistant material determined after precipitation with CPC[17]. As chondroitinase ABC degrades hyaluronate as well as the isomeric chondroitin sulphates, the amount of hyaluronate (leech hyaluronidase-sensitive GAGs) was subtracted from the amount of chrondroitinase-sensitive GAGS to determine the amount of radioactivity associated with chondroitin sulphates[17]. The other GAGs referred to represent ^{3}H-glucosamine-labelled GAGs resistant to degradation with chondroitinase ABC. About 50% of the chondroitinase ABC-resistant material produced by both the AER and dorsal/ventral limb ectoderm has been found to be sensitive to degradation by nitrous acid, and thus probably represents heparan sulphate. Values (%) represent the mean of three (90 min and 24 h) or two (17 h) determinations ± s.e.m.

* The relative amount of the appropriate ^{3}H-glucosamine-labelled component accumulated by the dorsal/ventral limb ectoderm or flank ectoderm was divided by the relative amount of that component accumulated by the AER.

Table 2 Total amounts of the various ^{3}H-glucosamine-labelled components accumulated by the AER, dorsal/ventral limb ectoderm and flank ectoderm after various labelling periods

Labelling period	Tissue	Hyaluronate (c.p.m. per μg DNA)	Chondroitin sulphate (c.p.m. per μg DNA)	Other GAGs (c.p.m. per μg DNA)	Glycoprotein (c.p.m. per μg DNA)
90 min	AER	703	1,966	1,046	3,810
	Dorsal/ventral limb ectoderm	234	1,859	1,168	3,613
	Flank ectoderm	196	654	347	1,467
17 h	AER	8,852	18,409	18,441	79,385
	Dorsal/ventral limb ectoderm	2,241	8,411	8,332	37,616
	Flank ectoderm	1,677	3,645	5,434	20,778
24 h	AER	12,209	23,574	26,688	86,962
	Dorsal/ventral limb ectoderm	2,821	12,033	13,420	50,797
	Flank ectoderm	2,958	4,872	9,267	29,933

Values are the means of three (90 min and 24 h) or two (17 h) separate experiments.

Table 3 Amounts of the various ^{3}H-glucosamine-labelled components accumulated by the dorsal/ventral limb ectoderm and flank ectoderm relative to the amounts accumulated by the AER

Labelling period	Tissue	Hyaluronate	Chondroitin sulphate	Other GAGs	Glycoprotein
90 min	Dorsal/ventral limb ectoderm	0.37±0.08	0.98±0.06	1.17±0.17	1.01±0.11
	Flank ectoderm	0.29±0.05	0.33±0.004	0.34±0.03	0.35±0.06
17 h	Dorsal/ventral limb ectoderm	0.25±0.12	0.45±0.10	0.45± 0	0.47±0.08
	Flank ectoderm	0.18±0.17	0.19±0.13	0.30±0.01	0.25±0.08
24 h	Dorsal/ventral limb ectoderm	0.29±0.05	0.54±0.04	0.52±0.05	0.62±0.06
	Flank ectoderm	0.33±0.16	0.26±0.09	0.41±0.15	0.37±0.13

The amount of the appropriate ^{3}H-glucosamine-labelled component (c.p.m. per μg DNA) accumulated by the dorsal/ventral limb ectoderm or flank ectoderm was divided by the amount (c.p.m. per μg DNA) of that component accumulated by the AER. Values are the means of three (90 min and 24 h) or two (17 h) separate experiments ± s.e.m.

relative amounts of the other ^{3}H-glucosamine-labelled components accumulated by the two tissues. The difference in the relative amount of hyaluronate accumulated by the AER compared with the flank ectoderm is not as great as that between the AER and dorsal/ventral limb ectoderm. However, as described below, the total amount of hyaluronate accumulated by the flank ectoderm during all labelling periods is considerably less than the total amount accumulated by the AER. Also, the pattern of GAG accumulation by the isolated AERs is strikingly different from the pattern of accumulation by the mesenchymal cells directly subjacent to the AER (see ref. 9).

Table 2 shows the total amounts (c.p.m. per μg DNA) of the various ^{3}H-glucosamine-labelled GAGs accumulated by the different ectodermal tissues, and Table 3 summarizes the differences in the total amounts of the various ^{3}H-glucosamine-labelled components accumulated by the dorsal/ventral ectoderm and flank ectoderm and the AER. During a 90-min labelling period, the AER accumulates almost threefold more hyaluronate than the dorsal/ventral limb ectoderm, whereas there is little, if any, difference in the total amounts of other ^{3}H-glucosamine-labelled components accumulated by the two tissues. Thus, after a 90-min labelling period there is a selective quantitative increase in the amount of hyaluronate produced by the AER over the immediately adjacent dorsal/ventral limb ectoderm. After either a 17- or 24-h labelling period, there is an increase in the accumulation of all ^{3}H-glucosamine-labelled materials by the AER compared with the dorsal/ventral ectoderm. Note, however, that whereas the amount of chondroitin sulphate, chondroitinase-resistant GAGs and glycoprotein produced by the AER was doubled compared with the dorsal/ventral limb ectoderm, the amount of hyaluronate accumulated increased fourfold. Thus, there is a striking disproportionate increase in hyaluronate accumulation by the AER compared with the dorsal/ventral limb ectoderm. Finally, after either short (90 min) or long labelling (17 and 24 h) periods, there is a considerable reduction (three- to fivefold) in the accumulation of all ^{3}H-glucosamine-labelled components by the flank ectoderm compared with the AER (Tables 2, 3).

Obviously, our results do not prove that the substantially larger amount of hyaluronate produced by the AER than by the other ectodermal tissues is involved in the unique outgrowth-promoting effect of the AER. The possibility that the hyaluronate produced by the AER is involved in the negative differentiative effect the AER exerts on subjacent mesenchymal cells is, however, particularly intriguing. We have previously suggested that the AER may inhibit cartilage differentiation by causing subjacent mesenchymal cells to secrete large amounts of hyaluronate which prevent a cell–cell interaction necessary to trigger differentiation and/or which feed back on the cells, inhibiting their production of cartilage matrix components[9]. It is conceivable, therefore, that the hyaluronate produced by the AER may be involved in inhibiting differentiation by acting on the immediately subjacent mesenchymal cells, causing them to maintain their own high rate of hyaluronate synthesis, or perhaps by simply contributing to the hyaluronate-rich matrix surrounding the subjacent mesenchymal cells. Notably studies by Toole[13,14] indicate that exogenous hyaluronate exerts an inhibitory effect on *in vitro* chondrogenic differentiation.

Induction of anti-H-2 antibodies without alloantigen exposure by *in vivo* administration of anti-idiotype

Jeffrey A. Bluestone, Susan O. Sharrow, Suzanne L. Epstein, Keiko Ozato & David H. Sachs

Transplantation Biology Section, Immunology Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

Anti-idiotypic reagents have been used recently to manipulate both idiotype (ID) expression and antigen-binding antibody activity of immunized animals[1–11]. The *in vivo* administration of anti-idiotypic antibodies followed by antigen exposure has usually resulted in suppression of ID-positive antigen binding molecules[6–8], although, in other circumstances, increased idiotype expression and antigen-binding activity has also been observed[1–5]. Extension of these findings to the immune response to transplantation antigens is of obvious practical and theoretical importance. There have been several reports describing the production of anti-idiotypic reagents against alloantisera[9–11], although the generation of anti-ID antibodies in this way has generally been difficult to reproduce[11]. Therefore, in the study reported here we used xenogeneic anti-idiotypic antisera raised against monoclonal anti-H-2K^k antibodies which offer the advantage of reproducibility of anti-idiotype production[12]. These anti-idiotypic reagents were produced by immunizing swine and rabbits with either purified 3-83P[13] or 11-4.1 (ref. 14), both of which are IgG2a, k anti-H-2K^k antibodies. We found that none of these reagents detected significant levels of idiotype in anti-H-2 antisera produced against H-2K^k antigens by conventional means. However, BALB/c mice treated with these anti-idiotypes consistently produced large amounts of idiotype, and in some animals this induced response included idiotype-positive antibodies which bound to H-2K^k antigens. Thus, treatment with anti-idiotype has been found to induce anti-H-2K^k antibodies in the absence of exposure to the H-2K^k antigen.

Immune antisera were absorbed with LPC-1 myeloma (IgG2a, k) coupled to Sepharose to remove all anti-normal mouse immunoglobulin. Purified anti-3-83P or anti-11-4.1 antibodies were obtained by specific adsorption to and elution from Sepharose columns bearing the appropriate idiotype. We have previously demonstrated that these purified anti-idiotypic reagents detect unique idiotypic determinants on the monoclonal antibodies but do not cross-react with each other or with a series of other monoclonal anti-H-2K^k antibodies, some of which share identical specificities[12]. The effects of *in vivo* administration of these anti-ID reagents on both the expression of ID and the generation of H-2K^k antigen binding molecules were examined.

Table 1 Idiotype expression on serum antibodies from BALB/c mice immunized with anti-idiotypic antibodies or alloantigen

		HAI titre ($\log_2$) of sheep red blood cells coated with:			
		3-83P ID		11-4.1 ID	
		Pig α	Rabbit α	Pig α	Rabbit α
Group	Treatment	3-83P	3-83P	11-4.1	11-4.1
(1)	BALB.K skin graft and spleen cells	≤1	≤1	≤1	≤1
(2)	Rabbit anti-3-83P antibodies	8–9	6–8	1–2	≤1
(3)	Pig anti-11-4.1 antibodies	1–2	≤1	5–6	5–6
(4)	Rabbit anti-normal mouse immunoglobulin	≤1	≤1	≤1	≤1
(5)	Pig anti-normal mouse immunoglobulin	1–2	<1	1–2	<1

In group 1, BALB/c mice were immunized against H-2^k antigens by a BALB.K tail skin graft and subsequent boosting i.p. with 2×10^7 BALB.K spleen cells per mouse. Other groups of BALB/c mice were treated on day 0 and 3 with 20 μg of the antibodies injected i.p. in saline. On day 42, mice were bled and separate pools of sera from each group of mice were assayed for both idiotype expression and for anti-H-2K^k activity (Fig. 1). Idiotype levels were determined using a haemagglutination inhibition assay (HAI) as described elsewhere[4].

In the first experiment (Table 1) groups of BALB/c mice were treated with alloantigen (C3H skin graft and lymphoid cells), anti-idiotypic antibodies, or anti-normal mouse immunoglobulin (eluted from LPC-1 coupled to Sepharose). The animals were bled on day 42 and a serum pool from each group tested for idiotype expression in a haemagglutination inhibition assay (HAI; ref. 15). The pool of anti-H-2K^k alloantiserum (cytotoxic titre 1:400) did not express detectable levels of ID, which confirmed previous results on pools of conventional anti-H-2^k antisera made in BALB/c and other strains of mice[12]. In contrast, treatment with purified anti-idiotypic antibodies (20 μg intraperitoneally (i.p.), days 0 and 3) resulted in the

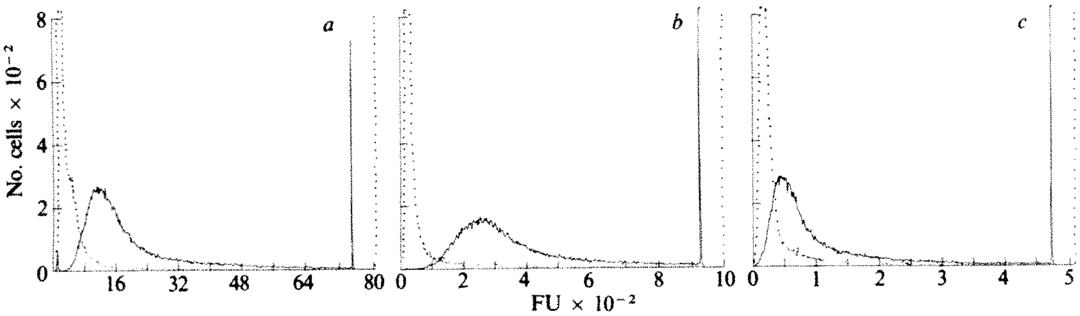

Fig. 1 Antiserum from alloimmunized and anti-idiotype treated mice were examined for anti-H-2K^k activity by flow cytofluorometry. Lymph node cells from C3H (H-2K^k) or C3H.OH (H-2K^d) mice were stained with test serum from individual mice of groups 1–4 (Table 1), counterstained with a mixture of fluoresceinated goat $F(ab')_2$ anti-mouse IgG1 (1:32) and fluoresceinated goat $F(ab')_2$ anti-mouse IgG2 (1:32) and analysed in a FACS II (Becton Dickinson). Fluorescence data were collected on 5×10^4 viable cells and displayed as a 1,000-channel cell frequency histogram in which fluorescence intensity was plotted (abscissa) against cell number (ordinate). Fluorescence intensity was converted to fluorescence units (FU; ref. 17) for comparison. In *a*, sera from a pool of mice immunized with a C3H tail skin graft and lymphoid cells were examined for anti-H-2^k activity on lymph node cells from C3H (solid line) and C3H.OH (dotted line) mice. *b*, Fluorescence profile of the binding of anti-H-2K^k antibodies in an Erhlich's induced ascites from mouse 1529, immunized on day 0 and 3 with 20 μg of purified rabbit anti-3-83P antibodies and boosted with 20 μg of anti-idiotype 1 week before being given the ascites tumours (group 2, Table 1). *c*, Profile of anti-H-2K^k binding of an ascites from mouse 1505 similarly treated with pig anti-11-4.1 anti-idiotypic antibodies (Group 3, Table 1).

induction of idiotype-positive (ID$^+$) molecules in the serum. The observed inhibition of haemagglutination by immune sera from anti-idiotype treated mice was not due to an anti-pig or anti-rabbit immunoglobulin response because: (1) idiotype-positive molecules induced in mice treated with pig anti-11-4.1 antibodies were detected by both rabbit and pig anti-idiotype agglutinators (Table 1), and (2) BALB/c mice treated with either pig or rabbit anti-normal mouse immunoglobulin produced no significant levels of idiotype-positive molecules. ID$^+$ molecules were detected as early as 1 week after anti-idiotype administration, reached a plateau at ~3 weeks, and remained detectable for several months after immunization. Only the homologous ID was expressed after *in vivo* treatment with anti-idiotype. For example, in group 2, the injection of anti-3-83P anti-idiotypic antibodies resulted in the production of 3-83P ID$^+$ but not 11-4.1 ID$^+$ molecules.

The ascites from anti-idiotype treated mice were next examined for anti-H-2K^k binding activity by flow cytofluorometry (Fig. 1). Ascites from individual immunized animals were incubated with C3H (H-2K^k) or C3H.OH (H-2K^d) lymph node cells. Fluoresceinated F(ab')$_2$ anti-IgG1 and F(ab')$_2$ anti-IgG2 antibodies were then added to the antibody-coated cells and the stained cells analysed using the fluorescence activated cell sorter (FACS II). Figure 1 illustrates the anti-H-2K^k activity of two mice, one from group 2 (1529) and one from group 3 (1505). Anti-H-2K^k binding activity was detected in three of six mice treated with rabbit anti-3-83P anti-idiotype and in two of five mice treated with pig anti-11-4.1. None of 10 control mice treated with either rabbit or pig anti-normal mouse immunoglobulin produced detectable levels of anti-H-2K^k antibodies (data not shown). The specificity of the antigen-binding molecules produced by the anti-idiotype treated mice was confirmed using H-2 congeneic recombinant strains of mice differing only at the H-2K^k region[16]. The anti-H-2 antibodies induced in these animals bound to B10.AKM (H-2K^k) but not B10.MBR (H-2K^b) lymph node cells.

To assess idiotype expression on these anti-idiotype induced anti-H-2K^k antibodies, we examined the ability of purified anti-idiotypic antibodies or anti-normal mouse immunoglobulin to block antibody binding to C3H lymph node cells. As seen in Fig. 2, anti-normal mouse immunoglobulin had no effect on the binding to the appropriate cells of either conventional allo-

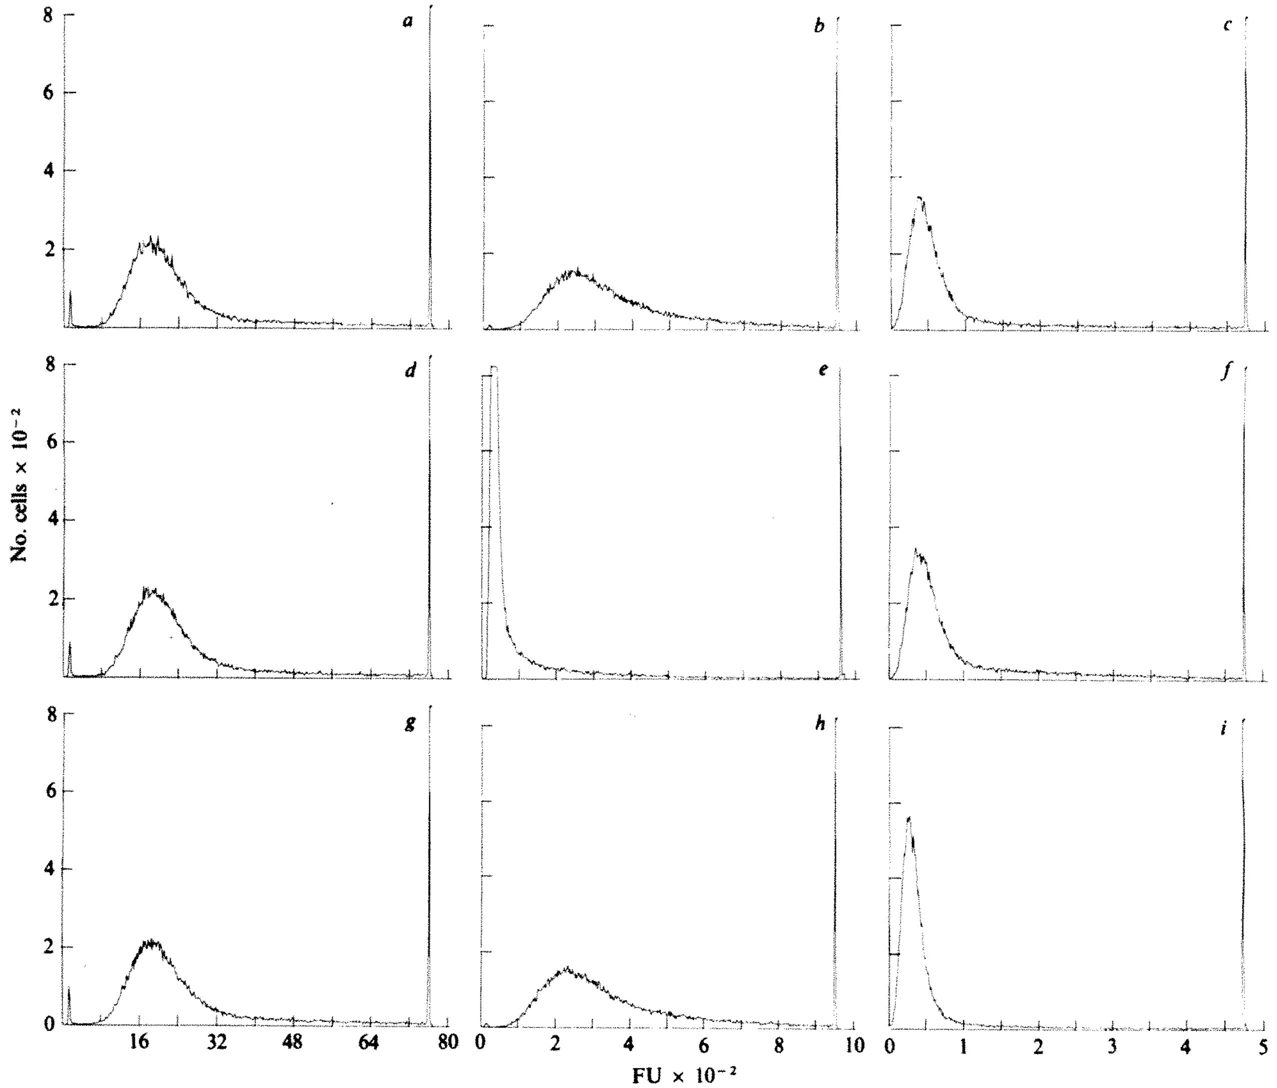

Fig. 2 Anti-H-2K^k antibodies from alloimmunized and anti-idiotype treated mice were examined for idiotype expression by a binding inhibition assay. Serum (25 μl) from treated mice was mixed with either 25 μl of anti-idiotype (100 μg ml^{-1}) or 25 μl of anti-normal pig immunoglobulin (100 μg ml^{-1}). After incubation for 1 h, the test sera plus inhibitor were incubated with lymph node C3H cells and binding assessed as described in Fig. 1 legend. Binding of conventional pooled alloantisera to C3H cells was not appreciably inhibited by pig anti-normal mouse IgG (*a*), pig anti-3-83P (*d*), or pig anti-11-4.1 (*g*). Columns 2 (profiles *b*, *e*, and *h*) and 3 (profiles *c*, *f* and *i*) illustrate the inhibitory ability of the same pig antibodies on the binding of anti-H-2K^k antibodies induced in mice treated with rabbit anti-3-83P (1529) or pig anti-11-4.1 (1505), respectively. As the fluorescence units (FU) in each set of profiles differ, the level of inhibition must be compared with the reactivity of the serum with the congeneic H-2K^d cells (Fig. 1). Such comparisons indicate that <10% of the anti-H-2K^k binding activity in mice treated with anti-idiotype remained after inhibition with the appropriate anti-idiotype (profiles *e* and *i*).

antibodies or anti-idiotype induced anti-H–2K^k antibodies. In addition, antigen binding of pooled, high-titre, conventionally raised anti-H–2K^k antibodies was relatively unaffected by either anti-3-83P or anti-11-4.1 anti-idiotypic antibodies.

However, anti-idiotypic antibodies completely inhibited the binding of anti-H–2K^k antibodies induced by homologous anti-ID, as shown by a shift in intensity of the labelled cells to a level equivalent to that of controls not preincubated with alloantibodies. Specifically, purified pig anti-3-83P antibodies completely inhibited the H–2K^k antigen binding activity of antibodies induced in mouse 1529 by rabbit anti-3-83P. In contrast, anti-11-4.1 antibodies had no effect on the binding of serum antibodies from mouse 1529 but significantly inhibited the binding of antibodies induced in mouse 1505 by pig anti-11-4.1 anti-idiotype. These results suggest that the anti-H–2K^k antibodies induced in anti-idiotype treated mice expressed idiotopes closely related to those of the original hybridoma anti-H–2K^k reagents. However, although both the original monoclonal anti-H–2K^k antibodies were of the IgG2a subclass, the idiotypic determinants were found to be expressed on immunoglobulins of both the IgG1 and IgG2 subclasses by successive adsorption to and elution from specific goat anti-mouse IgG1 and anti-mouse IgG2 coupled to Sepharose (data not shown).

The finding that anti-idiotypic reagents produced against each monoclonal anti-H–2K^k antibody recognized determinants detected on few alloantibodies or other monoclonal anti-H–2K^k antibodies of similar specificity is most consistent with a large repertoire of anti-H–2 antibodies binding a given allodeterminant. Thus, the normal immune response to H–2 antigens such as H–2K^k may include a large number of individual clones each of which expresses private, or non-cross-reactive idiotypic determinants. Such polyclonality may be the reason that production of anti-idiotypic sera against pooled alloantisera has been so difficult[11]. Despite such polyclonality, these studies have demonstrated that among the idiotype-positive molecules induced in anti-ID treated mice are molecules which bind specifically to H–2K^k antigens. The anti-H–2K^k activity induced represents expression of V region genes which are common to BALB/c mice but which are only occasionally used in the normal response to H–2K^k. Therefore, these findings are consistent with a possible sharing of variable region structures in the anti-H–2K^k monoclonal antibodies with those of alloantibodies induced by anti-idiotype.

The induction of antigen-binding ID$^+$ molecules in the absence of exposure to antigen does not usually occur in systems involving soluble antigens after treatment with heterologous anti-ID[1,2,4]. This difference may depend in part on the increased sensitivity of detection of antigen binding activity allowed by FACS II. However, these findings may also reflect an intrinsic difference in the response to histocompatability antigens compared with most other antigens[9,10]. The ability of lymphoid cells to recognize H–2 antigens is of central importance in the immune response. Anti-idiotypic antibodies to monoclonal anti-H–2 antibodies may be useful as a probe for analysing the cellular interactions involved in immune responses and as a new approach for the specific manipulation of these responses.

We thank Marion Knode and Nanci Mayer for technical assistance in the production and purification of the monoclonal antibodies and anti-idiotype.

Cell interactions modulate embryonal carcinoma cell differentiation into parietal or visceral endoderm

F9 is a clonal line of mouse teratocarcinoma-derived embryonal carcinoma (EC) cells which shows very little spontaneous differentiation *in vivo* or *in vitro*[1]. Recently, however, it was reported[2–6] that F9 monolayers treated with retinoic acid and dibutyryl cyclic AMP differentiate into an early embryonic cell type known as parietal endoderm, which is one of two distinct populations of extra-embryonic endoderm that differentiate in the normal mouse embryo shortly after implantation[7,8]. The other population is the visceral endoderm, and the two differ not only in their morphology and location within the embryo, but also in their biochemical properties[9–12]. Parietal endoderm cells, for example, do not synthesize α-fetoprotein[13] (AFP), whereas visceral endoderm cells do[13]. There is evidence[8] that during embryogenesis parietal and visceral endoderm are derived from a common precursor population known as the primary endoderm, and recent experiments with cultured mouse embryos[14] suggest that the phenotype of these cells can be modulated by contact with different embryonic tissues. We now show that if F9 EC cultures are treated with retinoic acid when they are in the form of small aggregates, they differentiate on the outer surface cells which morphologically resemble visceral rather than parietal endoderm. In addition, the cells synthesize and secrete AFP, identified by immunoprecipitation and immunoperoxidase reactions using specific anti-AFP immunoglobulin. One interpretation of this result is that F9 cells treated with retinoic acid differentiate first into multipotent cells analogous to the primary endoderm of the normal embryo which then express either the mature parietal or visceral phenotype depending on the nature of the intercellular contact signals they receive. We therefore believe that F9 EC cells may be even more useful than previously supposed for biochemical studies on factors controlling gene expression during mammalian embryogenesis.

Small clumps of 30–50 EC cells are grown in suspension in bacteriological Petri dishes in medium containing 5×10^{-8}M retinoic acid. After 2–4 days most aggregates resemble simple embryoid bodies[15,16] with an outer layer of endoderm surrounding a core of undifferentiated cells. These aggregates often become hollow, and for a while resemble cystic embryoid bodies[15] (Fig. 1*a*). Later, however, this organization breaks down as an increasing proportion of the inner cells develop an endoderm-like morphology, and internal tissues analogous to embryonic ectoderm and mesoderm have never been observed, even after prolonged incubation. When aggregates cultured for 7 days are examined in the electron microscope, several kinds of endoderm cell are found. As shown in Fig. 1*c* and *d*, most

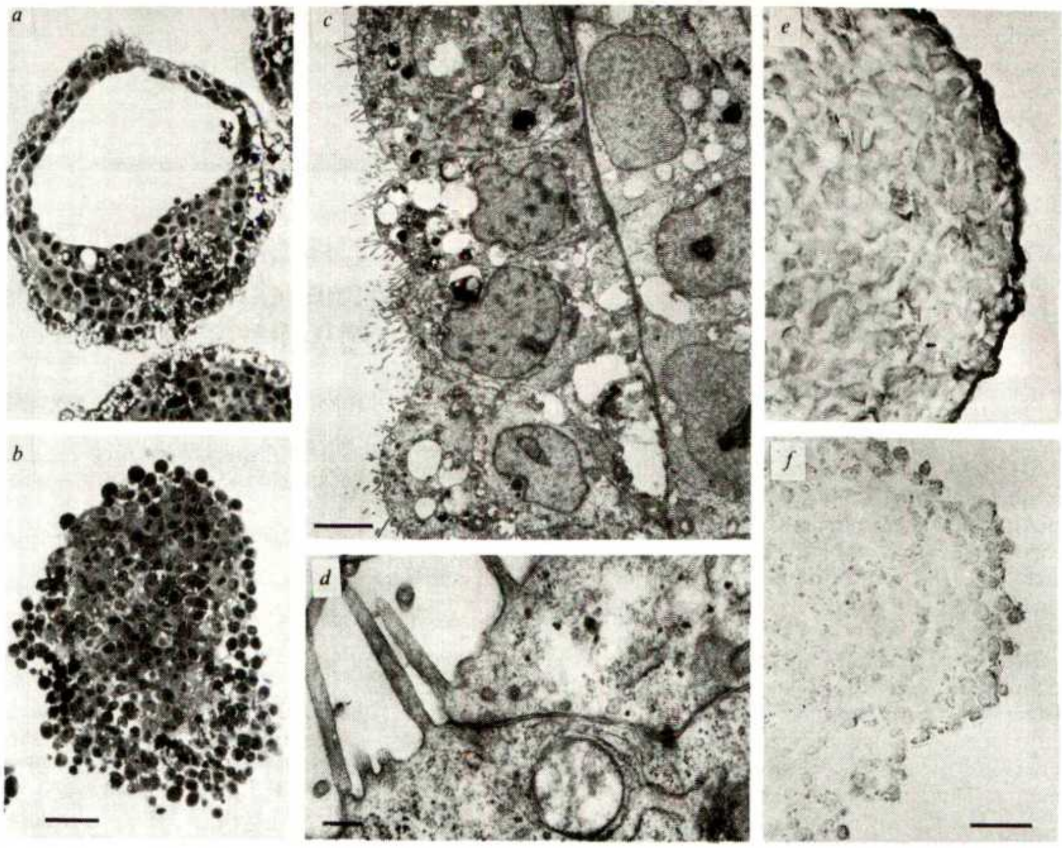

Fig. 1 Morphology of F9 cell aggregates treated with retinoic acid. *a*, Section through an aggregate of F9 cells cultured in the presence of 5×10^{-8} M retinoic acid for 7 days. Endoderm cells form an epithelial layer around the hollow core of still undifferentiated embryonal carcinoma cells. *b*, Section through an aggregate of F9 cells cultured in the presence of 1×10^{-7} retinoic acid and 10^{-3} M dibutyryl cyclic AMP for 5 days. In these conditions the endoderm cells do not form an epithelial layer but are rounded and loosely packed, with few intercellular junctional complexes. In the electron microscope all the differentiated cells have a typical parietal endoderm morphology. Scale bar, 50 μm for both *a* and *b*. *c*, Electron micrograph of visceral endoderm-like cells present in an aggregate of F9 cells exposed to 5×10^{-8} M retinoic acid for 7 days. The cells are joined apically by junctional complexes and have numerous microvilli, endocytotic vacuoles, lysosomes and lipid droplets. These features are all characteristic of visceral endoderm of the normal mouse embryo[7,14,17]. Scale bar, 5 μm; *d*, Detail of a desmosome and an apical junctional complex between two adjacent visceral endoderm-like cells in an aggregate exposed to 5×10^{-8} M retinoic acid for 7 days. Such intercellular connections are not found between parietal endoderm cells in the normal embryo[7,17]. Scale bar, 0.2 μm. *e*, *f*, Immunoperoxidase staining for AFP on sections of F9 aggregates. *e*, Cells were cultured for 5 days in the presence of 5×10^{-8} M retinoic acid in the standard culture medium and then for 2 days in serum-free medium[19]. This was to avoid retention of calf serum proteins which might cross-react with rabbit anti-mouse AFP. The antibody was also pre-absorbed with Sepharose-linked calf serum proteins to reduce further the possibility of staining calf AFP which could have been endocytosed by the F9 cells. The aggregates were fixed in acidified ethanol and embedded, sectioned and reacted as described elsewhere[13]. *f*, Aggregates cultured in standard medium containing 1×10^{-7} M retinoic acid and 10^{-3} dibutyryl cyclic AMP for 5 days were fixed, embedded, sectioned and reacted with rabbit anti-mouse AFP as described above, except that the antiserum was not pre-absorbed with calf serum proteins. No intracellular peroxidase staining is present. Scale bars, 20 μm *e* and *f*.

resemble visceral endoderm of the post-implantation mouse embryo[7,12,14,17] and have numerous microvilli and pinocytotic and lysosomal vacuoles, a thin endoplasmic reticulum and prominent intercellular apical junctional complexes. Others resemble parietal endoderm[7,12,17], with an extensive endoplasmic reticulum engorged with secretory material and few microvilli or intercellular junctional complexes. These cells are usually associated with pools of basement membrane material. The remainder have an intermediate morphology. Control aggregates incubated without retinoic acid never develop a continuous outer layer of endoderm, although some produce small 'blebs' of visceral endoderm-like cells.

As cells with a visceral endoderm morphology are present in aggregates incubated with retinoic acid we looked for the synthesis and secretion of the visceral endoderm marker protein, AFP. Aggregates were incubated with ^{35}S-methionine, and AFP immunoprecipitated from the culture medium with specific antiserum[13]. Synthesis of AFP could be detected after only 3 days' exposure to retinoic acid, and increased up to 7 days (Fig. 2*a*). At this time AFP represented about 0.05% of the total newly synthesized protein secreted by F9 aggregates, compared with a value of 4% for visceral yolk sacs isolated from 11.5-day embryos, although the comparison is only approximate because of the very different cellular composition and pool sizes of yolk sacs and aggregates. Figure 2*a* shows that the radioactive polypeptide immunoprecipitated by anti-AFP antiserum from the medium of F9 aggregates treated with retinoic acid co-migrates on SDS-polyacrylamide gels with AFP synthesized by visceral endoderm isolated from 13.5-day mouse embryos. Control F9 cell aggregates not exposed to retinoic acid synthesized very low and variable amounts of AFP (Fig. 2*a*), probably as a result of some spontaneous differentiation into endoderm. Experiments in which the concentration of retinoic acid was varied over 10^{-8}–10^{-6}M showed that the optimal concentration for inducing AFP production was 5×10^{-8}M. When aggregates exposed to retinoic acid for 7 days were sectioned and stained for AFP by the indirect immunoperoxidase technique using specific antiserum[13], a positive reaction was obtained in most endoderm cells (Fig. 1*e*). Control aggregates not exposed to retinoic acid had no intracellular staining, except where a bleb of endoderm cells was present (data not shown). Because the rabbit anti-mouse AFP antiserum was pre-absorbed with calf serum proteins and did not react with calf AFP in immunodiffusion assays, we are confident that the stain is identifying endogenously synthesized AFP. However, we cannot exclude the possibility that the AFP is synthesized and secreted by only a minority of the visceral endoderm cells and is then endocytosed from the medium by the remainder.

Earlier, Strickland and Sawey[4] failed to find evidence for AFP synthesis by F9 cells in monolayer cultures. In their experiments the cells were exposed to 1×10^{-7} M retinoic acid for 4 days. We have treated monolayers with 5×10^{-8} M retinoic acid, and observe significant AFP synthesis starting at 7 days, by which time the cultures are very dense and localized clumping between cells with endoderm and EC-like morphology has developed (Fig. 2*c*). In agreement with the observations of Strickland *et al.*[6], we find that F9 monolayers exposed to both retinoic acid and dibutyryl cyclic AMP differentiate into endoderm cells

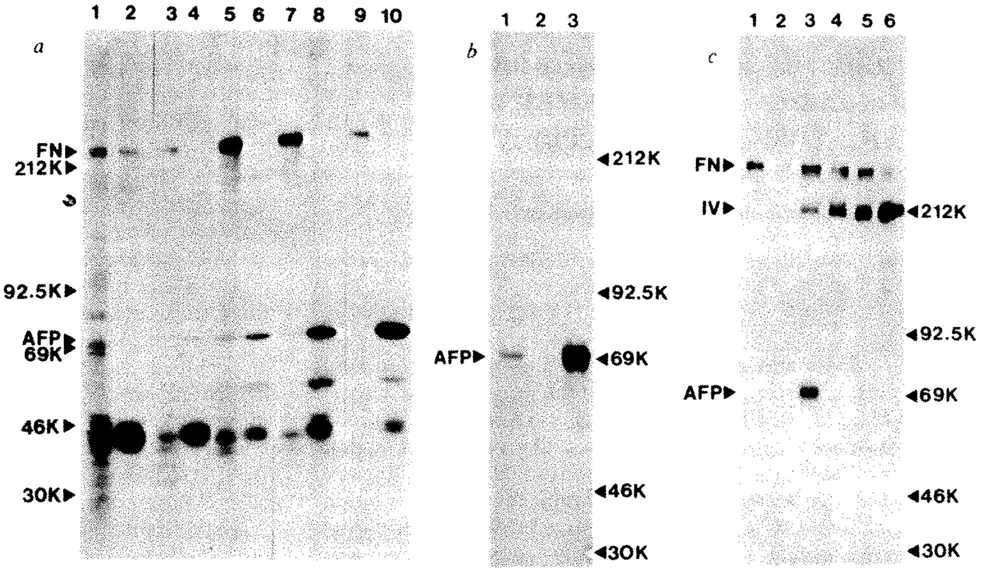

Fig. 2 Synthesis and secretion of AFP by F9 cells treated with retinoic acid. *a*, Time course of AFP synthesis by aggregates cultured in retinoic acid. Exponential cultures of F9 EC cells (from a line supplied by Colin Stewart, which had been recloned after *in vivo* passage as a tumour) were briefly trypsinized, and small aggregates resuspended in bacteriological Petri dishes in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal bovine serum (FBS) and 5×10^{-8} M retinoic acid (Sigma, added from a 10^{-4} M stock solution in alcohol and protected from light). Control aggregates were cultured without retinoic acid. The medium was changed every 48 h. After 3 days ~100 aggregates were removed every 24 h, washed twice in DMEM containing 1 μg ml^{-1} methionine and 10% dialysed FBS (labelling medium) and incubated for ~11 h in 1 ml labelling medium with 100μCi ^{35}S-methionine (specific activity 1,000 Ci mmol^{-1}; Radiochemical Centre), with and without retinoic acid. After incubation the aggregates were removed by sedimentation and 400-μl aliquots of the medium used for immunoprecipitation. Samples were diluted into 1 ml of 0.4 M NaCl, 0.005 M EDTA, 0.05 M Tris (*p*H 8.0) and 1% v/v NP40 (NET buffer) and 10 μl of rabbit anti-mouse AFP antiserum[13] added. After 1.5 h at room temperature 50 μl of protein A–Sepharose (Pharmacia, resuspended in NET buffer) were added and the incubation continued with continuous mixing at 4 °C for 1.5 h. The beads were then washed by centrifugation twice in NET buffer, once in 0.01 M Tris, *p*H 6.8, and finally boiled for 3 min in 30 μl gel sample buffer[18] (0.0625 M Tris, *p*H 6.8, 2% SDS, 10% glycerol, 5% β- mercaptoethanol). SDS-polyacrylamide gel electrophoresis was carried out according to the method of Laemmli[18], using 5–10% gradient slab gels. ^{14}C-labelled marker proteins (Radiochemical Centre) were included in the gel and their position is shown on the left-hand side of the figure. After electrophoresis the gels were fixed, impregnated with EN^{3}HANCE (NEN), dried and exposed to X-ray film (Kodak SB-5) at −70 °C. Tracks 1, 3, 5, 7 and 9, proteins immunoprecipitated with anti AFP antiserum from medium of control aggregates cultured for 3, 4, 5, 6 and 7 days in the absence of retinoic acid. The medium samples contained 1.59×10^6, 0.37×10^6, 0.41×10^6, 0.46×10^6 and 0.54×10^6 c.p.m. in total, acid-precipitable protein, respectively. Tracks 2, 4, 6, 8 and 10, proteins immunoprecipitated from medium of aggregates cultured for 3–7 days in the presence of 5×10^{-8} M retinoic acid. The medium contained 1.15×10^6, 0.42×10^6, 0.30×10^6, 0.30×10^6 and 0.53×10^6 c.p.m. in total acid-precipitable protein, respectively. Newly synthesized AFP migrates as a radioactive polypeptide of molecular weight (MW) ~70,000. The polypeptide of MW ~57,000 probably represents an AFP degradation product (E.A., unpublished observation), while the identity of the diffuse band at MW 46,000 is unknown. This band was not observed when the antiserum was pre-absorbed with adult mouse serum (see *b* and *c*). At all times, some radioactive fibronectin MW ~265,000 is nonspecifically bound to the protein A–Sepharose. From this, it can be seen indirectly that the amount of fibronectin synthesized and/or released into the culture medium by F9 cells is reduced after exposure to retinoic acid. Similar results to those shown were obtained with a line of F9 cells obtained from D. Solter. *b*, Co-migration of AFP synthesized by F9 aggregates and by normal visceral endoderm. After 6 days in culture in 5×10^{-8} M retinoic acid, aggregates were incubated for 12 h in labelling medium containing 200 μCi ml^{-1} ^{35}S-methionine and 5×10^{-8} M retinoic acid. Four visceral yolk sacs dissected from 13.5-day C3H/He mouse embryos were incubated for 18 h in labelling medium containing 100 μCi ml^{-1} ^{35}S-methionine. Aliquots of the culture medium were immunoprecipitated with 4 μg of IgG prepared from rabbit anti-mouse AFP antiserum pre-absorbed with adult mouse serum proteins. Track 1, immunoprecipitate of medium from F9 aggregates; track 2, immunoprecipitate of medium from visceral yolk sacs using 10 μl of pre-immune rabbit serum; track 3, immunoprecipitate of medium from visceral yolk sacs. *c*, Synthesis of AFP by F9 monolayers incubated with and without retinoic acid and dibutyryl cyclic AMP for 7 days. 1×10^4 F9 cells were seeded into 35-mm tissue culture dishes in culture medium with and without 5×10^{-8} M retinoic acid and 10^{-3} M dibutyryl cyclic AMP. The medium was changed every 48 h and after 7 days replaced with 1 ml of labelling medium containing 100 μCi ml^{-1} ^{35}S-methionine. After 13.5 h incubation the medium was removed and the cells trypsinized and counted. Cell numbers per dish were as follows: control, 5.63×10^6; with retinoic acid, 1.08×10^6; with retinoic acid and dibutyryl cyclic, 1.71×10^6. The volume of culture medium used for the immunoprecipitation was adjusted to take into account the difference in cell number. Total c.p.m. in acid-precipitable protein in the medium samples were as follows: control, 6.87×10^4 (in 58 μl); with retinoic acid, 6.56×10^5 (in 300 μl); with retinoic acid and dibutyryl cyclic AMP, 1.47×10^6 (in 189 μl). Medium was immunoprecipitated with either 4 μg rabbit anti-mouse AFP IgG (see *b*) or 10 μl of non-immune rabbit serum (NRS). Track 1, control medium immunoprecipitated with anti-AFP IgG; track 2, control medium immunoprecipitated with NRS; track 3, medium from cells treated with retinoic acid, immunoprecipitated with anti-AFP IgG; track 4, same medium immunoprecipitated with NRS; track 5, medium from cells treated with retinoic acid and dibutyryl cyclic AMP, immunoprecipitated with anti-AFP IgG; track 6, same medium immunoprecipitated with NRS. In addition to the nonspecific precipitation of fibronectin, tracks 3–6 show the nonspecific precipitation of type IV procollagen (MW ~190,000) synthesized by F9 cells in response to retinoic acid.

which synthesized large amounts of laminin and type IV procollagen and no fibronectin (unpublished data). As shown in Fig. 2*c*, these cells do not synthesize AFP, a result which supports their classification as exclusively parietal endoderm. F9 cells exposed to retinoic acid and dibutyryl cyclic AMP in aggregates (Fig. 1*b*) also develop a parietal endoderm morphology as judged by light and electron microscopy, and do not synthesize AFP or stain positively with anti-AFP antiserum using the indirect immunoperoxidase technique (Fig. 1*f*).

One interpretation of our results, and those of Strickland *et al.*[4,6], is that F9 cells exposed to retinoic acid first differentiate into endoderm cells which have the potential to express one of two alternative phenotypes. In the absence of intercelluar contacts with undifferentiated cells (for example, in low density monolayer cultures) or in the presence of high levels of cyclic AMP, these endoderm cells express the parietal phenotype. However, if they remain in contact with undifferentiated EC cells (for example, in suspension aggregates, or in high-density monolayer cultures), they receive signals promoting expression of the visceral endoderm phenotype. According to this model, the first endoderm cells to differentiate from F9 EC cells are analogous to the primary endoderm cells of the 4.5-day mouse embryo, and modulation of their phenotype in culture may therefore provide clues about the nature of the intercellular interactions thought to be involved in endoderm differentiation during normal embryogenesis[14].

Electron microscopy was performed by Rita Tilly.

Aromatic-dependent *Salmonella typhimurium* are non-virulent and effective as live vaccines

Susan K. Hoiseth & B. A. D. Stocker

Department of Medical Microbiology, Stanford University School of Medicine, Stanford, California 94305, USA

An auxotrophic mutant which requires a metabolite not available in vertebrate tissues should be unable to grow in such tissue and thus be non-virulent. Most mutations to auxotrophy do not affect virulence[1-3], presumably because the required metabolites are available at sufficient concentration. However, Bacon *et al.*[1,2] noted that a *Salmonella typhi* mutant requiring *p*-aminobenzoic acid (*p*AB) was less virulent (for mice) than its parent. *Salmonella*, unlike vertebrates, cannot assimilate exogenous folate and must synthesize it from *p*AB; the virtual absence of *p*AB from vertebrate tissues is shown by the efficacy of sulphonamide chemotherapy. Yancey *et al.*[4] reported reduced virulence for a *S. typhimurium* mutant with a requirement for 2,3-dihydroxybenzoate (DHB), the precursor of the bacterial iron-acquisition compound, enterochelin. As DHB is not a known vertebrate metabolite, it would be expected to be absent from mouse tissues. *Salmonella* synthesize *p*AB and DHB from chorismate, the final product of the aromatic biosynthetic (*aro*) pathway. A complete block at any step of this pathway should make *S. typhimurium* auxotrophic for two compounds not available in vertebrate tissues, and thus non-virulent. We describe here the use of a tetracycline-resistance transposon, Tn*10* (refs 5, 6), inserted in gene *aroA* to produce non-reverting, aromatic-requiring derivatives of virulent *S. typhimurium* strains. These derivatives were virtually non-virulent; their use as live vaccines conferred excellent protection against challenge with a virulent strain.

The *aro* transposon insertion used was *aroA554*::Tn*10*, in the chromosome of *S. typhimurium* strain LT2. As wild-type LT2 is only weakly pathogenic we transduced the *aroA554*::Tn*10* region into a virulent *S. typhimurium* strain, using phage P22 HT105/1 *int* (ref. 7) and selecting for tetracycline resistance. The virulent strain used as recipient, SL3201, is a mouse-passaged re-isolate of the genetically marked mouse-virulent *S. typhimurium* strain SL4522, of biotype FIRN[8]. Two of the transductants obtained, SL3217 and SL3218, required tryptophan, tyrosine and phenylalanine. Their additional requirements for *p*AB and DHB were observed on defined medium, made with purified agar to minimize *p*AB contamination, and containing citrate, a known iron chelator, to reduce iron availability; DHB was not needed if the medium was supplemented with ferrous sulphate. Strains SL3217 and SL3218 were then tested for pathogenicity by intraperitoneal (i.p.) injection of bacteria (grown in nutrient broth with tetracycline at 5 μg ml^{-1}) into adult mice of the *Salmonella*-susceptible[9] inbred line C57BL. Mice given 3×10^5 live bacteria of either of the two *aroA554*::Tn*10* strains showed no ill effects; the LD_{50} for the *aro*$^+$ parent strain, SL3201, was <20 bacteria.

Strains auxotrophic because of Tn*10* insertion in a biosynthetic gene can regain their lost biosynthetic ability and lose tetracycline resistance by 'clean excision' or deletion of the transposon[5,6]; for strains SL3217 and SL3218 the frequency of reversion to aromatic independence (and tetracycline sensitivity) was $\sim10^{-8}$ per bacterium per generation. Such *aro*$^+$ revertants had regained virulence ($LD_{50}<20$, i.p.). To obtain non-reverting *aro*$^-$ strains we made use of the tendency of Tn*10* to cause DNA alterations within the transposon itself, sometimes extending into adjacent chromosomal genes. Many such deletion or deletion–inversion events cause both loss of tetracycline resistance and inability of the affected gene to revert to the wild-type form[10,11]. Tetracycline-sensitive variants of the *aroA554*::Tn*10* transductant SL3218 were found amongst the survivors in a culture exposed to ampicillin at 2,500 μg ml^{-1} while growing in the presence of tetracycline (5 μg ml^{-1}), a concentration bacteriostatic for cells lacking Tn*10*. A tetracycline-sensitive variant thus obtained, SL3235, did not revert to *aro*$^+$ at detectable frequency ($<10^{-11}$ per bacterium per generation). We also derived an *aroA554*::Tn*10* transductant, SL1346, from a genetically marked subline, SL1344, of *S. typhimurium* strain S2337; this strain differs from SL3201 both in biotype and in that it is virulent for calves[12]. A non-reverting, tetracycline-sensitive variant, SL3261, was isolated from strain SL1346 by plating on nutrient agar containing autoclaved chlortetracycline and fusaric acid, a combination which inhibits growth of tetracycline-resistant bacteria[13]. Both the stable *aroA*$^-$ strains, SL3235 and SL3261, were non-virulent for mice of another *Salmonella*-susceptible inbred line, BALB/c (ref 9) (no deaths from inocula of $\sim3\times10^6$ bacteria i.p., compared with LD_{50} of <20 for the *aro*$^+$ parent strains).

In addition to the requirement for aromatic amino acids, *p*AB and DHB, *aro* mutants will lack two other products of chorismate: ubiquinone, made via *p*-hydroxybenzoate, and menaquinone, made via *o*-succinylbenzoate. Lack of some chorismate-derived metabolite may account for two recently noted consequences of *aro* defect: failure to hypermodify a uridyl base in tRNA, reported by Björk[14] for *aro* mutants in *Escherichia coli*, and failure to produce H_2S from thiosulphate, noted by us for *S. typhimurium* with non-leaky blocks at *aroA* or *aroD*. We considered the possibility that some such consequence of *aro* defect might account, in part or entirely, for the non-virulence of *aro*$^-$ strains of *S. typhimurium*. However, a preliminary experiment showed that a large inoculum (2×10^6 bacteria i.p.) of the non-virulent *aro*$^-$ strain, SL3261, caused fatal infections in most BALB/c mice provided with drinking water containing both *p*AB and DHB; the same inoculum caused no apparent ill effects in mice which received *p*AB alone or DHB alone, or neither benzoate. This suggests that requirement for *p*AB and for DHB each by itself suffices to make strain SL3261 non-virulent for mice maintained on a normal diet, and that inability to synthesize other products of chorismate is not relevant to the non-virulence of *aro*$^-$ *S. typhimurium*.

Vaccination by injection of killed *Salmonella* confers only poor protection (reduction in mortality) against challenge with a virulent strain[9]. We therefore tested the ability of our stable *aro*$^-$ strains, given i.p. as live vaccine, to protect against later challenge with a virulent *S. typhimurium* strain, given i.p. or by feeding (Table 1). The *S. typhimurium* strain used as challenge, SL1344 (the genetically marked virulent grandparent of *aro*$^-$

Table 1 Challenge by i.p. or oral administration of virulent *S. typhimurium* strain SL1344 (*aro*$^+$) to BALB/c mice immunized by i.p. injection of live *aro*$^-$ *S. typhimurium*

aro$^-$ live vaccine Strain	Dose	Challenge by *aro*$^+$ strain SL1344 Deaths/No. tested (days to death)
a Challenge by injection of 5×10^5 bacteria i.p. 34 days after live vaccine		
Controls	None	5/5 (day 2, 3, 3, 4, 5)
SL3261	2×10^4 i.p.	1/5 (day 3)*
	2×10^5 i.p.	0/5*
	2×10^6 i.p.	0/5*
b Challenge by feeding 3×10^7 bacteria 30 days after live vaccine		
Controls	None	5/5 (day 7, 8, 9, 9, 12)
SL3261	3×10^4 i.p.	0/5†
	3×10^5 i.p.	0/5†
	3×10^6 i.p.	0/5†
SL3235	3×10^4 i.p.	0/5†
	3×10^5 i.p.	0/5†
	3×10^6 i.p.	0/5†

Mice used were 15–17-week-old BALB/c males.
* All surviving mice were apparently well on day 60 after challenge.
† All mice alive and apparently well on day 120 after challenge.

0028-0836/81/210238—02$01.00

live vaccine strain SL3261), is virulent for mice, given i.p. or by feeding, and for calves by the oral route[12]. The mice used (the susceptible BALB/c line) were given graded i.p. inocula of one or the other stable aro^- strain and were challenged 1 month later with the virulent strain, either 5×10^5 bacteria i.p. or 3×10^7 bacteria given by feeding (on bread cubes, after a 12-h fast). Mice challenged by feeding were housed one per cage to prevent cross-infection. Each of the two aro^- strains, given i.p. in doses of 3×10^4, 3×10^5 or 3×10^6 (five mice per dose), gave complete protection against the oral challenge (no deaths and no apparent illness in 120 days of observation), whereas all five non-immunized control mice were dead by day 12. The two larger doses (2×10^5 and 2×10^6) of the aro^- strain SL3261 protected all mice (five mice per dose) against i.p. challenge and the smallest dose used, 2×10^4 live bacteria, protected four of five mice (Table 1). Thus i.p. injection of as few as 2×10^5 live aro^- bacteria into mice of a *Salmonella*-susceptible inbred line, BALB/c, gave complete protection against later i.p. injection of 5×10^5 virulent *S. typhimurium* (that is, >25,000 LD_{50}).

These results are in striking contrast to the failure of killed vaccines to protect such mice; Robson and Vas[9] found that six i.p. doses of killed *S. typhimurium* vaccine failed to protect BALB/c (or C57BL) mice against the lethal effect of i.p. injection of even as few as 10 cells of a virulent *S. typhimurium* strain. Oral administration of live bacteria of a non-virulent *galE* mutant of *S. typhi* has recently been shown to prevent typhoid fever in school children in Egypt[15]. Taken together, the data suggest that live vaccines may be useful for protecting man or domestic animals against *Salmonella* infections. Our results further suggest that strains with complete, non-reverting blocks in aromatic biosynthesis may be appropriate for such purposes.

Denervated endplates have a dual population of junctional acetylcholine receptors

Tami A. Levitt & Miriam M. Salpeter

Section of Neurobiology & Behavior, and School of Applied & Engineering Physics, Cornell University, 146 Clark Hall, Ithaca, New York 14853, USA

The acetylcholine receptors (AChRs) at the neuromuscular junctions of mature innervated muscle are distinguished, in part, from extrajunctional receptors of embryonic muscle fibres by their metabolic stability[1–5] and high concentration at the tops of the postjunctional folds[6,7]. After denervation, the rate of degradation of receptors at the neuromuscular junction progressively increases[8–12] even though their local concentration does not change[7,8,11]. Two alternatives suggest themselves—there may be a simultaneous, progressive increase in degradation rate of all junctional receptors after denervation, or the increase may reflect the composite behaviour of two populations of junctional receptors with different metabolic stabilities: those existing before denervation ('original AChRs') and those inserted afterwards ('new AChRs'). Our study has been designed to distinguish between these possibilities. We have now found that up to 8–10 days after denervation, the original receptors have a degradation half life of about 8 days which is indistinguishable from that of innervated junctional receptors. After that time, their degradation half life increases to about 2.5 days. However, all new AChRs, introduced at junctional sites after denervation, have a half life characteristic of extrajunctional receptors (about 1 day). Our data thus support the hypothesis of a composite population of receptors at denervated neuromuscular junctions.

The turnover rate of junctional AChRs (either denervated or innervated) was assessed by the loss of radioactivity bound to the neuromuscular junction after labelling with ^{125}I-α-bungarotoxin, the virtually irreversible inhibitor of the muscle's nicotinic AChR[13,14]. The validity of this procedure has been established in previous studies[1–3,15–19], although a slow unbinding of α-bungarotoxin has been reported in culture[3]. We first compared the degradation rate of the receptors at innervated junctions with that of the receptors at denervated junctions that were present before denervation (original AChRs). Adult mice (27–37 g) were injected with ^{125}I-α-bungarotoxin intravenously (tail vein), 2.5 μg per 100 g body weight (the LD_{50} was established to be about 3.5 μg per 100 g). At 3 h after the injection, the right sternomastoid muscle was denervated under Nembutal anaesthesia by removing 1–2 mm of nerve as close to the muscle as possible, leaving the contralateral muscle as an innervated control. (In control animals, the specific junctional counts in the left and right muscles are not significantly different at the time of injection.) At 1–2-day intervals up to 20 days later, three to nine animals were anaesthesized and killed by intracardial perfusion with 4% paraformaldehyde. The two sternomastoid muscles were removed and stained for acetylcholinesterase[20] to identify the endplate band. Each muscle was

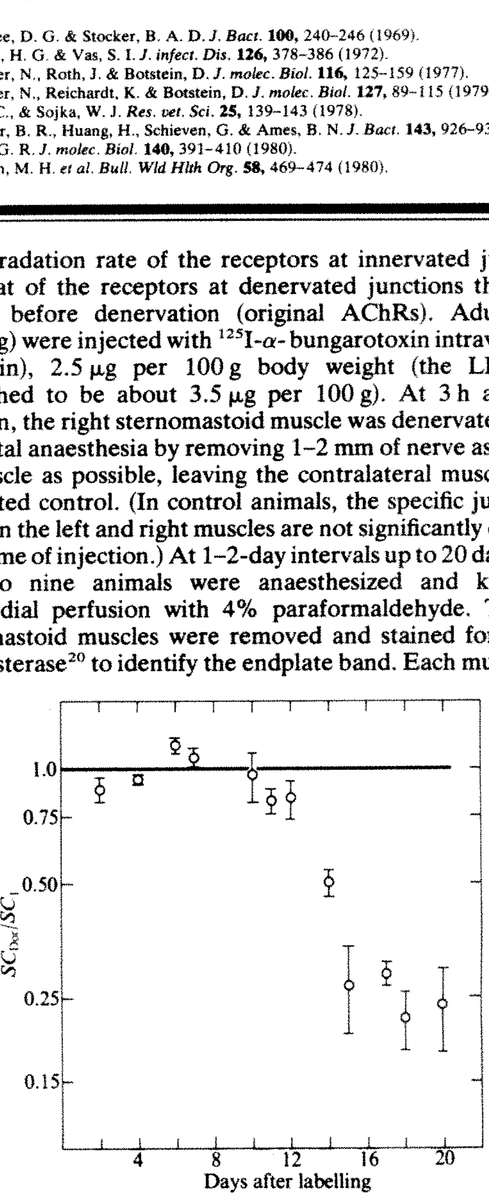

Fig. 1 Mice were injected with ^{125}I-α-bungarotoxin 3 h before denervation of the right sternomastoid muscle, thus labelling the original population of AChRs present before denervation. The ratio of specific endplate label of the denervated (SC_{Dor}) and innervated (SC_I) muscles was determined at different days thereafter. Values become significantly different from unity (solid line) after ~10 days of denervation. Error bars are s.e. of the mean of the ratios for three to nine animals per point.

0028-0836/81/210239—03$01.00

cut into three pieces, one containing the stained endplates, and the residual radioactivity of each piece was assayed by γ counting. The specific endplate radioactivity was determined by subtracting the radioactivity bound to the muscle pieces without endplates, from the activity in the piece containing the endplates on a per weight basis. We will call the specific endplate label at innervated junctions SC_I, that at denervated junctions which is due to the original receptors labelled before denervation SC_{Dor}, and that due to the total AChR population labelled any time after denervation SC_D.

Figure 1 plots the ratio of residual label, SC_{Dor}/SC_I, with time after denervation. This ratio is not significantly different from unity up to 8–10 days after denervation but becomes significantly lower thereafter. The early part of the post-denervation curve is consistent with the work of Berg and Hall[4], who observed that the decay rate of original AChRs does not change up to 5 days after denervation. The drop in the ratio (Fig. 1) indicates an increase in degradation rate of the original junctional AChRs by 10 days after denervation.

The degradation half lives of these innervated and denervated junctional receptors, labelled at the time of denervation, was determined as shown in Fig. 2. The label remaining with time at the innervated junctions (Fig. 2*a*) shows a single exponential decay (fit by linear regression) having a half time of 7.5 ± 1 days, similar to that previously reported[1–5,8]. The residual label at the denervated junctions (Fig. 2*b*) due to original receptors shows (by linear regression) two exponential decays, with a half life of 8.5 ± 3 days until ~9 days after denervation, and of 2.5 ± 0.5 days thereafter. (From our data, we cannot determine whether the degradation rate of the original receptors changes sharply at 9 days or whether, as may be more likely, there is a gradual shift from an 8-day to a faster degradation half time.)

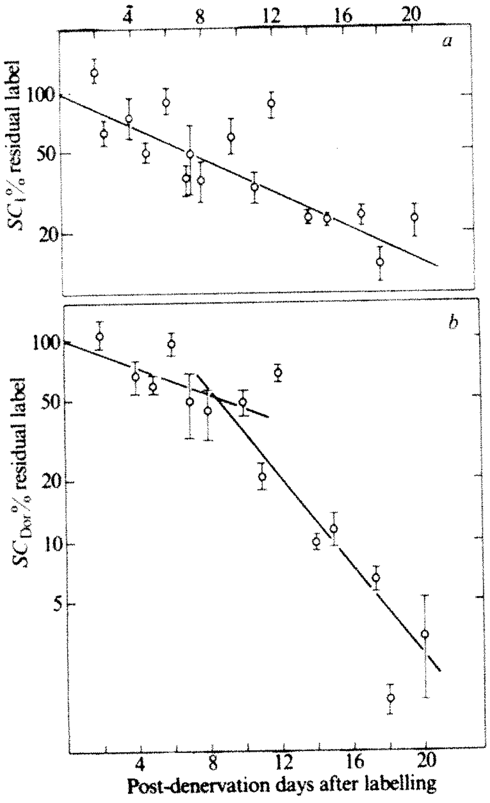

Fig. 2 Specific endplate label at different days after labelling (from all animals included in Fig. 1, plus a few additional innervated points) plotted separately for the innervated SC_I (*a*) and denervated SC_{Dor} (*b*) junctions. All curves are normalized to 100% at time of labelling, error bars are s.e. of the mean for three to nine animals per point. *a*, The innervated AChRs have a $t_{1/2}$ of 7.5 ± 1 days (by linear regression). *b*, The values for denervated original receptors can be fitted by two regression lines giving a degradation $t_{1/2}$ of 8.5 ± 3 days until 9 days after denervation and one of 2.5 ± 0.5 days thereafter. (As the $t_{1/2}$ of the original denervated receptors up to 9 days after denervation is not significantly different from that of innervated AChRs, an average value of 8 days will be used for both receptors during that period.) Although a gradual change from $t_{1/2}$ of about 8 days to a faster rate can also fit the data, we will, for convenience, assume that $t_{1/2}$ changes sharply and use the following mathematical formulation in subsequent calculations to assess the fraction of original receptors remaining at any given time (t) after denervation. When $t \leq 9$ days: $f(t) = 2 \exp -(t/8.0)$, and when $t > 9$ days: $f(t) = 2 \exp -[(9/8.0 + (t-9)/2.5)]$.

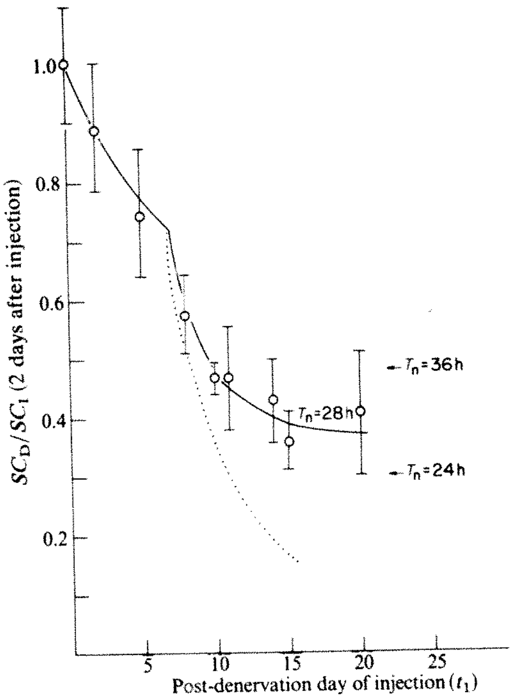

Fig. 3 Mice were injected with ^{125}I-α-bungarotoxin at different days (t_1) after denervation, thus labelling the AChRs as well as the remaining original population. The ratio of specific endplate label at denervated to innervated junctions (SC_D/SC_I) was determined 2 days after labelling. Experimental values (○) are from ref. 12 (with a few added points for confirmation). Curves were calculated on the basis of two alternative hypotheses: (1) (solid line), assuming that the junctional AChRs at denervated junctions consist of a dual population with different metabolic characteristics: the original receptors degraded as given in Fig. 2*b*, and new receptors, with a half life T_n. A value for T_n of 28 h gave the best fit to the data. The experimental data are within the range of values for T_n of 24–36 h (arrows) commonly associated with extrajunctional AChRs[1–5,15,16,18,19,21,22]. (2) (dotted line), assuming a dual population as given in (1) above, but with turnover rate of the original AChRs remaining with a $t_{1/2}$ of 8.0 days throughout, and the decreasing ratios in Fig. 1 representing a progressive decrease in the overall size of the denervated endplates. This model clearly does not fit the data. Additional evidence that the endplate does not decrease in overall number of sites was obtained (as reported in the text) from the ratio (SC_D/SC_I) of 1.3 ± 0.3 for 16-day denervates 3 h after labelling.

To test whether the drop in ratio SC_{Dor}/SC_I in Fig. 1 could be due to a decrease in the overall size of the denervated junctions as the denervated muscle atrophied, we injected four animals 16 days after denervation, waited 3 h to allow for removal of nonspecific label, removed the muscles and determined the specific endplate label by subtracting non-endplate label as described above. If there is no decrease in the number of AChRs at the denervated junction, the ratio (SC_D/SC_I) 3 h after injection should not be significantly different from unity. A value of 1.3 ± 0.3 (s.e.m.) was obtained. This is in agreement with Frank *et al.*[21], who found no change in toxin binding at denervated endplates for up to 2.4 weeks after denervation. As electron microscope autoradiography has shown that the AChR site density remains unchanged up to 16 days after denervation[8], we conclude that the total size of the denervated junction did not decrease. Additional evidence that the denervated endplate size did not decrease is presented in Fig. 3. Thus, the increased degradation rate of original AChRs by 8–10 days after denervation reflects an increased turnover rate (that is, as the original receptors are degraded, they are replaced by new AChRs on a one-to-one basis).

However, the behaviour of the original AChRs cannot fully explain the behaviour of total junctional AChRs at denervated junctions. We previously[12] examined the turnover of total junctional AChRs labelled at different times after denervation, and found that these total junctional AChRs begin to show a progressive increase in their turnover rate within 2 days of denervation, and reach a turnover half time of 30 h by 15 days. Even a week after denervation, when the original junctional receptors still decay slowly (with a $t_{1/2}$ of ~8 days, as given in Fig. 2*b*), the average turnover half life for total junctional receptors at the denervated junction had increased considerably (to ~2 days)[12]. A similar fast turnover rate was obtained for the total junctional AChRs specifically located at the postjunctional membrane of 8-day denervated neuromuscular junctions by electron microscope autoradiography[8], indicating that the faster turnover time reported for total junctional receptors is not an artefact of the γ-counting procedure.

To reconcile the data obtained for the original receptors in Fig. 2*b* with those for the total junctional receptors at denervated junctions reported previously[8,12] and in Fig. 3, we tested the assumption that after denervation, the original junctional receptors are degraded with the overall time course described in Fig. 2*b*, but that they are replaced by new receptors with a faster turnover half life (T_n). Based on this model we calculated the expected SC_D/SC_I for the experimental conditions of our earlier study[12]. In that earlier study, the average turnover rate of total junctional receptors at denervated neuromuscular junctions was obtained over successive 2-day periods by injecting animals with ^{125}I-α-bungarotoxin on different days after denervation (t_1) and determining the residual junctional label 2 days later (Δt). Therefore, in that study, the contribution to SC_D due to the original receptors labelled at time t_1 and evaluated at time Δt is $f(t_1)\times 2\ \exp-(\Delta t/t_{1/2})$. The $t_{1/2}$ is either 8 or 2.5 days, or a combination of both (depending on the value of t_1); and $f(t_1)$ is the fraction of original receptors remaining at the junction at time t_1 (Fig. 2*b*). In addition, as the absolute site density of AChRs remains constant after denervation[8], the new receptors available for labelling at time t_1 are $[1-f(t_1)]$, and their contribution to the specific endplate label (SC_D) at time $(t_1+\Delta t)$ is $[1-f(t_1)]\times 2\ \exp-(\Delta t/T_n)$, where T_n is the half life of the new receptors, and is the only free parameter in this model. Figure 3 plots the experimental points for SC_D/SC_I for successive 2-day periods (Δt) as obtained in our previous study (plus new data for confirmation) and compares it with the theoretical curve (solid line) based on the above model, using $T_n = 28$ h for best fit to the data. Figure 3 shows that this model reproduces the shape of the experimental results, with the T_n well within the range reported for extrajunctional AChRs[1-5,15,16,18,19,21,22]. Reiness *et al.*[3] have reported a slow unbinding of α-bungarotoxin from AChRs *in vitro*. If we assume a similar unbinding rate ($t_{1/2}$ of 13 days) in our system *in vivo*, and include this value in the above model, the shape of the theoretical curve does not fit the experimental data. Therefore, if unbinding of toxin is occurring in our system, it must be at a considerably slower rate than that seen by Reiness *et al.*[3]. Another model (dotted curve) which assumes a decrease in size of the denervated junction also does not fit the data.

We conclude that the denervated neuromuscular junction contains a dual population of junctional receptors with distinct metabolic characteristics. The first consists of junctional AChRs which are present at the time of denervation and start with a $t_{1/2}$ of about 8 days and eventually (by about 9 days) lose their metabolic stability. The second consists of new receptors, which have the same metabolic characteristics as extrajunctional receptors and replace (on a one-to-one basis) the original receptors as these are degraded. Earlier studies have already shown that the metabolic stability and high-density clustering of junctional AChRs are not linked either in development or after denervation[8-10,23,24]. The nerve seems to have a different role in determining these two properties of junctional AChRs. Initially it is required to induce the high-density AChR localization on the postjunctional membrane. Once established, however, this localization is maintained and can even be regenerated in the absence of the nerve[25-27]. The present study, on the other hand, shows that a continued presence of the nerve (or some nerve-related activity) is necessary for junctional receptors both to acquire and subsequently maintain metabolic stability, even in mature muscle.

This research was supported by grant NS09315 from the National Institute of Neurology and Communicative Disorders and Stroke, National Institutes of Health. We thank Ralph Loring for his help during this study. Presented in preliminary form at Neuroscience meeting, November 1980.

Sexual dimorphism in a photoreceptor

N. Franceschini*†, R. Hardie*, W. Ribi*
& K. Kirschfeld*

* Max-Planck-Institut für biologische Kybernetik, 7400 Tübingen, FRG
† Institut de Neurophysiologie et Psychophysiologie, CNRS, 13277 Marseille Cedex 9, France

The recent observation of fluorescence emission from photoreceptor cells in flies[1] offers a new opportunity to map the distribution of the various spectral types in a highly organized retinal mosaic. Previous studies had led to the conclusion that in each ommatidium the two central receptor cells are quite distinct from their six neighbours in terms of anatomical projection[2,3], visual pigment and physiology[4]. We show here that in a restricted, well defined region of the male eye only, one of these central cells resembles its six neighbours not only in having the same visual pigment and physiological properties, but also in sending its axon to the same neuropile. A clue to the function of this sexually dimorphic retinal organization is given by the fact that these male-specific cells dominate the frontal-dorsal part of the retina (fovea) which is used by the male to track females in aerobatic chases[5,6]. We suggest that the male fovea, already known to drive sex-specific higher-order neurones[7], has sacrificed colour vision for other more vital kinds of information processing such as improving quantum catch and possibly also contrast transfer or movement detection.

Each ommatidium in the compound eye of the housefly (*Musca domestica*) contains eight photoreceptors which are

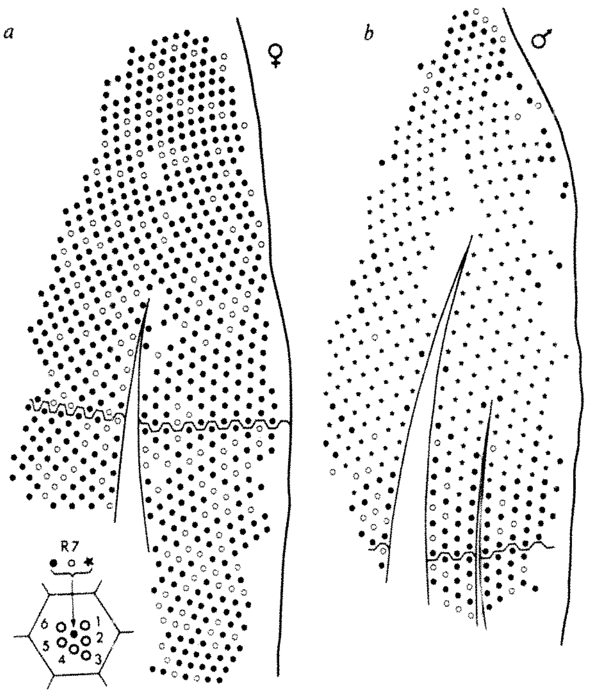

Fig. 1 Inset, arrangement and numbering of the rhabdomeres in a fly ommatidium (distal cross-section of a ventral ommatidium). Rhabdomere R8 is a proximal extension of R7. The inset indicates in brackets the three symbols used for R7 in the adjoining maps. *a*, *b*, Maps of the frontal part of the right retina showing the distribution of the three types of R7 receptor cells in the compound eye of a female (*a*) and male (*b*) housefly (*M. domestica*, white eye). Each dot or star represents the distal tip of rhabdomere R7 (see inset) as seen *in vivo* in each ommatidium, using epifluorescence microscopy (blue excitation) combined with optical neutralization of the cornea[1] (water immersion objective ×25/0, 65). Empty spaces represent ommatidia in which the fluorescence colour of R7 could not be clearly distinguished. ●, Green-fluorescing R7s (UV + blue-sensitive cells[4]); ○, non-fluorescing R7s (pure UV-sensitive cells[4]); asterisks, red-fluorescing R7s (dual peak, UV + blue-green-sensitive cells, see Fig. 2). The zig-zag line represents the equator of the eye, that is, a (virtual) line of dorso-ventral symmetry, about which the R1–6 rhabdomeric pattern (see inset) is inverted. About 70% green-fluorescing and 30% non-fluorescing R7s make up the female retina (*a*) and the ventral part of the male retina (*b*). The red-fluorescing R7s are present in the frontal-dorsal region of the male eye exclusively (*b*). Note how they gradually invade the retina above the equator. These maps (each of which encompasses approximately one-fifth of the fly retina) were reconstructed from 35(a) and 38(b) colour photographs with overlapping borders. Although such maps are most conveniently made in white-eyed flies, the situation seems to be qualitatively similar in wild type.

usually classified as six large peripheral cells, R1–6 surrounding two smaller central cells, R7 and R8 (see Fig. 1, inset). The photoreceptive segments (rhabdomeres) of the latter are arranged one above the other to form a single light-guiding structure[3]. As recognized by Cajal[2], the axons of R1–6 cells project only as far as the first optic ganglion (the lamina) whereas the axons of both R7 and R8 pass through this neuropile and eventually synapse first in the second optic ganglion (the medulla). A similar retinal dichotomy of long and short visual fibres seems to be a general feature of diurnal compound eyes.

The lamina is organized into optic cartridges each of which normally receives axons from six R1–6 cells 'looking' in the same direction of space, but belonging to different ommatidia[8,9]. The signal summation which occurs within each cartridge[10] necessarily increases the signal-to-noise ratio, and hence the sensitivity of these visual channels whose information is relayed to the medulla by second-order monopolar neurones[2,3,9,11]. As the individual properties of the single receptors are buried in this summation process, it is not surprising that the six cells feeding each cartridge all have the same (dual-peak) spectral sensitivity[12,13].

In contrast to the homogeneity of the R1–6 population throughout the retina, the population of central cells, R7 and R8, is highly heterogeneous. Three classes of receptor cells R7 have been found using *in vivo* epifluorescence microscopy. While R1–6 cells always fluoresce red under blue excitation, R7 rhabdomeres exhibit three distinct colours: red, green and black (that is, nonfluorescing), depending on the ommatidium[1].

We have screened large regions of the retina by rotating the fly stepwise on a precision goniometer under the immersion objective of the epifluorescence microscope, and constructed precise maps of the distribution of the R7 types from photographic series (Fig. 1). The most striking conclusion from these maps is that females do not possess any red-fluorescing R7 and that these are exclusively encountered in the frontal-dorsal part of the male eye where they account for between 85 and 95% of all R7s (asterisks in Fig. 1*b*).

This sex-specific retinal architecture stimulated a closer investigation of the properties of the red-fluorescing R7s. As their fluorescence colour was similar to that of R1–6 we thought they would have the same photopigment, and hence spectral sensitivity, as their six neighbours. Intracellular recordings and stainings revealed that the spectral sensitivities were almost indistinguishable (Fig. 2), a finding corroborated by microspectrophotometry of individual R7 rhabdomeres (ref. 14). Taken together, these two methods suggest that the red-fluorescing R7s have inherited not only the R1–6 rhodopsin, responsible for the peak near the 480 nm, but also apparently the UV-sensitizing pigment[13], responsible for the second peak near 360 nm (Fig. 2). The two other types of R7 have spectral sensitivities quite different from those of R1–6 cells[4].

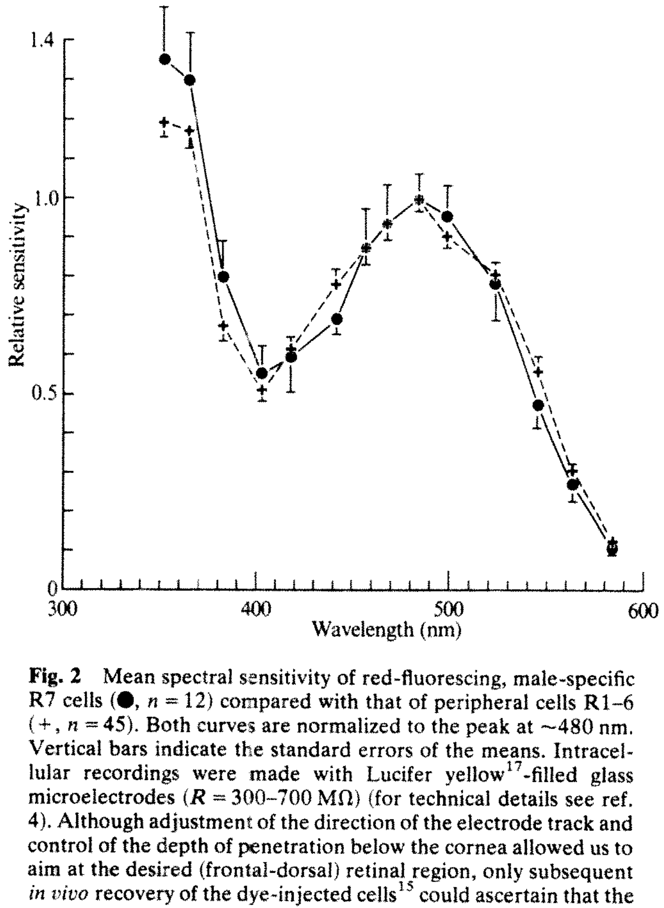

Fig. 2 Mean spectral sensitivity of red-fluorescing, male-specific R7 cells (●, $n = 12$) compared with that of peripheral cells R1–6 (+, $n = 45$). Both curves are normalized to the peak at ~480 nm. Vertical bars indicate the standard errors of the means. Intracellular recordings were made with Lucifer yellow[17]-filled glass microelectrodes ($R = 300$–700 MΩ) (for technical details see ref. 4). Although adjustment of the direction of the electrode track and control of the depth of penetration below the cornea allowed us to aim at the desired (frontal-dorsal) retinal region, only subsequent *in vivo* recovery of the dye-injected cells[15] could ascertain that the R7s recorded were indeed from a retinal region dominated by red-fluorescing R7s (asterisks in Fig. 1*b*). In contrast to the two other types of R7 of the retina[4] (Fig. 1), the male-specific R7 cells seem to have a spectral sensitivity similar to that of R1–6 cells. *M. domestica*, white eye.

Electrophysiologically the responses of the male-specific R7s are so similar to those of R1–6 cells that it proved impossible to tell them apart during recording and only *in vivo* recovery of blindly injected cells[15] revealed that we had recorded from them.

These R7 cells resemble R1–6 cells even at the ultrastructural level. Thus, electron micrographs showed that, compared with other R7 cells, the red-fluorescing ones have larger cell bodies and axons, and also wider rhabdomeres (Fig. 3)—all features which approximate to the situation in R1–6 cells. Most surprisingly, electron microscope serial sectioning established that, like R1–6 cells, the axons of these male-specific R7 cells also form connections with second-order neurones in the lamina (Fig. 3*c*), while axon profiles from stained cells revealed that their axons also stop short in the lamina (Fig. 3*g*) instead of projecting to the medulla like the other R7s of the eye.

In a restricted, well defined region of the eye of male houseflies, the R7 photoreceptors thus seem to have been programmed to resemble the peripheral R1–6 photoreceptors in terms of visual pigment, electrophysiological properties and many fine details of anatomy. Curiously, the underlying R8 photoreceptors in this region go only halfway in this respect. They apparently contain the same visual pigment as R1–6 but remain anatomically distinct, still retaining the long visual fibre input to the medulla[14].

In looking for a function for this intriguing sexual dimorphism we are attracted by the recently discovered sex-specific chasing behaviour of male flies[5,6,16] and the sex-specific neurones found in the lobula of male flies[7]. Both the behaviour and the neurones receive their main visual input from the region of the eye (the fovea) where the red-fluorescing R7s are located. The male's chasing behaviour involves the tracking of a small, fast-moving spot (the female fly) and, in visual tasks requiring high temporal resolution, light quanta are as vital as at low light levels[16]. In this respect the participation of a seventh, spatially and spectrally matched input to the summation process at the first synaptic level could be considered an adaptation to increase further the signal-to-noise ratio (although by a small factor) in a quantum-limited task of obvious biological importance.

However, additional functions are suggested by details of the lamina terminals of the male-specific R7s, revealed by intracellular staining. Their axons do not penetrate as deeply into the cartridge layer as those of R1–6. Furthermore, just before they terminate, they produce a right-angled branch which runs ~10 μm (that is, to about the next cartridge)—always towards the frontal margin of the eye (Fig. 3*g*). If this lateral process mediated inter-cartridge interactions, it could subserve a peripheral form of movement detection. Alternatively, it could modify the contrast transfer properties of second-order neurones by providing lateral inhibition.

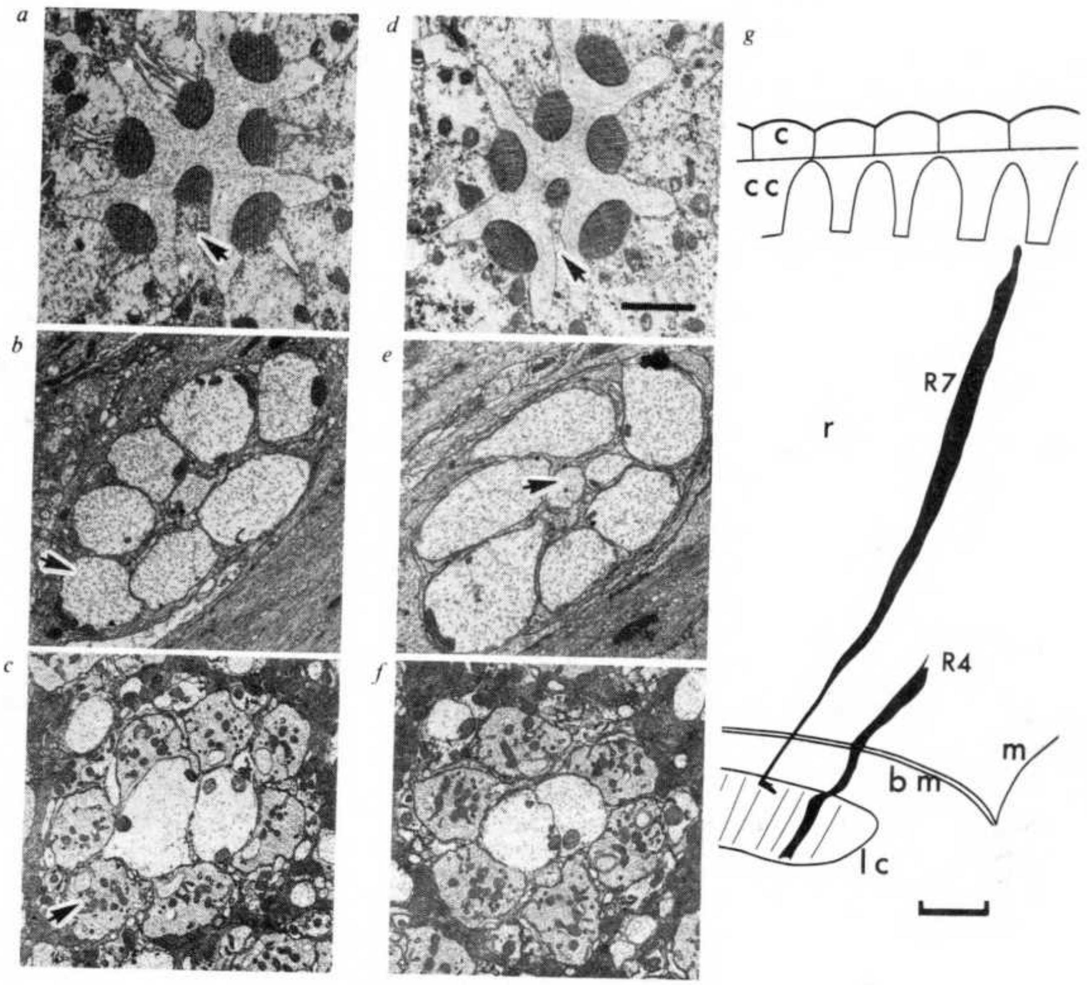

Fig. 3 *a–f*, Electron-micrographs of serial cross-sections which follow the receptors from two ommatidia: one containing a red-fluorescing R7 (*a–c*) and the other a green-fluorescing R7 (*d–f*). At the electron micrograph level, ommatidia containing non-fluorescing R7s (not shown) were indistinguishable from those containing green-fluorescing R7s. Before sectioning, the ommatidia were first identified from their *in vivo* fluorescence. Reliable correspondence between the fluorescence map and the electron micrograph map was achieved by the use of two landmarks recognizable by both methods—the equatorial line and a characteristically mis-oriented rhabdomere pattern. In each electron micrograph the R7 cell is indicated by an arrow. *a*, *d*, Cross-sections through the retina. Note that the rhabdomere and cell body of the red-fluorescing R7 (*a*) are larger than in the green-fluorescing R7 (*d*). *b*, *e*, Cross-sections just below the basement membrane showing the receptor axons as they leave the retina. Whereas the axon of the green-fluorescing R7 is small and surrounded by a ring of R1–6 axons (*e*), that of the red-fluorescing R7 is large and is itself a member of the ring (*b*). *c*, *f*, Cross-sections of the cartridges on the lamina. At this level the green-fluorescing R7 axon (not visible) has separated from the R1–6 axons which, alone, form a ring around two second-order monopolar cells (*f*). In contrast, the axon of the red-fluorescing R7 is a member of the ring and also forms connections with the second-order cells (*c*). *g*, Tracing of an entire male-specific, red-fluorescing R7 stained intracellularly with Lucifer yellow[17]. Note the shallow terminal in the lamina and the lateral process which is bent at right angles to the cell axis and runs ~10 μm before stopping. For comparison the terminal (only) of an R1–6 cell (actually R4) is shown, with the axon running, typically, to the bottom of the cartridge layer. c, Corneal facets; cc, crystalline cone; r, retina; m, frontal margin; bm, basement membrane; lc, lamina cartridge layer. Scale bar, 1 μm (*a–f*); 30 μm (*g*).

Whereas other parts of the retina possess an impressive array of colour receptors[4], the male fovea is necessarily colour blind. We suggest that this sacrifice is made to enhance one or more of the above mentioned processes (quantum catch, contrast transfer and movement detection), all of which can be seen as advantageous for the exacting task in which the male fovea seems to be mainly involved.

We thank Ms A. Rudolph and A. Totin for technical assistance and Drs M. M. Bate and D. G. Stavenga for critical reading of the manuscript. The dye Lucifer yellow was provided by Dr W. Stewart[17]. This work was supported by the MPG (FRG) and grants from the CNRS and DGRST (France).

Direct transfer of a lysosomal enzyme from lymphoid cells to deficient fibroblasts

I. Olsen, M. F. Dean, G. Harris & H. Muir

Kennedy Institute of Rheumatology, 6 Bute Gardens,
London W6 7DW, UK

Fibroblasts grown *in vitro* can secrete lysosomal enzymes into the culture medium which can then be taken up by endocytosis into other fibroblasts[1–4]. Such cells have been used as a source of enzyme for replacement therapy in the mucopolysaccharidoses[5–7], a group of related storage diseases resulting from inherited deficiencies in specific lysosomal enzymes, although the mechanism of action is unclear. Because lymphoid cells can interact directly with fibroblasts[8,9] and transfer DNA to them[10], we examined the possibility that a lysosomal enzyme could be transferred from normal lymphocytes to deficient fibroblasts by a mechanism other than secretion followed by endocytosis. We report here that fibroblasts from a patient with mucopolysaccharidosis type VII acquired β-glucuronidase (EC 3.2.1.31) activity as a result of direct cell-to-cell contact with lymphocytes.

Monolayer cultures of β-glucuronidase-deficient fibroblasts (GM 151 cells) contained no detectable enzyme activity, even at high cell density. After co-culture with lymphocytes, β-glucuronidase was detected in all the GM 151 cells examined (Fig. 1*a*). Direct measurement of enzyme activity acquired by the fibroblasts after interaction was not possible, because between 1 and 10% of the added lymphocytes adhered firmly to them even after repeated washing (Fig. 1*b*). Quantitative cytochemical assay in single GM 151 cells was possible, however, because the lymphocyte–fibroblast association was readily disrupted by trypsin.

The β-glucuronidase activity acquired by GM 151 cells increased rapidly during the first 24 h of co-culture, and decreased over the next several days (Fig. 2). In eight other separate experiments, maximum levels of between 29.9 and 48.1 nmol per h per 10^6 cells (mean 40.7 ± 2.1 s.e.) were acquired after 24 h.

The cytochemical assay accurately measured β-glucuronidase activity, as shown in Fig. 3. Note that the activity acquired by GM 151 cells (40.7 nmol per h per 10^6 cells) was above that in fibroblasts from two (clinically normal) people heterozygous for the β-glucuronidase allele, GM 1850 and GM 2074 (27.1 and 12.2 nmol per h per 10^6 cells, respectively), and also greater than that required for full correction of the metabolic deficiency in mucopolysaccharidosis type VII (ref. 11).

The β-glucuronidase activity acquired by 10^5 GM 151 cells was directly proportional to the number of lymphocytes added during 24 h of co-culture, up to 10^7 lymphocytes per culture dish (see Table 1). This optimum number of cells was therefore used for subsequent co-culture.

The persistence of acquired β-glucuronidase activity was examined. If, after the initial 24 h of co-culture, the non-adherent lymphocytes were replaced by fresh medium for a further 24 h, the β-glucuronidase activity decreased from an initial 40.7 nmol per h per 10^6 cells to 25.8, the same as that in fibroblasts incubated in the continued presence of lymphocytes (Fig. 2). Furthermore, the addition of 10^7 fresh lymphocytes after the initial 24 h of co-culture produced only a small further increase, to 33.1 nmol per h per 10^6 cells. The β-glucuronidase activity acquired by GM 151 cells during an initial 24 h of co-culture decreased even further during the next 48 h, either in the continued presence of the lymphocytes (19.4 nmol per h per 10^6 cells) or after they had been replaced by fresh medium (14.8 nmol per h per 10^6 cells). However, when the non-adherent lymphocytes were removed after 24 h of co-culture, and the GM 151 cells re-cultured for 48 h at high cell density, β-glucuronidase activity persisted at a very high level (39.4 nmol per h per 10^6 cells). This suggests that the decrease in activity after 24 h of co-culture was due to cell division rather than enzyme degradation.

Table 1 The effect of lymphocyte concentration on the appearance of β-glucuronidase activity after 24 h of co-culture with 10^5 GM 151 cells

Lymphocytes added per culture dish	β-Glucuronidase activity in GM 151 cells (nmol per h per 10^6 cells)
0	0
3×10^5	0
1×10^6	10.1
3×10^6	15.7
1×10^7	48.1
3×10^7	38.9

Monolayers of GM 151 cells were grown directly on 35-mm culture dishes and the co-culture initiated by the addition of the washed lymphocytes resuspended in 1 ml of Eagle's minimal essential medium (MEM), supplemented with fetal calf serum (FCS). After 24 h of co-culture, the non-adherent lymphocytes were removed and the adherent cells detached with 0.25% trypsin as described in Fig. 2 legend. After incubation with naphthol AS-BI-β-glucuronide and post-coupling with fast blue RR, quantitative cytochemistry of individual GM 151 cells was performed. The arithmetic means were calculated and converted to β-glucuronidase activity expressed as nmol per h per 10^6 GM 151 cells, as shown in Fig. 3.

It is not clear why prolonged co-culture or fresh lymphocytes did not increase further the β-glucuronidase activity acquired by GM 151 cells. Direct assay using 4-methylumbelliferyl β-D-glucuronide (see Fig. 3 legend), showed that the 10^7 lymphocytes added initially to 10^5 GM 151 cells, contained 10–40 nmol per h of β-glucuronidase activity (1–4 nmol per h per 10^6 lymphoid cells. After 24 h of interaction, almost all the lymphocytes were recovered, while the 10^5 GM 151 cells had acquired ~4 nmol per h of enzyme. This level of acquired enzyme, 40.7 nmol per h per 10^6 cells, was over 10 times above that of the lymphocytes, and was equivalent to 10–40% of the total lymphocyte activity initially added. However, preliminary experiments showed that there was also significant increase in the β-glucuronidase activity of the recovered lymphocytes themselves as a result of direct interaction with GM 151 cells. Furthermore, lymphocytes that had already been co-cultured could induce another round of enzyme acquisition when

0028-0836/81/210244—04$01.00

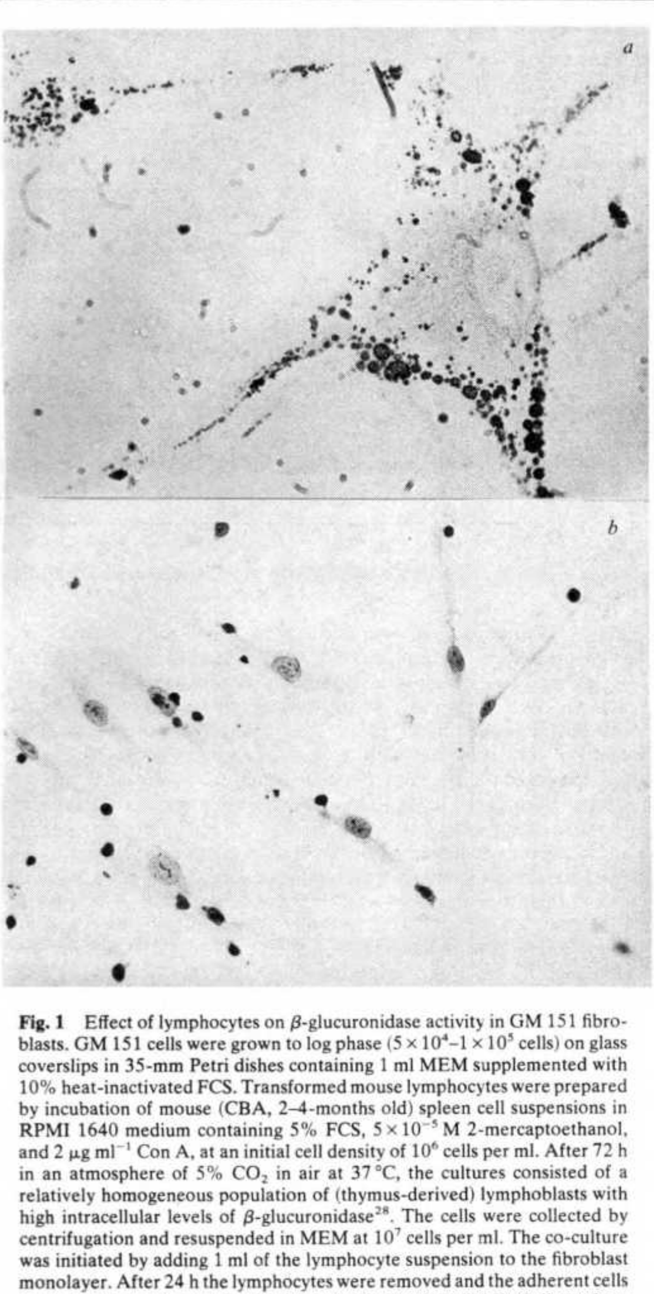

Fig. 1 Effect of lymphocytes on β-glucuronidase activity in GM 151 fibroblasts. GM 151 cells were grown to log phase (5×10^4–1×10^5 cells) on glass coverslips in 35-mm Petri dishes containing 1 ml MEM supplemented with 10% heat-inactivated FCS. Transformed mouse lymphocytes were prepared by incubation of mouse (CBA, 2–4-months old) spleen cell suspensions in RPMI 1640 medium containing 5% FCS, 5×10^{-5} M 2-mercaptoethanol, and 2 μg ml^{-1} Con A, at an initial cell density of 10^6 cells per ml. After 72 h in an atmosphere of 5% CO_2 in air at 37 °C, the cultures consisted of a relatively homogeneous population of (thymus-derived) lymphoblasts with high intracellular levels of β-glucuronidase[28]. The cells were collected by centrifugation and resuspended in MEM at 10^7 cells per ml. The co-culture was initiated by adding 1 ml of the lymphocyte suspension to the fibroblast monolayer. After 24 h the lymphocytes were removed and the adherent cells washed twice with 1 ml of phosphate-buffered saline (PBS). Cell numbers were determined by direct counting, using a haemocytometer. *a*, β-glucuronidase activity was measured as follows. Adherent fibroblasts were incubated with 1 ml of substrate (100 μg ml^{-1} naphthol AS-BI-β-D-glucuronide in 0.1 M acetate buffer, *p*H 4.5). After 3 h at 37 °C, the dishes were washed with PBS and 1.0 ml of freshly prepared fast blue RR (1 mg ml^{-1} in 0.01 M KP_i, *p*H 7.4) was added for 10 min at 4 °C. The dishes were washed with PBS, methanol, then distilled water and air dried. The coverslips were removed, fixed on to slides and mounted with Polymount for visual examination and photography. GM 151 cells cultured alone did not stain in these conditions. The accumulation of enzyme is seen in densely staining vesicular organelles which look like lysosomes. ×500. *b*, Adherent cells were fixed in methanol, washed with distilled water and air dried. The coverslips were removed, fixed on to slides and stained with Giemsa. The lymphocytes are smaller and more densely stained. Occasionally lymphoid cells were seen within GM 151 cells, but there was no sign of significant phagocytosis. ×175.

subsequently co-cultured for 24 h with a second monolayer of GM 151 cells. Thus the β-glucuronidase activity of the lymphoblast population was not exhausted by interaction, and the fibroblasts themselves seemed to limit acquisition of activity.

Quantities of β-glucuronidase secreted by cultured cells were determined by direct assay of the supernatant media using 4-methylumbelliferyl β-D-glucuronide as a substrate. Lymphocyte culture medium and medium from lymphocyte–GM 151 co-cultures both contained less than 5 nmol per h per ml of β-glucuronidase after 24 h. Incubation of GM 151 cells with these media for 24 h did not result in any detectable intracellular enzyme activity. The presence of a precursor to β-glucuronidase, which becomes enzymatically active after uptake by GM 151 cells, is therefore unlikely. This is consistent with the absence of such a precursor for this enzyme in murine macrophages[12]. The addition to GM 151 cells of partially purified β-glucuronidase from mouse 3T3 fibroblasts (S. Diment and M. F. Dean, unpublished data) also at 5 nmol per h per ml, was similarly without effect. Moreover, after the addition of cell-free enzyme extracts derived from 10^7 lymphocytes, GM 151 cells acquired barely detectable activity.

Endocytosis of released enzyme was further examined using mannose-6-phosphate, a competitive inhibitor of receptor-mediated uptake of several lysosomal hydrolases, including β-glucuronidase[13–15]. At 1 mM, it markedly inhibited endocytosis of exogenous enzyme prepared from 3T3 cells, but had no effect on the acquisition of β-glucuronidase by direct interaction with lymphocytes (Table 2). To produce comparable levels of enzyme activity in GM 151 cells, it was necessary to add much more exogenous β-glucuronidase derived from 3T3 cells than that present in 10^7 lymphocytes.

Concanavalin A(Con A)-mediated uptake[16] of enzyme secreted by the lymphocytes also cannot account for the acquisition of β-glucuronidase activity in GM 151 cells during co-culture, because the addition of Con A (2 μg ml^{-1}), either by itself, with the culture media, or with enzyme prepared from lymphocytes, had no promoting effect on β-glucuronidase activity in GM 151 cells. The effect of α-methylmannoside (α-MM) was next examined as it inhibits Con A-mediated phagocytosis of lysosomal enzymes[17]. Con A-transformed lymphocytes were washed in 100 mM α-MM and then co-cultured with GM 151 cells for 24 h in the presence of 25 mM α-MM. The level of β-glucuronidase acquired by GM 151 cells was almost identical to that of control cultures. Furthermore, co-culture with lymphocytes transformed by bacterial lipopolysaccharide similarly resulted in the appearance of enzyme activity in GM 151 cells. High levels of β-glucuronidase were also acquired when fibroblasts were co-cultured with cells not exposed to mitogens, such as human peripheral blood lymphocyte/monocyte preparations and monocyte-depleted mouse spleen cells.

Cells from patients with mucopolysaccharidosis type VII produce an inactive protein which cross-reacts with antibody prepared against active enzyme[18,19]. It is unlikely, therefore, that any factor secreted by the lymphocytes[20–23] led to the active expression of a previously repressed structural gene.

These experiments suggest that enzyme acquisition by GM 151 cells did not involve secretion of β-glucuronidase by lymphocytes and its subsequent uptake by GM 151 cells. To test

Table 2 β-glucuronidase activity in GM 151 cells: comparison of direct cell-to-cell contact with endocytosis of exogenous enzyme

	β-glucuronidase activity in GM 151 cells (nmol per h per 10^6 cells)		
Additions to 10^5 GM 151 cells	Direct contact	Millipore* chambers	Mannose-6-P (1 mM)
10^7 lymphocytes (15)	29.9	0	39.1
Exogenous 3T3 enzyme (200)	49.9	24.1	6.1

GM 151 cells were grown to log phase (1×10^5 cells) in 35-mm culture dishes; 1 ml of medium containing 10^7 lymphocytes or partially purified enzyme was added, and the cultures continued for 24 h. Values in parentheses indicate the β-glucuronidase activity added (total nmol per h per culture dish) in the form of intact lymphocytes or purified enzyme. These values were determined by direct biochemical assay using 4-methylumbelliferyl β-D-glucuronide substrate. β-glucuronidase activity was measured cytochemically in single GM 151 cells and the mean values converted to nmol per h per 10^6 cells. GM 151 cells cultured alone had no detectable activity in these conditions.

* Millipore filters (0.22-μm pore diameter) were fitted to 20-mm diameter glass rings. The chambers, open at the top and raised on three polythene legs (2 mm high, 4 mm diameter), were placed on top of growing GM 151 monolayers, and lymphocytes or enzyme were added to the chambers. In the reverse type of co-culture, the fibroblasts were first grown on the filter inside the chamber, and the lymphocytes then placed outside in the dish. The results were identical in both culture conditions.

whether direct cell-to-cell contact was necessary, both types of cell were cultured in the same dish but were separated by Millipore filters. In these conditions, GM 151 cells did not acquire any measurable β-glucuronidase activity (Table 2). We demonstrated that free β-glucuronidase could diffuse through the Millipore membrane and be taken up by GM 151 cells on the other side by placing partially purified enzyme from 3T3 fibroblasts inside the chambers. After 24 h, enzyme uptake was 50% of that observed when the enzyme was added directly to the medium, possibly because of some adsorption of enzyme to the membrane or reduced diffusion through it. When lymphocytes and enzyme were placed in the chambers together, the uptake was again 50% of controls, showing that the lymphocytes themselves had no influence on diffusion of enzyme.

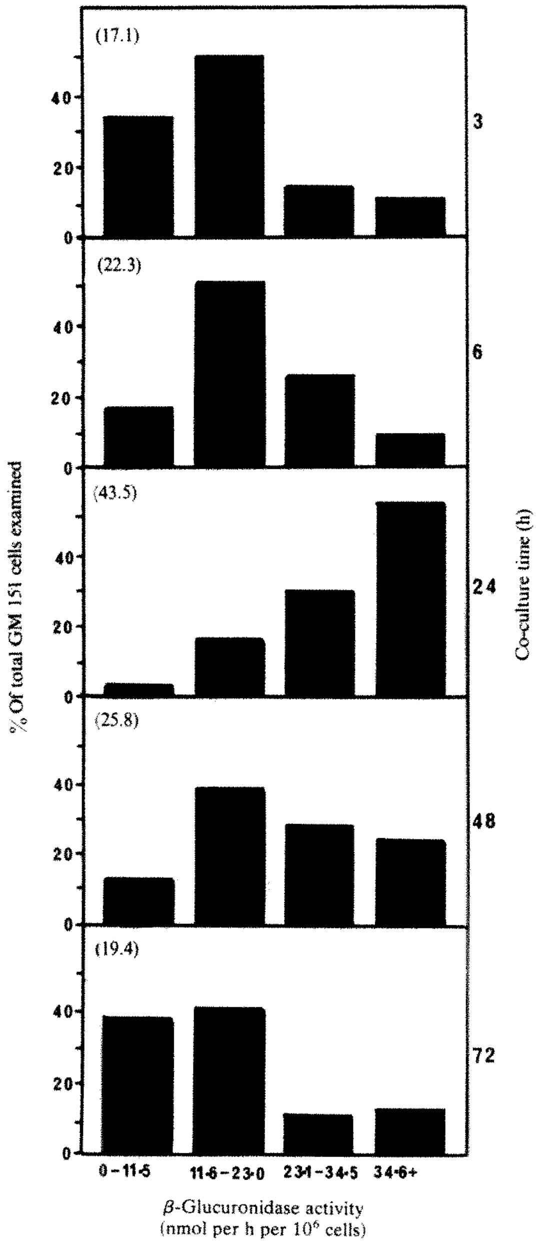

Fig. 2 Changes in β-glucuronidase activity in GM 151 cells during co-culture with lymphocytes. Monolayers of 10^5 GM 151 cells were grown directly in 35-mm culture dishes and the co-culture initiated by the addition of 10^7 lymphocytes. At the end of the co-culture periods (3–72 h), non-adherent lymphocytes were removed with PBS (37 °C), and the adherent cells trypsinized (0.25% trypsin for 10 min at 37 °C). After neutralization with serum, the cells were centrifuged, washed with PBS, and incubated with naphthol AS-BI-β-D-glucuronide substrate for 3 h at 37 °C. The cells were centrifuged, again washed with PBS, coupled with fast blue RR, washed again and resuspended in PBS. Aliquots of the mixed cell suspension were air dried on slides, then washed in methanol and water, and re-dried and mounted. GM 151 cells were readily distinguishable by their shape and larger size. The absorption densities (at 600 nm) of 30–100 individual fibroblasts were determined on a Vickers microdensitometer M-85 using a B5 mask. Results are shown as the proportion of GM 151 cells measured within a designated range of activity, which was calculated from the absorption densities using the standard curve shown in Fig. 3. Numbers in parentheses are the arithmetic means of the single-cell β-glucuronidase activities, expressed as nmol per h per 10^6 cells. Note the gaussian distribution of β-glucuronidase activity throughout the co-culture period, rather than two distinct populations of fibroblasts, one positive and the other negative for enzyme.

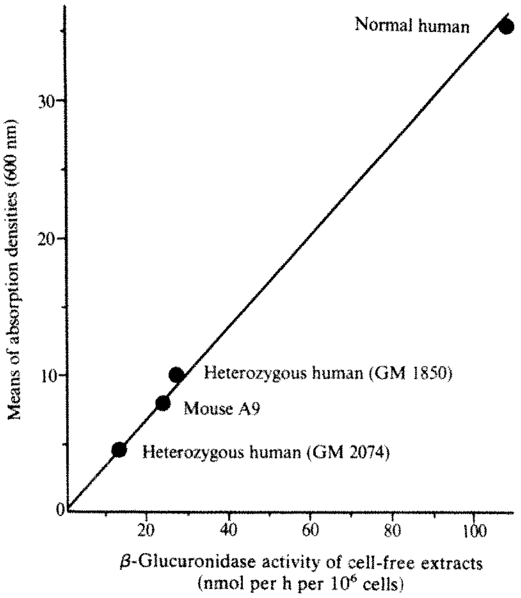

Fig. 3 Correlation of cytochemical and biochemical assays of β-glucuronidase in fibroblast cells. Mouse A9 cells, normal human fibroblasts and fibroblasts from two β-glucuronidase heterozygotes, GM 1850 and GM 2074, were grown directly on Petri dishes to late log phase. The monolayers were washed with PBS and the cells removed with trypsin. For quantitative single-cell cytochemistry, aliquots of the cell suspensions were analysed as described in Fig. 2 legend. All the cell lines had normal gaussian distributions of absorption densities, and the arithmetic means of these were calculated. For direct biochemical assay of β-glucuronidase activity, frozen and thawed extracts were prepared from aliquots of the same suspensions of fibroblasts. These were incubated for 1 h at 37 °C in 2 mM 4-methylumbelliferyl β-D-glucuronide in 0.1 M acetate buffer, *p*H 4.5 in a final volume of 0.25 ml. One ml of 0.4 M glycine buffer, *p*H 10.4, was added and the fluorescence at 448 nm measured on a Locarte fluorimeter (excitation 368 nm). β-glucuronidase activity is expressed as nm per h per 10^6 fibroblast cells used to prepare the cell-free enzyme extract. From the linear relationship between the means of the single-cell cytochemical measurements and the direct biochemical assays of β-glucuronidase in extracts of disrupted cells, a value of 2.9 nmol per h per 10^6 cells per unit density was obtained. This was used to calculate β-glucuronidase activity acquired as a result of co-culture with lymphocytes, expressed as nmol per h per 10^6 GM 151 cells.

Identical results were obtained with fibroblasts from a different patient with mucopolysaccharidosis type VII (GM 121). These findings indicate that the acquisition of β-glucuronidase activity was not due to the release of enzyme from lymphoid cells followed by its uptake by deficient fibroblasts. Thus although the precise nature of the interaction between lymphocytes and fibroblasts is unknown, direct cell-to-cell contact seems to be essential for the acquisition of enzyme activity. The present results might also explain the naturally occurring exchanges of β-glucuronidase observed in tetraparental mice[24], the presence of α-mannosidase activity in chimaeric mannosidosis calves[25], and perhaps also the transient clinical benefits following leukocyte infusion in Sanfilippo's[26] and Hunter's[27] syndromes.

We thank Miss Stephanie Diment for β-glucuronidase from 3T3 cells, Mrs R. Smith and Mrs C. Clifton for technical assistance, and Dr Chayen of the Kennedy Institute for the microdensitometer facilities. We acknowledge the supply of the

deficient fibroblasts by the Human Genetic Mutant Cell Repository.

Diazepam induces mitotic arrest at prometaphase by inhibiting centriolar separation

Leif C. Andersson*†, Veli-Pekka Lehto†, Svante Stenman†, R. Andrew Badley‡ & Ismo Virtanen†

We report here that we have found an accumulation of condensed mitotic figures in cultures of various human haematopoietic cell lines treated with diazepam (40–80 μg ml^{-1}). The mode of mitosis arresting activity of diazepam was analysed with cultured human fibroblasts. Unlike conventional anti-mitotic drugs, diazepam did not affect the microtubular integrity at the concentrations used. Instead, it seems to block mitosis by inhibiting the deviation of centrioles in the prometaphase.

The different appearances of demecolcine-arrested and diazepam-arrested mitoses are seen in Fig. 1, which shows cytocentrifuged cell smears from cultures of the human hairy cell leukaemia line, JOK-1[1]. The mitotic arrest seems to be complete as the same frequency of mitotic figures was seen after 6 and 18 h in parallel cultures treated with 5 μg ml^{-1} demecolcine or 50 μg ml^{-1} diazepam.

The mechanism of the diazepam-induced mitotic arrest was further studied with cultured human fibroblasts. The mitotic apparatus of untreated fibroblasts in metaphase showed a typical spindle-shaped structure in indirect tubulin-specific fluorescence (IIF) (Fig. 2*a*) and in double-fluorescence staining for DNA, a bright plate of condensed chromosomes in the middle of the spindle (Fig. 2*b*). Non-dividing fibroblasts in the same cultures showed a fibrillar tubulin-specific staining throughout the cytoplasmic domain (Fig. 3*a*). Fibroblasts cultured in the presence of demecolcine (0.2 μg ml^{-1}) for 6 h showed only a diffuse tubulin-specific fluorescence both in interphase cells (Fig. 3*b*) and in mitotic cells (Fig. 2*c*) with dispersed chromosomes (Fig. 2*d*).

A distinct accumulation of mitotic cells (up to 25–30%) with condensed chromosomes was seen in fibroblast cultures treated with 80 μg ml^{-1} diazepam for 12 h. When the mitotic cells were stained for tubulin by the IIF technique, an asterisk-like array of microtubules was seen directed towards the centre of the condensed chromosomal plate (Fig. 2*e, f*). A distinct pair of centrioles could be seen in the centre of the microtubule asterisk (Fig. 2*e*, inset). Cells in telophase stage, with a completed chromosome separation, were not observed in diazepam-treated cultures, and the appearance of microtubules in non-

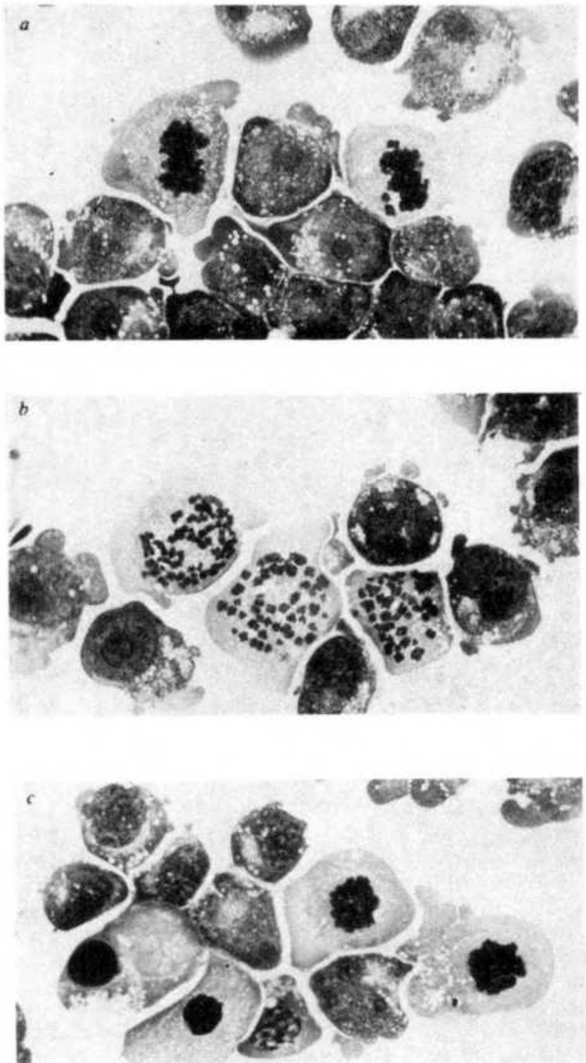

Fig. 1 May–Grünwald–Giemsa stained smears of JOK-1 cells cultivated in RPMI-1640 medium supplemented with 10% fetal calf serum (FCS). *a*, Control culture; *b*, culture treated with 0.5 μg ml^{-1} demecolcine for 6 h; *c*, culture treated with 50 μg ml^{-1} diazepam for 6 h. Diazepam (Orion) was dissolved in dimethyl sulphoxide (DMSO). The diazepam-treated cultures contained 0.04–0.08% DMSO. DMSO at these concentrations did not measurably interfere with cell growth. The frequency of mitotic figures at 6 and 18 h after initiation of cultures were 1.5 and 2.5% in control cultures, 6 and 23% in demecolcine-treated cultures, and 11.5 and 25.5% in diazepam-treated cultures. ×800.

0028–0836/81/210247—02$01.00

mitotic cells was unaltered (Fig. 3). This is different from the effect seen with conventional anti-mitotic drugs (for example, demecolcine, vinblastine sulphate), which arrest cultured cells at mitosis by disrupting the microtubules of the mitotic apparatus[2,3], as is also indicated by the diffuse staining in IIF with anti-tubulin antibodies[3] and dispersion of chromosomes.

Clark and Ryan recently reported that tranquillizers of the benzodiazipine group inhibit the proliferation of 3T3 fibroblasts in pre-S stage[4]. Our findings indicate that diazepam specifically introduces a block in the prometaphase by an unique mechanism: without affecting the microtubular integrity the centriolar separation is inhibited, giving rise to an asterisk-like mitotic apparatus. Interestingly, such a variant mitotic apparatus has also recently been described to occur at low frequency during spontaneous mitosis of PTK_2 cells[5].

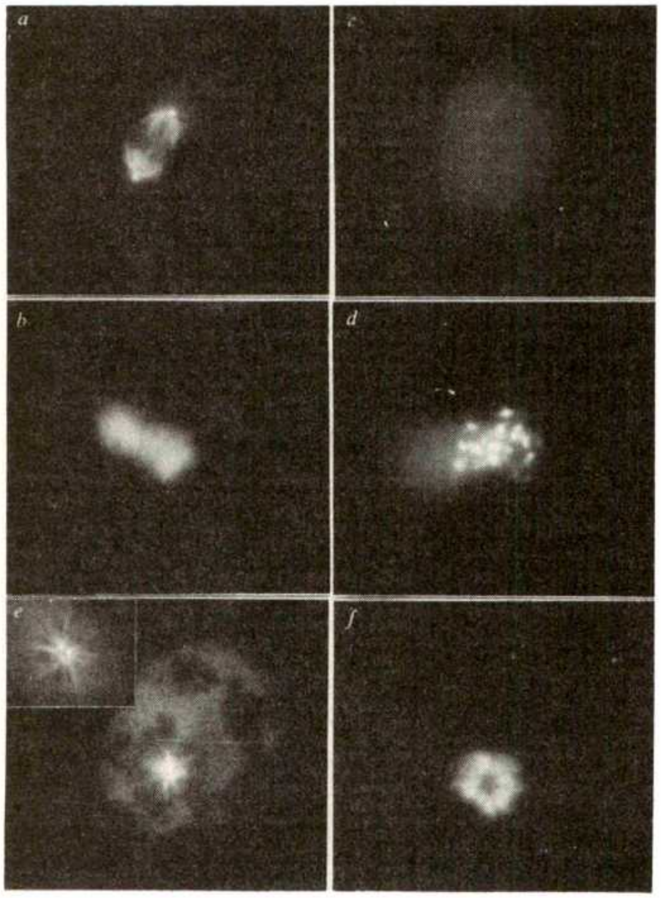

Fig. 2 Human embryonal fibroblasts were cultured in RPMI-1640 medium plus 10% FCS. For IIF microscopy the cells, cultured on small glass coverslips, were fixed in methanol for 10 min at −20 °C. Microtubules were visualized using rabbit antibodies against tubulin from calf brain[6,7]. Fluorescein isothiocyanate-coupled anti-rabbit IgG (Cappel) was used as a second antibody. Chromosomes were visualized by a double-fluorescence technique using the Hoechst no. 33258 fluorochrome[8]. In untreated fibroblasts at metaphase a bright spindle-like tubulin-specific fluorescence is seen in *a*. Note the bright spots, representing centrioles, at the poles of the spindle. In double-fluorescence with the Hoechst fluorochrome (*b*) the chromosomes were seen as a bright plate in the middle of the spindle. When fibroblasts were cultured in the presence of 0.2 $\mu g\ ml^{-1}$ demecolcine for 6 h, rounded mitotic cells accumulated in the cultures. In such cells only a diffuse tubulin-specific staining (*c*) and scattered chromosomal figures (*d*) were seen. When human fibroblasts were cultured in the presence of diazepam (80 $\mu g\ ml^{-1}$ for 12 h), IIF microscopy with anti-tubulin antibodies revealed an asterisk-like mitotic apparatus (*e*) directed towards the centre of the condensed chromosomal plate as seen in double fluorescence microscopy with the DNA-fluorochrome (*f*). The centrioles, visualized as bright spots with tubulin-antibodies, were seen as a distinct doublet in the centre of the microtubule asterisk (*e*, inset). ×680.

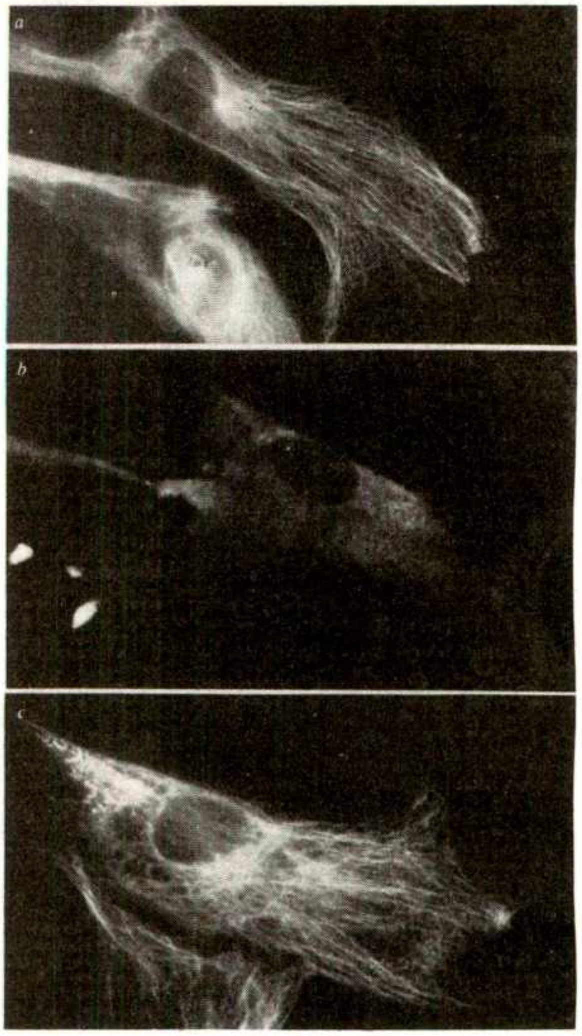

Fig. 3 In normal non-dividing cultured fibroblasts microtubules were visualized by the IIF technique as fibrillar cytoplasmic arrays throughout the whole cytoplasmic domain (*a*). After addition of demecolcine only a diffuse cytoplasmic tubulin-specific fluorescence was seen in the treated cells (*b*). In fibroblasts cultured in the presence of diazepam (80 $\mu g\ ml^{-1}$), normal fibrillar arrays of microtubules were seen (*c*). ×400.

Intermediate filaments in 3T3 cells collapse after intracellular injection of a monoclonal anti-intermediate filament antibody

Michael W. Klymkowsky

MRC Neuroimmunology Project, Department of Zoology and
Comparative Anatomy, University College London,
London WC1E 6BT, UK

The function of intermediate filaments within cells is unclear, largely because there are no known reagents or physical conditions which specifically affect their organization (see ref. 1 for review). I report here that the intracellular injection of a monoclonal IgG1 antibody specific for intermediate filaments[2] causes the rapid and reversible collapse of all intermediate filaments within 3T3 mouse fibroblasts while leaving the organization of microfilament bundles and microtubules apparently unaltered. Direct observation of cells undergoing intermediate filament collapse indicates that such collapse occurs without obvious effects on cell morphology or motility.

Monoclonal antibody against an intermediate filament antigen (IFA)[2] was purified from ascites fluid raised in *nu/nu* mice on a column of *Staphylococcus* A–Sepharose (Pharmacia), concentrated by vacuum dialysis, dialysed into injection buffer (114 mM KCl, 20 mM NaCl, 3 mM $MgCl_2$, 3 mM NaH_2PO_4, *p*H 7 with KOH (ref. 3)) and spun at 100,000*g* for 30 min before use. About 2×10^{-14}l (ref. 4) of antibody at a concentration of 3 mg ml^{-1} was injected into 3T3 (clone A31) cells growing on glass coverslips for 20–48 h. During and after injection, cells were maintained at 37°C until they were fixed after various periods of time with methanol for 10 min at −20°C. The cells were then stained sequentially with fluorescein-coupled goat anti-mouse immunoglobulin (G-anti-MIg-F) to visualize microinjected antibodies and by rabbit anti-tubulin[5], rabbit anti-cytoplasmic myosin[6] or more monoclonal anti-IFA antibodies followed by rhodamine-coupled goat anti-rabbit immunoglobulin (G-anti-RIg-Rd) or G-anti-MIg-Rd. Appropriate control experiments indicated that all reagents used were specific (data not shown). After washing, the coverslips were mounted in glycerol and viewed with a Zeiss Universal microscope equipped with phase contrast and epifluorescence optics.

When fixed within 1 h of injection and stained with G-anti-MIg-F, many injected cells were seen to have their intermediate filaments collapsed within a bundle near or around the cell's nucleus. When such cells were exposed to more anti-IFA antibody followed by G-anti-MIg-Rd, no intermediate filament staining was observed (Fig. 1) outside the collapsed bundle. On exposure of these to either anti-tubulin or anti-cytoplasmic myosin antibodies, followed by G-anti-RIg-Rd, most microtubules and microfilament bundles were unaffected by the collapse of intermediate filaments (Fig. 2). Moreover, the collapsed intermediate filaments did not label with either the anti-tubulin or anti-myosin antibodies (Fig. 2). Cells injected with tetramethylrhodamine-coupled bovine serum albumin or antibody directed against cytoplasmic myosin[6] never showed collapsed intermediate filaments, excluding the possibility that filament collapse was a response to injection.

The collapse of intermediate filaments by injected anti-IFA antibody was reversible, as demonstrated by time-course experiments such as those outlined in Table 1. Filament collapse was most marked at 1–3 h post-injection when more than 70% of injected cells had collapsed intermediate filaments; with time the percentage decreased and the extent of filament collapse in individual cells diminished until, at 16 h after injection, many cells had fully extended intermediate filaments, although these were still decorated with anti-IFA antibody. Autophagy of injected antibody[7] might have reduced the intracellular concentration of antibody to a level insufficient to maintain filament collapse.

Table 1 Time course of collapse of intermediate filaments by injected anti-IFA antibody

Time after injection (h)	Cells recovered	Cells with collapsed intermediate filaments
1	90	79 (88)
3	89	63(71)
6	94	45(48)
16	68	16 (24)

100 cells were injected on each coverslip and after staining, the entire coverslip was scanned. The fact that less than 100% of the cells were 'recovered' reflects both cell death due to injection trauma and the inability to recognize cells due either to reduction of staining level to near background, or interfering flaws in mounting. Numbers in parentheses are the percentage of recovered cells found to be collapsed.

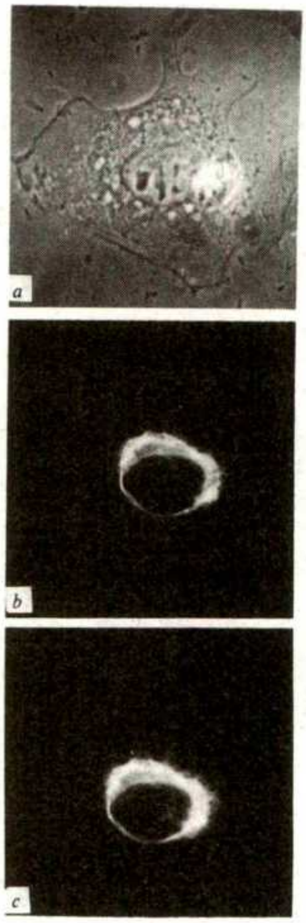

Fig. 1 Phase (*a*) and immunofluorescence of 3T3 cell injected with anti-IFA 1 h previously, fixed and then stained sequentially with G-anti-MIg-F, anti-IFA and G-anti-MIg-Rd. Intermediate filaments are collapsed around the nucleus (*b*, fluorescein optics) and secondary staining with anti-IFA shows no intermediate filaments outside the collapsed bundle (*c*, rhodamine optics). Cells were injected in HEPES-buffered minimal Eagle's media (MEM) + 10% fetal calf sera (FCS) + 50 μg ml^{-1} gentamycin and then returned to bicarbonate-buffered MEM + 10% FCS and kept in 8% CO_2 at 37 °C until fixation. ×700.

0028–0836/81/210249—03$01.00

To study the effects of intermediate filament collapse on cell morphology and movement, purified tetramethylrhodamine-conjugated anti-IFA (anti-IFA-Rd) was injected into 3T3 cells and the cells were followed by time-lapse video using a Zeiss inverted microscope equipped with phase contrast and epifluorescence optics coupled to a silicon-intensified target video camera (RT Laboratories) and video recording system. Cells were examined using epifluorescence optics at the end of the observation period. Injected anti-IFA antibody spread rapidly throughout the cell and decorated intermediate filaments. Most cells retained their pre-injection morphologies, although a small proportion underwent a rapid but reversible contraction; as this type of acute shape change was just as frequently observed after injection of buffer alone, it was probably due to the injection process itself. Most injected cells showed intermediate filament collapse within 1–3 h and the morphologies and movements of the majority of such cells could not be distinguished from uninjected cells in the same field. An example of intermediate filament collapse in two injected cells is shown in Fig. 3. Because all the cells were continuously moving and changing shape, I cannot exclude the possibility that the collapse of intermediate filaments was associated with subtle changes in cell shape or movement.

The collapse of intermediate filaments induced by anti-IFA antibody was not restricted to 3T3 cells. The intermediate filaments of baby hamster kidney-21 (BHK-21) cells and secondary chick heart fibroblasts also underwent intermediate filament collapse after antibody injection and retained substantially unaltered morphologies. Very large cells often failed to show antibody-induced filament collapse. Whether this is the result of a failure to inject sufficient quantities of the antibody or is due to a true difference in the intermediate filaments of such cells is unclear.

The mechanism of anti-IFA antibody-induced collapse of intermediate filaments is unknown. The antibody has been shown to bind to vimentin, the major protein in intermediate filaments in 3T3 cells[2]. However, the simple binding of an antibody to filaments within living cells does not invariably change the organization of those filaments. For example, rabbit anti-cytoplasmic myosin antibodies injected into 3T3 cells decorated microfilament bundles but had no appreciable effect on the distribution of either microfilament bundles or intermediate filaments within the cells (data not shown). Moreover, various monoclonal antibodies which react with tonofilaments in PtK_2 cells[8] decorate these filaments after injection but do not change their distribution; anti-IFA antibodies, on the other hand, collapse tonofilaments in PtK_2 cells after injection[9].

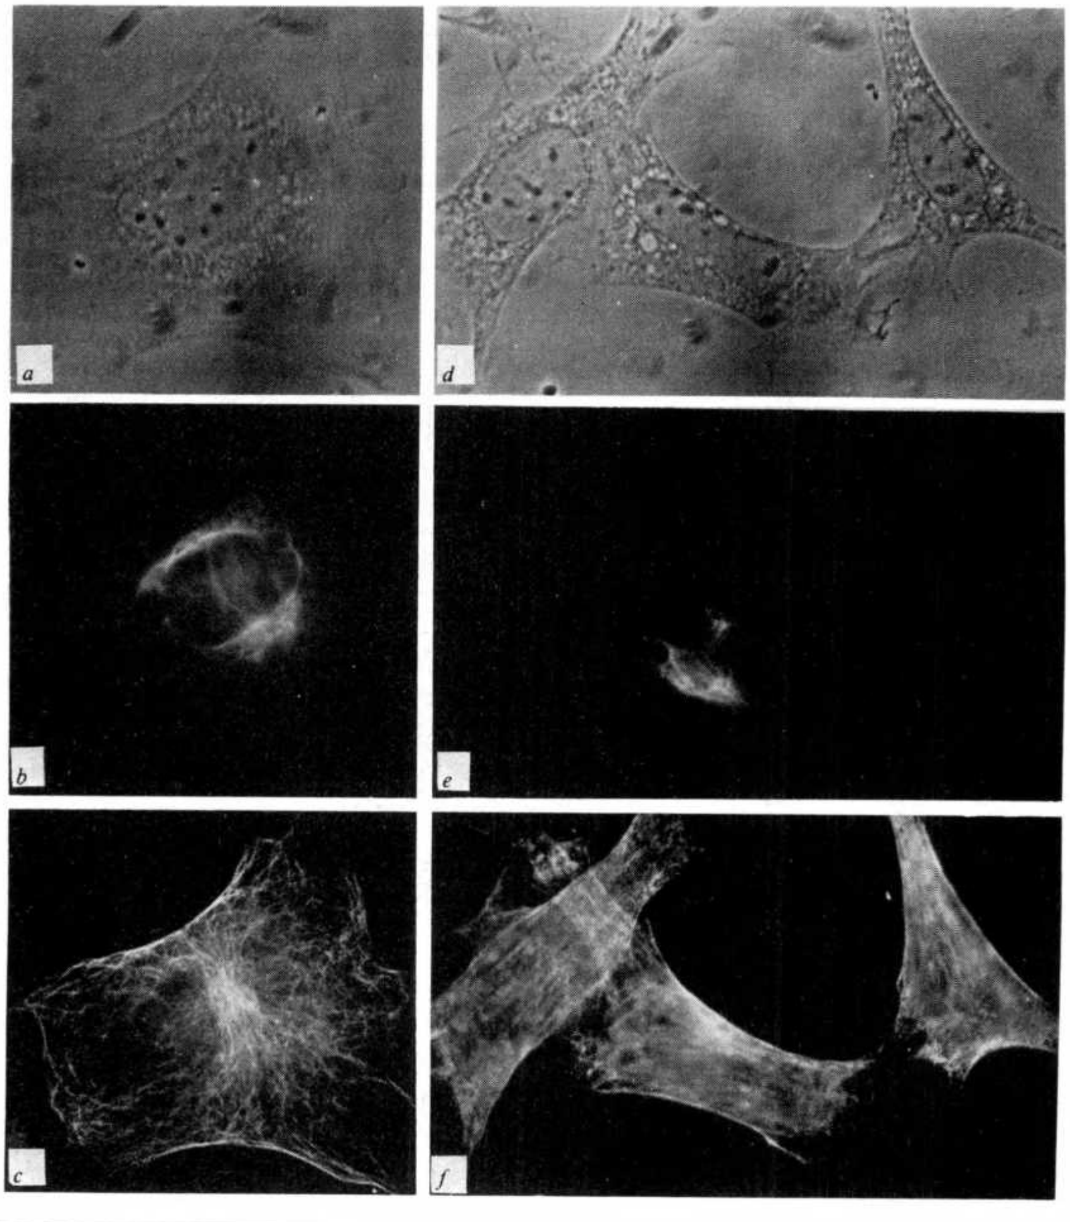

Fig. 2 Phase (*a*, *d*) and immunofluorescence of anti-IFA injected 3T3 cells (1–1·5 h before fixation) that have been stained sequentially with G-anti-MIg-F, rabbit anti-tubulin (*a*, *b*, *c*) or rabbit anti-myosin (*d*, *e*, *f*) and G-anti-RIg-Rd. Both rabbit anti-tubulin and myosin and anti-rabbit-Ig-Rd were diluted into purified mouse immunoglobulin (final concentration ~2 mg ml^{-1}) to block possible cross-reactivity with G-anti-MIg-F. G-anti-RIg-Rd had been pre-adsorbed with mouse immunoglobulin. Intermediate filaments (*b*, *e*, fluorescein optics) are collapsed by injected anti-IFA but microtubule and microfilament bundle organization appear unaltered (*c*, *f*, rhodamine optics). ×1,060.

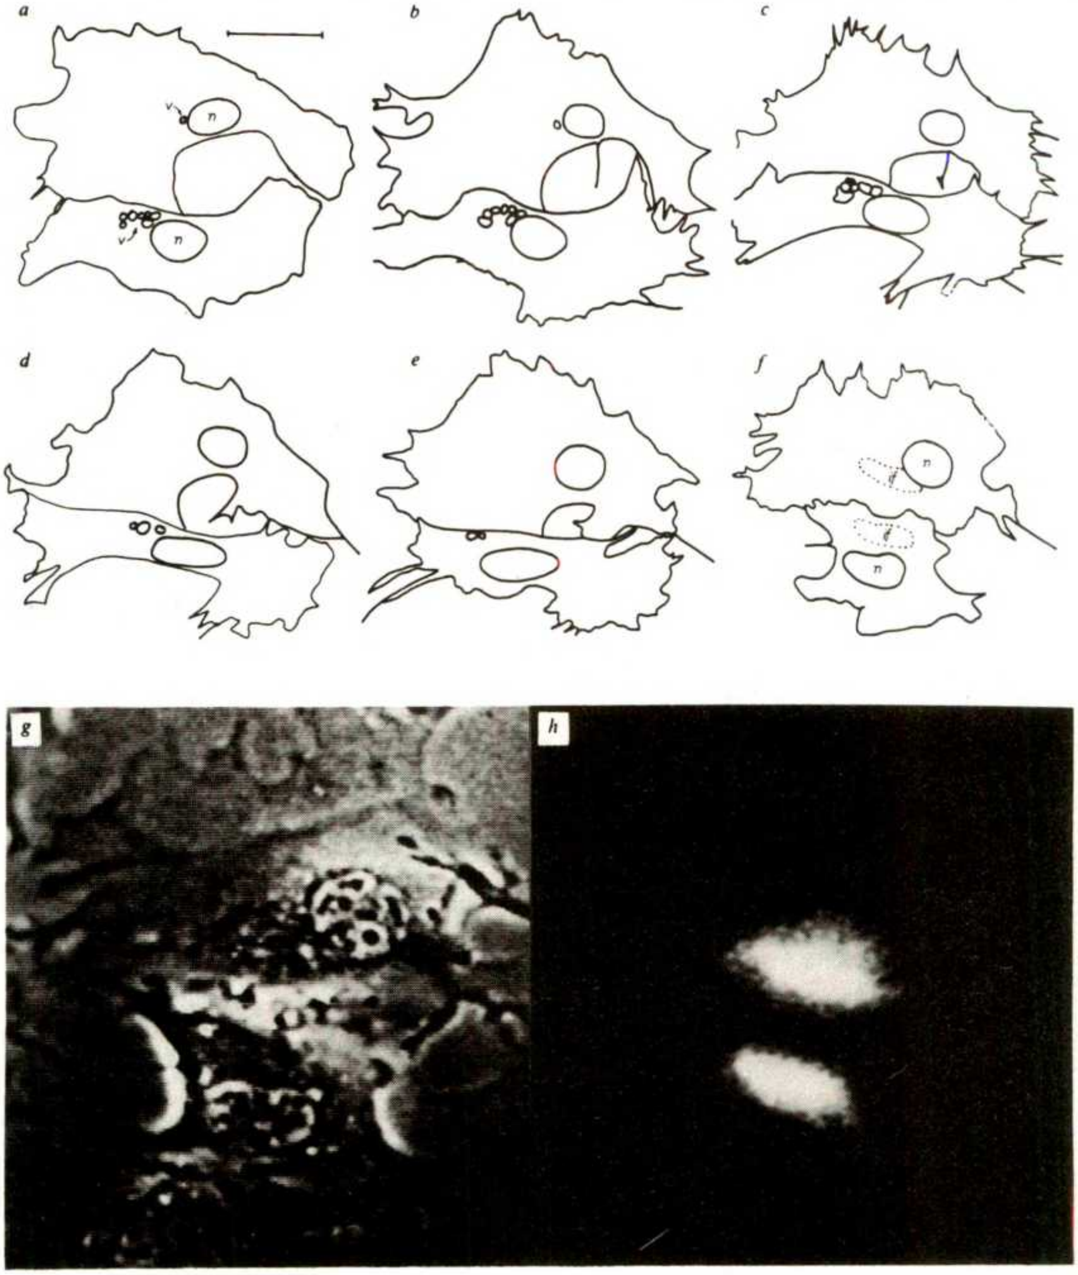

Fig. 3 Two cells injected with anti-IFA-Rd were followed continuously by time-lapse video. Outlines of the cells were traced from the video images before (*a*) and 2.5 min (*b*), 17 min (*c*), 36.5 min (*d*), 59.5 min (*e*), and 76 min (*f*) after injection. The cells were viewed under rhodamine optics 76 min after injection, revealing their collapsed intermediate filaments (region defined by dotted boundary and 'if' in *f*). The phase contrast (*g*) and rhodamine optics images (*h*) of the cells 76 min after injection as photographed from the video monitor are also shown. The cells' nuclei 'n' are labelled (*a*, *f*) and vacuoles 'v' (in *a*), which subsequently disappear. Similar shape changes to those seen in these two injected cells are frequently seen in normal, uninjected 3T3 cells over this period of time. Cells were maintained at 37 °C in HEPES-buffered MEM + 10% FCS + 50 μg ml^{-1} gentamycin throughout. To minimize evaporation of media the culture dish was overlaid with paraffin oil. Cells survived and divided apparently normally in these conditions for longer than 24 h. Scale bar, 50 μm.

Increasing indirect evidence suggests that intermediate filaments and microtubules are functionally and perhaps physically associated with each other[10]. The effects of microtubule depolymerization, whether by specific drugs or physical conditions, results in the eventual collapse of intermediate filaments, not unlike that seen after injection of anti-IFA, although with a much slower time course[1]. The results presented here indicate that whereas the extended organization of intermediate filaments may well depend on microtubules, the converse is clearly not the case. Apparently, intermediate filaments can be specifically withdrawn from the cytoskeletal network of the cell without obvious effects on the organization of microfilament bundles or most microtubules, or on gross cell morphology or movement. These findings suggest that intermediate filaments may have a more subtle role than previously believed.

While this manuscript was in preparation, similar results were reported in abstract form by Lin and Feramisco[11] using a monoclonal IgM antibody directed against a 95,000 molecular weight protein associated with intermediate filaments.

I thank members of the MRC Neuroimmunology Project, especially Dr R. Pruss for anti-IFA antibody and Drs M. Raff, M. Noble, E. B. Lane and S. Bevan, for their stimulating suggestions and encouragement, Dr T. Preston for the use of his micromanipulator, and Drs P. Sheterline and J. Fallon for gifts of anti-tubulin antisera and anti-cytoplasmic myosin antibodies respectively. I am a Muscular Dystrophy Association of America postdoctoral fellow.

Regulation of human platelet myosin light chain kinase by the catalytic subunit of cyclic AMP-dependent protein kinase

D. R. Hathaway*, C. R. Eaton & R. S. Adelstein†

Section on Molecular Cardiology, Cardiology Branch, National
Heart, Lung, and Blood Institute, Building 10, Room 7B–15,
National Institutes of Health, Bethesda, Maryland 20205, USA

A rise in the concentration of cyclic AMP inhibits secretion in human platelets[1–3]. In mammalian cells the mechanism of action of cyclic AMP involves activation of a protein kinase and results in protein phosphorylation[4]. It has previously been shown that myosin light chain kinase purified from smooth muscle is a substrate for the catalytic subunit of cyclic AMP-dependent protein kinase[5] and that phosphorylation of smooth muscle myosin kinase results in a decrease in its activity[6]. Here we present evidence that platelet myosin kinase is a substrate for the catalytic subunit of protein kinase and that phosphorylation of this myosin kinase, isolated from a non-muscle cell, decreases the activity of this enzyme. Dephosphorylation of platelet myosin kinase by a purified phosphatase[7] restores its original activity. A decrease in myosin kinase activity in platelets would increase the relative amount of unphosphorylated myosin, which unlike phosphorylated myosin, cannot interact with actin[8,9]. These findings suggest a mechanism by which cyclic AMP might modulate actin–myosin interaction in platelets and other non-muscle cells.

The platelet myosin kinase used was purified by affinity chromatography using a column of calmodulin–Sepharose 4B (refs 10, 11). Figure 1 shows the time course of incubating purified platelet myosin kinase, $[\gamma\text{-}^{32}P]$ATP and the catalytic subunit of protein kinase in the presence and absence of protein kinase inhibitor. In the presence of the catalytic subunit, ^{32}P was rapidly incorporated into platelet myosin kinase, whereas incubation in the presence of the protein kinase and its specific inhibitor decreased the amount of ^{32}P incorporation by ~90%. Incubation in the absence of protein kinase showed only minimal amounts of incorporation of ^{32}P after 1 h. A time course experiment carried out in the absence of protein kinase showed no evidence for autophosphorylation during earlier times (not shown).

To verify that platelet myosin kinase served as the phosphate acceptor, a sample of myosin kinase that had been incubated for 45 min with $[\gamma\text{-}^{32}P]$ATP and protein kinase was subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE). The major protein peak ($M_r = 100{,}000$), corresponding to myosin kinase, coincided with the only peak of protein-bound ^{32}P. When PAGE was carried out in the absence of SDS, a single peak of myosin kinase activity, which contained all the ^{32}P, was eluted from the gel (data not shown).

The stoichiometry of phosphorylation was determined both by Millipore filtration of phosphorylated myosin kinase following precipitation with trichloroacetic acid and by quantifying the amount of protein and ^{32}P migrating with myosin kinase in SDS-PAGE. In four separate preparations an average of 1.2 mol of phosphate per mol of myosin kinase was incorporated. However, these results do not exclude the possibility that more than one site can be phosphorylated.

Figure 2 shows the effect of phosphorylation on platelet myosin kinase activity and is a double reciprocal plot of data derived from activation of myosin kinase over a range of calmodulin concentrations. Two effects of phosphorylation are observed. First, phosphorylation results in a threefold decrease in maximal enzymatic activity (from 0.148 to 0.054 nmol min^{-1}). Second, the concentration of calmodulin required for half-maximal enzyme activity is threefold greater for phosphorylated myosin kinase than for the unphosphorylated species (2.8×10^{-8} M compared with 0.9×10^{-8} M).

The effect of phosphorylating myosin kinase is reversible, as shown in Fig. 3, which compares the specific activity of unphosphorylated, phosphorylated and dephosphorylated platelet myosin kinase at two different concentrations of calmodulin. Figure 3 also shows an autoradiogram indicating the state of phosphorylation of the kinase before and after incubation with phosphatase. The enzyme used to dephosphorylate myosin kinase was the purified phosphatase I prepared from turkey gizzards[7], which was free of protease activity. The ability of smooth muscle phosphatase I to dephosphorylate platelet myosin kinase and restore the higher activity of the unphosphorylated enzyme is consistent with a role for this phosphorylation in regulating the activity of myosin kinase.

Phosphorylation of the 20,000-M_r light chain of platelet myosin and other non-muscle myosins has been shown to have two important effects: (1) it is required for the actin-activation of the Mg-ATPase activity of myosin[8,9,12–14], and (2) it promotes the assembly of myosin filaments in physiological conditions[15]. The enzyme catalysing phosphorylation of platelet myosin has been purified and shown to have an absolute requirement for

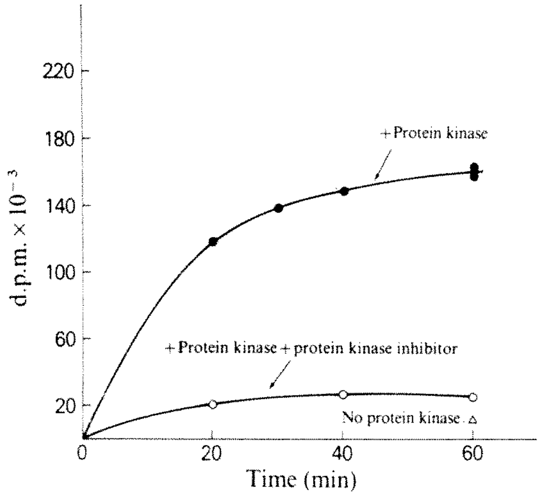

Fig. 1 Time course of phosphorylation of platelet myosin light chain kinase by the catalytic subunit of cyclic AMP-dependent protein kinase in the presence and absence of the specific inhibitor of protein kinase. Myosin light chain kinase was purified as described by D.R.H. and R.S.A.[10] except that the crude extract was applied to a 20-ml column of AH-Sepharose 4B and eluted with 0.5 M NaCl, replacing the DEAE-Sephacel chromatography, and Sephacryl S-300 was used rather than S-200. The purified kinase (5×10^{-8} M) was incubated at 23 °C in 50 mM Tris-HCl (*p*H 7.5), 5 mM $MgCl_2$, 25 μM $[\gamma\text{-}^{32}P]$ATP (2×10^7 c.p.m. nmol^{-1}) and 2×10^{-7} M cyclic AMP-dependent protein kinase (a gift of Dr E. H. Fischer). This was done in the presence (○) and absence (●) of the specific inhibitor of cyclic AMP-dependent protein kinase[18] (a gift from Dr L. Rappaport). Time points were taken at 20, 30, 40 and 60 min, and the amount of ^{32}P incorporated into the myosin kinase was determined by Millipore filtration and liquid scintillation counting of the filter disks[12]. A single time point was taken in the absence of protein kinase (△), showing no phosphorylation of the platelet myosin kinase. When histone IIA was phosphorylated at comparable concentrations using the same amount of protein kinase, the time course of phosphorylation was similar to that obtained with platelet myosin kinase. Phosphorylation of platelet myosin kinase was not dependent on Ca^{2+}.

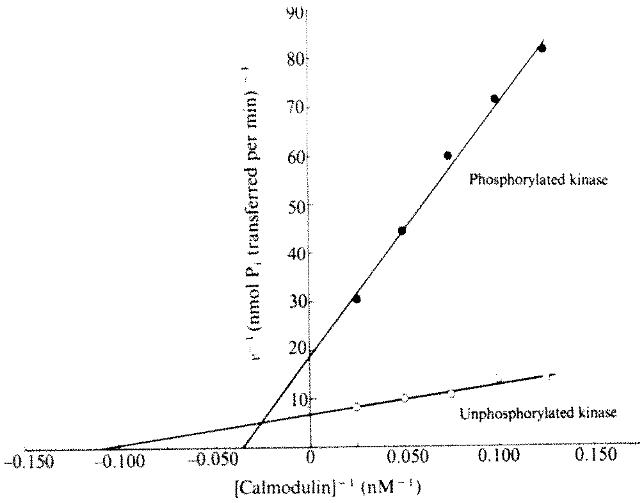

Fig. 2 Double reciprocal plot showing the effect of phosphorylation on the activity of platelet myosin light chain kinase. The myosin kinase (3×10^{-7} M) was incubated for 45 min at 23 °C with 40 mM Tris-HCl (*p*H 7.5), 5 mM $MgCl_2$ and 4×10^{-7} M cyclic AMP-dependent protein kinase, in the presence (●) and absence (○) of 50 μM ATP. The resulting phosphorylated and unphosphorylated samples of myosin kinase were then each assayed over a range of calmodulin concentrations from 9×10^{-9} M to 4×10^{-8} M. Calmodulin was prepared from bovine brain by the method of Klee[19]. The concentration of platelet myosin kinase was 3.3×10^{-8} M. The assays were carried out for 1 min at 23 °C in 50 mM Tris-HCl (*p*H 7.3), 10 mM $MgCl_2$, 0.1 mM $CaCl_2$, 100 μM [γ-^{32}P]ATP (2×10^6 c.p.m. nmol^{-1}) and 25 μM smooth muscle myosin 20,000-M_r light chain. This myosin light chain fraction was prepared as outlined previously[5]. Total assay volume was 100 μl.

Ca^{2+} and the ubiquitous calcium-binding protein, calmodulin[10,11].

Previous work has shown that the enzyme catalysing myosin phosphorylation in smooth muscle can be phosphorylated by the catalytic subunit of cyclic AMP-dependent protein kinase[5]. Phosphorylation has a marked effect on the ability of the smooth muscle enzyme to bind calmodulin, but only a small effect on V_{max} (ref. 6). The results reported here for platelet myosin kinase differ in that phosphorylation of the platelet myosin kinase decreases both the ability of the enzyme to bind calmodulin and the activity of the enzyme when extrapolated to an infinite concentration of calmodulin (V_{max}). This difference in the effect of phosphorylation on the kinetic parameters of the two enzymes may simply reflect the species difference between the turkey gizzard smooth muscle kinase and that isolated from human platelets. On the other hand, it is possible that the purified platelet myosin kinase, which has a molecular weight 30,000 less than the smooth muscle kinase (100,000 compared with 130,000), has undergone partial proteolysis. Such proteolysis, which does not alter the requirement of the enzyme for calmodulin or the ability to respond to phosphorylation, could be responsible for a subtle alteration in the kinetic response. Further work will be necessary to rule out this latter possibility.

Cyclic nucleotide-mediated phosphorylation of myosin kinases may provide an important mechanism for modulating contractile activity in non-muscle cells. A rise in the intracellular concentration of cyclic AMP would result in the phosphorylation of myosin kinase and hence decrease myosin kinase activity. The net result of this decreased activity would be an inhibition of contractile activity because it would result in a relative increase in the unphosphorylated form of myosin. Indirect evidence for cyclic AMP-mediated regulation in smooth muscle cells has been provided by Kerrick *et al.*[16], who showed that addition of the catalytic subunit of cyclic AMP-dependent protein kinase to chemically skinned smooth muscle fibres resulted in a decrease in both tension and the phosphorylation of smooth muscle myosin light chains.

Daniel *et al.*[17] have shown that platelet secretion can be correlated with the phosphorylation of platelet myosin, indicating that secretion results from contraction of platelet actomyosin. This finding, together with data from physiological experiments suggesting that agents which increase cyclic AMP in platelets act to inhibit secretion[1-3], is consistent with our *in vitro* findings that phosphorylation of platelet myosin kinase by cyclic AMP-dependent protein kinase results in inhibition of myosin kinase activity. Of course, it is possible that cyclic AMP works through more than one pathway to cause a decrease in contractile activity in platelets. To confirm the physiological significance of the mechanism outlined here, future experiments must: (1) demonstrate phosphorylation of platelet myosin kinase *in vivo* in response to a rise in intracellular levels of cyclic AMP and (2) correlate this phosphorylation with inhibition of a contractile event. However, our present data suggest that phosphorylation of myosin kinase by cyclic AMP-dependent protein kinase is one mechanism by which cyclic AMP regulates contractile activity in platelets and other non-muscle cells.

We thank Mr William Anderson Jr and Mr James M. Miles for technical assistance, and Mrs Exa Murray for preparing this manuscript.

Specific activity of myosin kinase (μmol per mg per min)

	1 x 10-9M Calmodulin	3 x 10-9M Calmodulin
UNPHOSPHORYLATED	0.21	0.98
PHOSPHORYLATED	0.09	0.45
DEPHOSPHORYLATED	0.23	0.96

Fig. 3 The effect of dephosphorylation of myosin kinase activity. Platelet myosin kinase was incubated in the presence and absence of 1.25 μM catalytic subunit of cyclic AMP-dependent protein kinase. Also present in both tubes were 50 mM Tris-HCl (*p*H 7.3), 10 mM $MgCl_2$, 0.1 mM $CaCl_2$ and 20 μM [γ-^{32}P]ATP. After 30 min at 23 °C, 20 mN EDTA was added to each sample to inhibit further phosphorylation. The sample with the protein kinase was then divided into two parts, to one half of which was added 6×10^{-9} M purified smooth muscle phosphatase I[7] (a gift of Dr Mary Pato). The resulting three tubes (U = no protein kinase, no phosphatase; P = +protein kinase, no phosphatase; D = +protein kinase, +phosphatase) were incubated for 15 min at 23 °C before assay. The left-hand side is an autoradiogram showing the state of phosphorylation of the phosphorylated (P) and dephosphorylated (D) samples. There is no evidence for autophosphorylation of the myosin kinase in the unphsophorylated (U) sample. The dye front is indicated. In wells P and D, halfway between the ^{32}P band due to the myosin kinase and the dye, is a light band which is probably due to autophosphorylation of the catalytic subunit of protein kinase. The samples were assayed at the two calmodulin concentrations shown, using 1×10^{-9} M platelet myosin kinase. The assays were terminated after 15 min (1×10^{-9} M calmodulin) or 8 min (3×10^{-9} M calmodulin) at 23 °C, with other conditions as in Fig. 2 legend.

Note added in proof: Recent experiments indicate that phosphate is incorporated into two different sites in platelet myosin kinase (C.R.E. and R.S.A., unpublished), as recently reported for smooth muscle myosin kinase[6].

Localized gating of egg Na$^+$ channels by sperm

Meredith Gould-Somero

Department of Biology, B-022, University of California, San Diego, La Jolla, California 92093, USA

Eggs of many species respond to sperm with a positive shift in membrane potential, the fertilization potential[1], which in several[2–5] but not all[6] species mediates a block to polyspermy. How the sperm elicits the fertilization potential is not known, although it is the earliest known response of eggs to sperm, occurring within 1–2 s of mixing the gametes. In the marine worm, *Urechis caupo*, the fertilization potential results from an increase in Na$^+$ permeability which is amplified during the first 15 s by a voltage-gated Ca^{2+} action potential[7]. The Na$^+$ channels are gated not by voltage, but by sperm, a sperm opening only a fraction of available channels[7]. The experiments reported here indicate that the open Na$^+$ channels are localized in a 'patch' near the fertilizing sperm.

Because the amplitude of the fertilization potential depends on the external Na$^+$ concentration ([Na$^+$])[7], it is possible to distinguish between a localized and a uniform distribution of open Na$^+$ channels if the concentration of Na$^+$ at the site of fertilization is altered independently of that over the rest of the egg. The experimental apparatus, described in Fig. 1 legend, consisted of a perforated nickel screen in which the egg was seated separating two chambers containing seawater of the same or different [Na$^+$]; [Na$^+$] was either 470 mM (natural seawater) or 1/10th that amount. By injecting a dense sperm suspension into this chamber, then removing the egg and measuring the area to which sperm were bound, at ×400 with an ocular micrometer, we calculated that 5–10% of the egg surface was exposed to the solution in the lower chamber. Because the resistance through the egg interior is small relative to that across the membrane, the egg is isopotential, and the electrode in the upper surface of the egg accurately records the fertilization potential initiated by a sperm at the opposite side of the egg. Furthermore, the lower chamber was not electrically isolated from the upper chamber, as the two chambers were connected by a low resistance pathway even with an egg seated firmly in the hole. The resistance across the open hole, measured with an ohmmeter, was about 10 kΩ, and increased by only 1–4 kΩ with an egg in the hole. These resistances are trivial compared with that across the egg membrane ($\geqslant 100\ \mathrm{M\Omega}$), and thus introduce no significant error into the electrical measurements. Sperm, however, did not cross from one chamber into the other during the experiments. Microscopic examination of 10 eggs inseminated in the lower chamber showed that sperm were bound only to that portion of the egg (easily identified by a bleb, or deformation in the egg surface coat) that had been in the lower chamber. (Supernumerary *Urechis* sperm do not unbind rapidly from the eggs after fertilization.)

The results of six combinations of 470 and 47 mM Na$^+$ seawater with sperm added to one or the other chamber (Fig. 2, Table 1) show that a sperm must open a localized patch of Na$^+$ channels in its vicinity. Figure 2*a–d* shows that the initial amplitudes of the fertilization potentials are dependent on [Na$^+$] at the fertilization site regardless of the [Na$^+$] bathing the rest of the egg. Figure 2*e* shows that average plateau potentials (see legend) are also predicted by the [Na$^+$] at the site of fertilization. With approximately the upper 90% (see above) of the egg

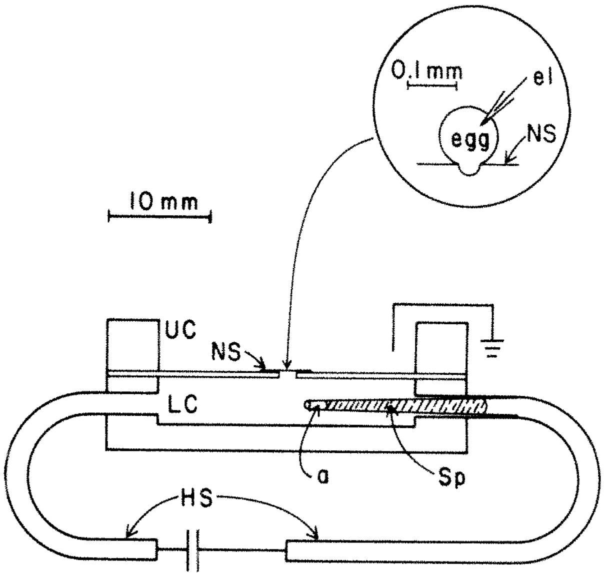

Fig. 1 Diagram of the experimental chamber modified from the original design of Robinson and Jaffe[13]. An egg (120 μm diameter) is seated in a 45-μm diameter hole in a nickel screen (NS; Perforated Products Inc.) separating two chambers (UC, upper chamber; LC, lower chamber) which can contain seawater of differing [Na$^+$]; sperm are added to one of the two chambers. A small piece of nickel screen is glued with non-toxic Paraplast over the hole in the thin plastic barrier separating upper and lower chambers. All but one hole in the nickel screen is plugged with Paraplast, and this hole is the only opening between upper and lower chambers. The respective volumes of seawater in the upper and lower chambers are 0.7 and 2 ml. Each of the two entry ports in the lower chamber is connected by thin plastic tubing to a 10-μl Hamilton syringe (HS). The left-hand syringe is used to create a slight suction that will seat the egg firmly in the hole. The right-hand syringe delivers sperm to the lower chamber. The sperm delivery tube contains about 5 μl sperm suspension (Sp) prevented from prematurely entering the chamber by an air bubble (a) at the tip. (Before inserting the tube in the chamber, external sperm are killed by washing the outside of the tube in deionized water.) To inject the sperm suspension into the lower chamber, the plungers of the two syringes are arranged back to back as shown, permitting simultaneous addition and withdrawal of equal volumes so that the position of the egg in the hole is not disturbed. Eggs were observed (at ×100 with a Wild stereomicroscope) to ensure they did not move in the hole. Sperm are delivered to the upper chamber dropwise from a pipette. At the beginning of an experiment, both upper and lower chambers are filled with seawater of the [Na$^+$] desired in the lower chamber, the sperm delivery tube is inserted into the lower chamber (or the port is plugged if sperm are to be added from above), the egg is seated in the hole and penetrated with a microelectrode, then the solution in the upper chamber is changed, if desired, by perfusion with a simple siphon plus vacuum suction system (not shown). The upper chamber was modified with plastic partitions and a baffle as described previously[7] to ensure complete solution exchange during perfusion. The solution in the upper chamber was continuously perfused whether or not its composition differed from that in the lower chamber. One-tenth [Na$^+$] seawater was prepared by diluting natural seawater with Na$^+$-free artificial seawater (NaCl replaced with choline-Cl). Methods for microelectrode measurements were those used by Jaffe *et al.*[7]. Methods for maintaining *Urechis* and obtaining and handling gametes are described elsewhere[14].

Table 1 Average plateau potentials of the fertilization potentials obtained by varying [Na⁺] at the site of fertilization independently of [Na⁺] on the rest of the egg surface

Condition*	Average plateau potential $\bar{x}$ (mV)	s.e.m.†	(n)	P‡
$\frac{470}{470\text{s}}$	+18.2	2.4	(5)	
$\frac{47}{470\text{s}}$	+17.8	6.5	(5)	<0.02
$\frac{47\text{s}}{470}$	−14.3	4.4	(3)	>0.05
$\frac{47}{47\text{s}}$	−26.7	2.0	(3)	
$\frac{470\text{s}}{47}$	+18.0	3.0	(3)	<0.02
$\frac{470}{47\text{s}}$	+3.2	2.2	(5)	

See legend to Fig. 2*e* for method of calculation of average plateau potential. Data in the first four lines of the table are the same as in Fig. 2*e*.

*$\frac{\text{mM Na}^+\text{ in upper chamber}}{\text{mM Na}^+\text{ in lower chamber}}$, s indicates chamber to which sperm were added.

†Standard error of the mean (standard deviation/$n^{1/2}$).

‡Calculated by the *t*-test, comparing the means of the two samples indicated by the brackets.

surface in low-Na⁺ seawater and the lower 10%, to which sperm are added, in high-Na⁺ seawater, the average fertilization potential amplitude, +17 mV, is the same as that obtained with high [Na⁺] bathing the entire egg. However, if sperm are added to the upper egg surface in low [Na⁺], the average plateau potential, −14 mV, is significantly less (see Table 1). The −14 mV potential obtained with 47s/470 and the −27 mV potential with 47/47s are not significantly different at the 95% confidence level (Table 1, s indicates the chamber to which sperm were added). In reciprocal experiments, the [Na⁺] in the two chambers was reversed, with the upper 90% of the egg in high [Na⁺] and the lower 10% in low [Na⁺]. Again, fertilization in low [Na⁺] resulted in a plateau potential (+3 mV) significantly more negative than that (+18 mV) obtained with fertilization in high [Na⁺] (Table 1). However, a more positive potential was observed with 470/47s (+3 mV) than with 47/47s (−27 mV). This could be due to leakage of Na⁺ from the upper into the lower chamber through the egg's thick (>1 μm) surface coat. (A slight suction from upper to lower chamber is applied to hold the egg in the hole, and the solution bathing the lower surface of the egg is not renewed by perfusion.) Alternatively, the patch of Na⁺ channels opened by sperm may be large enough to include some of the egg surface in the opposite chamber.

Table 2 Fertilization potential characteristics of eggs seated in the experimental apparatus compared with controls resting in the bottom of a Petri dish

Natural seawater	Average plateau potential (mV)	Fertilization potential resistance (MΩ)	Unfertilized egg resistance (MΩ)
Eggs in holes	+17±2.3 (5)	146±23 (3)	
Controls	+25±1.3 (3)	135±20 (3)	548±55 (3)
1/10th [Na⁺] seawater			
Eggs in holes	−26±2.0 (3)		
Controls[7]	−21±1.6 (10)		

Average plateau potential was calculated for the first 3 min as described in Fig. 2 legend for eggs in this study; in the study of Jaffe *et al.*[7], values were calculated for the first 5 min. Resistance measurements for the controls were obtained during the 2–3-min interval after the rise of the fertilization potentials, by passing pulses of inward current ranging from −0.2 to -3×10^{-10}A, and calculating the slope resistance of the resulting current–voltage plots, which were linear. Slope resistances for the unfertilized eggs were obtained in the same way except that the membrane potential was first set to a value (+15 to +24 mV) comparable with that during a fertilization potential, and the inward current pulses superimposed. These $I-V$ plots were also linear. Resistances for the eggs in holes were determined from the voltage deflection resulting from a single inward current pulse (-1.8×10^{-10}A) at 2 min after the rise of the fertilization potential. For experiments with eggs in holes, sperm were added to the lower chamber. The values are averages ±s.e.m. (standard deviation/$n^{\frac{1}{2}}$), with n in parentheses.

Controls indicate that the observed 'patch' is not an artefact of the experimental conditions. First, the fertilization potentials of eggs in the experimental apparatus appear normal. The maximum amplitudes and average plateau potentials of eggs seated in holes are similar to those of control eggs resting in a grooved plastic dish (Table 2). In addition, measurements of egg membrane resistance during fertilization potentials in natural seawater showed that sperm-induced increases in egg membrane conductance ($G=1/R$) are also similar in experimental and control eggs; in both situations, the conductance increased approximately fourfold over that in unfertilized eggs (Table 2, columns 2, 3), indicating that the opening of Na⁺ channels is not significantly restricted by the experimental chamber. Second, eggs seated in the nickel screen activate normally. Activation was scored in four of the eggs that were fertilized from below in normal seawater. While the eggs remained seated in the hole, all four underwent normal germinal vesicle breakdown, although the germinal vesicle was in the upper portion of the egg, and in all four, surface coat elevation occurred around the entire egg. Three of these eggs were removed from the hole and cultured further; all formed polar bodies and cleaved.

The finding that sperm open a patch of Na⁺ channels is consistent with our earlier suggestion (see above and ref. 7) that the fertilization potential may be analogous to the receptor potential plus action potential system found in many chemo- and mechanosensitive cells. The Na⁺ channels are not contributed by the sperm membrane, but must pre-exist in the egg because fertilization potentials can be elicited by artificial agents (trypsin[8]) in the absence of sperm[7]. However, we do not know whether the Na⁺ channels are opened by an interaction of sperm and egg membrane components before bilayer fusion (the neurotransmitter–receptor analogy) or whether fusion must occur to initiate a fertilization potential. Whether sperm–egg fusion occurs rapidly enough (within a few seconds of insemination) to initiate the fertilization potential is not known (see Discussion, ref. 7). It also remains to be determined whether the Na⁺ channels are opened by a direct interaction of sperm and

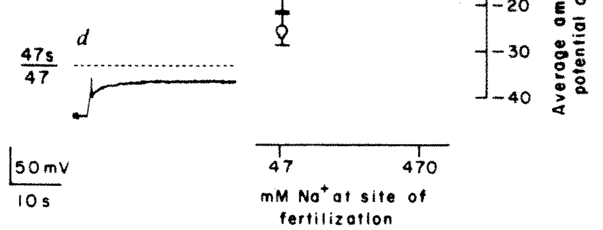

Fig. 2 Fertilization potentials obtained by varying the [Na⁺] at the site of fertilization independently of that over the rest of the egg surface. *a–d*, Original chart records showing initial portions of fertilization potentials obtained in the conditions indicated: $\frac{\text{mM Na}^+\text{ in upper chamber}}{\text{mM Na}^+\text{ in lower chamber}}$, s indicates chamber to which sperm were added. *e*, Average plateau potentials as a function of [Na⁺] at the site of fertilization. The values were obtained by averaging the potentials at 0.5, 1, 1.5, 2, 2.5 and 3 min after the initial rise of the fertilization potentials. *Urechis* egg fertilization potentials typically remain positive for about 7 min. The bars indicate the standard deviation of the mean (see Table 1 for the value of *n*). ●, Both chambers contain 470 mM Na⁺, sperm added from below; ○, the lower chamber contains 470 mM Na⁺ and the upper chamber 47 mM Na⁺; ○, both chambers contain 47 mM Na⁺, sperm added from below.

egg membrane components, or whether intermediate 'messengers' (for example, Ca^{2+}) are involved. Based on iontophoretic injection experiments, Cross[9] has proposed that a sperm-induced rise in free Ca^{2+} beneath the egg plasma membrane may initiate the fertilization potential in frog eggs. Another interesting question that remains to be answered is whether the patch of open Na^+ channels is confined to the site of sperm egg membrane contact, or whether it extends laterally.

In addition to contributing to our understanding of the gating mechanism for the fertilization potential, the results reported here raise the question of the possible significance of the 'patch' for later development. In *Urechis* eggs, the plane of the first cleavage generally passes through the point of sperm entry (within 10° of this point in 70% of the eggs[10,11]). The localized patch of open Na^+ channels may be involved in establishing this polarity[12].

This work was supported by NSF grants PCM76-84552 and PCM80-03759 to M.G-S. and by NIH grant 5 SO7RR07011-14 to the University of California, San Diego. I thank J. Raper, who was midwife to the idea for the experiment, K. Robinson for his gifts of a prototype chamber and nickel screen, and L. Holland, L. A. Jaffe and S. Hagiwara for helpful discussions.

Stringency without ppGpp accumulation

**Antonella Spadaro, Angelo Spena,
Vittorio Santonastaso & Pierluigi Donini**

International Institute of Genetics and Biophysics, Via Marconi 10,
80125 Naples, Italy

Wild-type *Escherichia coli* deprived of a required amino acid shows a stringent response involving various alterations in the cell's normal physiology, including the arrest of net synthesis of stable (ribosomal and transfer) RNA, lipids, phospholipids and peptidoglycans[1]. The stringent response is found in cells of the Rel^+ (stringent) but not Rel^- (relaxed) phenotype. The intracellular concentration of guanosine 5′-diphosphate-3′-diphosphate (ppGpp) and guanosine 5′-triphosphate-3′-diphosphate (pppGpp) increases dramatically in amino acid-deprived Rel^+ cells due to the enzymatic activity of the *relA* gene product[2], which also stimulates ppGpp synthesis *in vitro*[3]. The correlation between stringent response and increase in the intracellular concentration of ppGpp has been interpreted as evidence that this nucleotide has a causal role in stringency[1]. However, as recent findings show that the correlation does not always hold, ppGpp cannot be considered to act as a unique effector molecule and the idea of a causal role for ppGpp in stringent control has become questionable[4,5]. Here we describe experiments that cast further doubt on the proposed biological role of this nucleotide, as they show that stringent control can occur in the absence of ppGpp accumulation.

The genome and the physiology of *Salmonella typhimurium* are closely related to those of *E. coli*, and it can be safely assumed that the principal aspects of stringent control do not differ substantially in the two species. In fact, in *S. typhimurium* the net synthesis of stable RNA has been shown to be under stringent control and *relA* mutants similar to those found in *E. coli* have been isolated[6]. In addition, ribosomes prepared from *relA*$^+$ *S. typhimurium* produce ppGpp *in vitro*[7]. We were therefore not surprised to find that amino acid deprivation of cultures of *relA*$^+$ *S. typhimurium* auxotrophs normally causes the accumulation of ppGpp to the same high levels observed in *E. coli* in the same conditions. However, one notable exception is shown in Fig. 1. When strain TA1001 (*hisT*, *hisD* 2655) was deprived of its sole amino acid requirement, histidine, the level of ppGpp did not rise. Even with repeated experiments there was only an occasional modest (at most twofold) increase in the ppGpp level which did not last for >5 min. When such an increase was observed, it was also seen in control experiments where the culture was filtered and resuspended in medium containing histidine. We therefore attribute this nonreproducible, slight and transient increase in ppGpp to the filtration procedure itself and not to amino acid deprivation. In these experiments the level of pppGpp never rose to values detectable by our methods.

Strain TA1001 was obtained by co-transducing the markers *aroC*$^+$, *hisT*1514 and *purF*$^+$ into strain TA997 (*aroC*5, *purF*145, *hisD*2655) (R. Cortese, personal communication). Figure 1 shows that when strain TA997 was deprived of histidine, both ppGpp and pppGpp rose to high levels, as expected for a *relA*$^+$ strain. The basal level of ppGpp was similar in both strains.

Strain TA1001 has no amino acid requirements other than histidine. It can, however, be deprived of serine by treatment with the amino acid analogue, serine hydroxamate. After such

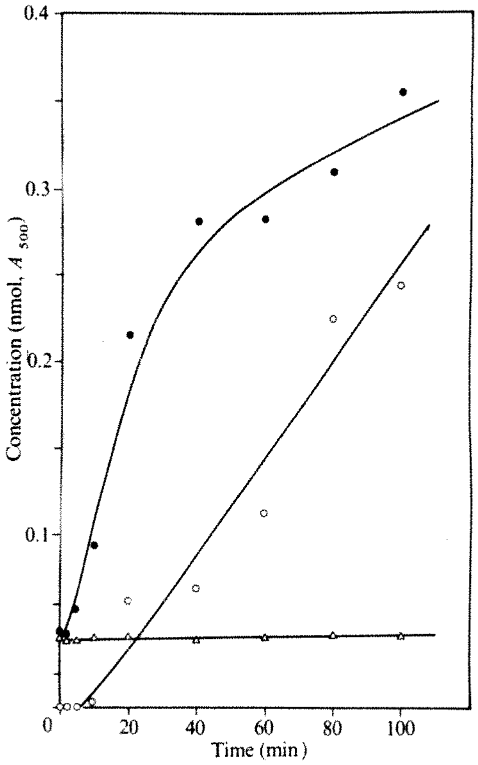

Fig. 1 Intracellular concentration of ppGpp and pppGpp in strains TA1001 and TA997 deprived of histidine. Bacteria were grown at 37 °C in low-phosphate medium[4] containing 10^{-3} M H_2HPO_4 to a concentration of 2×10^8 cells per ml, 100 μCi ml^{-1} $^{32}H_3PO_4$ were added and after one doubling the cells were filtered on Millipore filters and resuspended in medium lacking histidine, but containing 100 μ Ci ml^{-1} $^{32}H_3PO_4$. Samples were taken and analysed as described elsewhere[4]. △, ppGpp, strain TA1001; ●, ppGpp, strain TA997; ○, pppGpp, strain TA997.

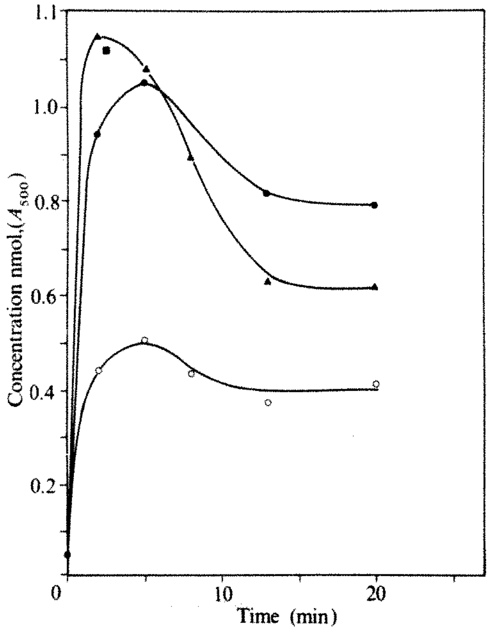

Fig. 2 Intracellular concentration of ppGpp in strain TA1001 and auxotrophic derivatives of TA1001 deprived of different amino acids. The same procedure was used as for Fig. 1. ●, Strain TA1001 deprived of serine by addition of 400 μg ml^{-1} serine hydroxamate; ○, strain PD11 deprived of threonine; ▲, strain PD12 deprived of arginine. Strains PD11 (*his*D2655, *his*T1514, *thr*A557::Tn*10*) and PD12 (*his*D2655, *his*T1514, *arg*B1837::Tn*10*) were obtained by transduction into TA1001.

treatment, very high levels of ppGpp and pppGpp are produced (see Fig. 2). Strain TA1001 can also be transduced by phage P22 carrying *S. typhimurium* DNA with the transposon Tn*10* inserted in and inactivating a gene belonging to an amino acid biosynthetic pathway. Figure 2 also shows that two such derivatives of TA1001, one requiring arginine and the other threonine, also produce ppGpp and pppGpp when deprived, respectively, of these two amino acids. Thus, strain TA1001 is not intrinsically incapable of raising its ppGpp and pppGpp levels during amino acid deprivation, but does not do so when deprived of histidine and perhaps other amino acids. Figures 1 and 2 show that in *S. typhimurium* the extent of the ppGpp response depends on the required amino acid, as in *E. coli*[4].

Figure 3*a*, *b* shows that deprivation of histidine causes the arrest of protein and stable RNA synthesis to the same extent in strains TA997 and TA1001, which suggests that strain TA1001 has inherited a functional *rel*A$^+$ gene from its TA997 parent. To prove that this arrest of stable RNA synthesis in strain TA1001 is dependent on *rel*A$^+$ function, the effect of histidine deprivation on stable RNA synthesis was determined in strain PD2, a *rel*A derivative of TA1001 constructed by transduction. Figure 3 shows that in this strain, stable RNA synthesis is under relaxed control, thus confirming that strain TA1001 harbours a *rel*A$^+$ gene and demonstrating that the arrest of stable RNA synthesis described in Fig. 3*b* is indeed attributable to stringent control. The level of ppGpp does not change when strain PD2 is deprived of histidine. Furthermore, no change in the ppGpp level is observed when serine deprivation is induced by serine hydroxamate addition—confirmation that the *rel*A allele is present in this strain.

Strains TA997 and TA1001 are isogeneic with the exception of the small segment of bacterial genome carrying the cotransducible markers *pur*F, *his*T and *aro*C. The fact that ppGpp metabolism is normal in TA997 strongly suggests that the defect present in TA1001 harbours one or more additional mutations close to *his*T. The *his*T gene product catalyses the pseudouridine modification in the anticodon region of the many tRNAs that contain pseudouridine in this region[8]. Mutations in the *his*T gene alter the regulation of several amino acid biosynthetic pathways[8], and histidine tRNA derived from a *his*T mutant is defective in translation[9]. Thus, it is possible that the alteration in ppGpp and pppGpp metabolism in strain TA1001 is another consequence of the subnormal pseudouridylation of histidine tRNA. The three amino acids which produce a normal response (Fig. 2) in TA1001 are cognate to tRNA species all or most of which have no pseudouridine in the anticodon region, and are therefore not affected by the *his*T mutation. Note that one of a different class of histidine regulatory mutants, *his*U, is altered in the control of the accumulation of stable RNA during carbon and energy source transitions[10].

We do not know whether the abnormal response of TA1001 to histidine deprivation is due to a block in the production of

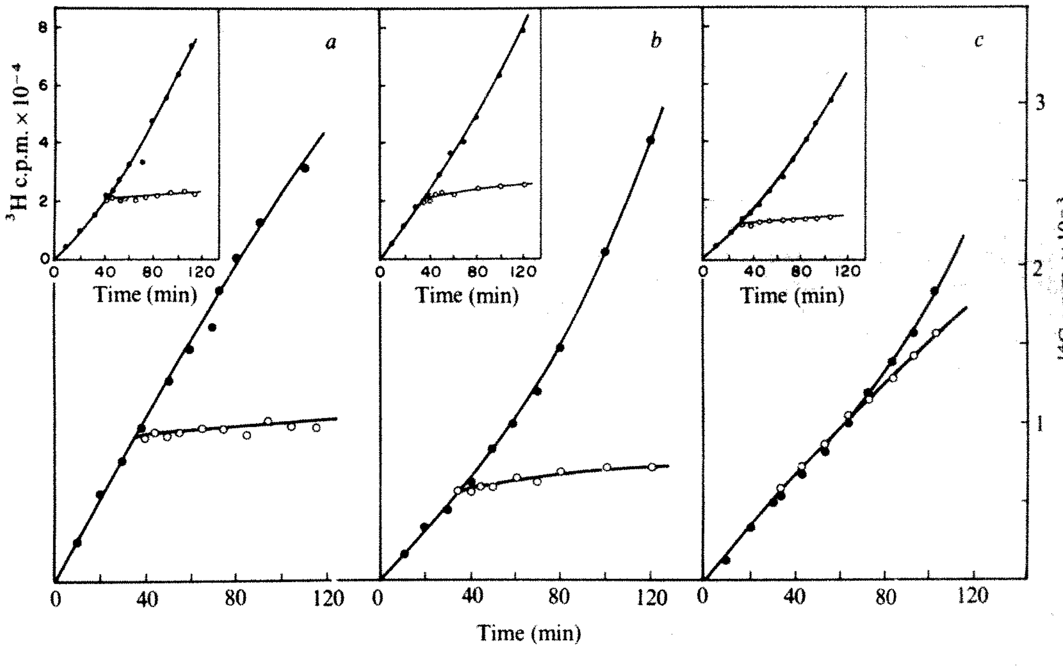

Fig. 3 RNA and protein synthesis in strains TA997, TA1001 and PD2 deprived of histidine. Bacteria were grown to a concentration of 4 × 10^8 cells per ml in low-phosphate medium, and ^{14}C-uridine (0.01 μ Ci ml^{-1}, 5 μg ml^{-1}) and ^{3}H-isoleucine (1 μ Ci ml^{-1}, 3.5 μg ml^{-1}) were added. Half the culture was filtered after 30 min and resuspended in medium lacking histidine but containing the labelled precursors at the same specific activities as before. Samples were taken up in 5% TCA, filtered on Millipore filters and counted in a Packard Tri-Carb scintillation counter. Large graphs show incorporation into RNA; insets show incorporation into protein. *a*, TA997; *b*, TA1001; *c*, PD2. ●, Not deprived; ○, deprived. PD2 (*his*D2655, *his*T1514, *rel*A1::Tn*10*) was constructed by transducing *rel*A1::Tn*10* into TA1001.

ppGpp or to an increase in its degradation. The main conclusion that can be drawn from the above observations is that an increase in the intracellular concentration of ppGpp is not a necessary condition for stringent control of the net synthesis of stable RNA. This leads to one of the two following conclusions: either ppGpp has no causal role in stringent control of RNA accumulation, or inhibition by ppGpp is not the only mechanism, but exists alongside and competes with at least one other mechanism also dependent on the *rel*A$^+$ gene. In case of failure of the ppGpp mechanism, the putative accessory mechanisms would become totally responsible for stringent control. With respect to the control of RNA accumulation, the latter hypothesis finds some support in several studies which have shown that a considerable fraction of the decrease in net synthesis of stable RNA can be attributed to degradation of the RNA[11,12]. Thus, it may be that in TA1001, stringent control of RNA synthesis is totally degradational.

The results obtained with strain TA1001 also make it rather unlikely that the effector molecule in stringent control could be a derivative of ppGpp, such as guanosine 5′-diphosphate-3′-monophosphate (ppGp), as has been suggested[5]. The role of the guanosine polyphosphates in bacterial physiology is now, more than ever, an open question which a thorough examination of the properties of strain TA1001 may elucidate.

We thank Drs Giovanna Ames, John Roth, Riccardo Cortese and Francesco Blasi for providing strains and helpful advice.

Nuclear sodium and potassium

Philip L. Paine, Terry W. Pearson, Louis J. M. Tluczek & Samuel B. Horowitz

Cellular Physiology Laboratory, Department of Biology, Michigan
Cancer Foundation, 110 East Warren Avenue, Detroit,
Michigan 48201, USA

Na$^+$ and K$^+$ influence gene expression[1–3], and it is important to know the concentrations and chemical activities of these cations in the cell nucleus and to understand their control. However, measurements are hampered by the small size of nuclei, and also because (1) the steep Na$^+$ and K$^+$ activity gradients across cell membranes can cause experimental manipulations to provoke rapid (~0.1 s half-time for a 10 μm cell) artefactual cation redistributions; (2) intracellular activities cannot be directly inferred from concentrations because Na$^+$, K$^+$ and water exist partly in bound form. We circumvent these difficulties by using a giant cell (amphibian oocyte), cryogenic methods to limit diffusion, and an artificial intracellular reference phase[4,5]. Century *et al.*[6] found K$^+$ more concentrated in the oocyte nucleus than in cytoplasm, and the reverse for Na$^+$. Our data for the *Desmognathus o. ochrophaeus* (salamander) oocyte are similar: the nucleus contains 30±3 μequiv Na$^+$ and 144±3 μequiv K$^+$ per ml H_2O; the cytoplasm contains 87±2 μequiv Na$^+$ and 87±2 μequiv K$^+$ per ml H_2O (means±s.e.m.). These data could imply that the nucleus actively transports Na$^+$ and K$^+$, but strong evidence suggests otherwise: the nuclear envelope, with pores of effective radius 45 Å (ref. 7), is too permeable to maintain small solute concentration gradients[8–10], and microelectrodes measure equal nuclear and cytoplasmic cation activities[11–13]. Here, we confirm and extend these findings, showing that nucleus/cytoplasm cation concentration differences are due to (1) partial exclusion of diffusive Na$^+$ and K$^+$ by cytoplasm and (2) differential Na$^+$ and K$^+$ binding by nucleus and cytoplasm.

Oocytes were microinjected at 34 °C with 50–100 nl of 14% gelatin sol, sometimes containing ^{3}H-sucrose. The gelatin, which displaces a volume of cytoplasm, was gelled by immersing the oocyte in iced Ringer's solution for 5 min. Subsequent incubation was at 5 °C. The gelled gelatin or reference phase (RP) excludes organelles and structural elements, and its water comes to diffusional equilibrium with intracellular solutes[4,5]. Oocytes were then frozen at −160 °C in dichlorodifluoromethane, and stored in liquid nitrogen. Nucleus, RP and cytoplasm were isolated at −45 °C by ultralow-temperature microdissection, weighed, dried and reweighed to determine water content, and extracted in water by boiling[6,14]. Cation concentrations were determined by atomic absorption spectroscopy and ^{3}H-sucrose by liquid scintillation counting.

Intracellular ^{3}H-sucrose does not distribute uniformly at equilibrium[5,15], nuclear and RP concentrations being equal, but about three times that of the cytoplasm (Fig. 1). Because sucrose distributes uniformly when gelatin is dialysed against saline[15], we deduce that the nucleus/cytoplasm asymmetry is not due to nuclear binding, but to sucrose's reduced solubility in, or exclusion from, cytoplasmic water.

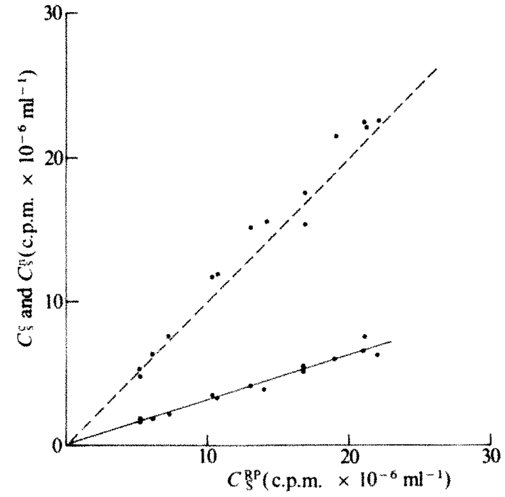

Fig. 1 Nucleus/RP (dashed line) and cytoplasm/RP (solid line) represent concentrations of ^{3}H-sucrose (C_s). Oocytes were manually dissected from ovaries in ice-cold Ringer's solution containing (mM) 104.5 NaCl, 2.5 KCl, 1.2 $MgSO_4$, 6.6 $NaHCO_3$, 1.2 Na_2HPO_4, 2.0 NaH_2PO_4 and 0.7 $CaCl_2$ (*p*H 7.2), and injected with gelatin containing ^{3}H-sucrose, incubated for 4–20 h, dissected by ultralow-temperature microdissection, and analysed as described in the text. C_s^c, C_s^n and C_s^{RP} are ^{3}H-sucrose concentrations (per ml H_2O) in cytoplasm, nucleus and RP, respectively. The least-squares line for cytoplasm/RP data is $C_s^c = 0.31C_s^{RP} + 0.01$ (×10^6 c.p.m. ml^{-1}). The dashed line is isomolar, $C_s^n = C_s^{RP}$; the least-squares line determined for the nucleus/RP data (not shown) is $C_s^n = 1.04C_s^{RP} + 0.15$ (×10^6 c.p.m. ml^{-1}).

0028-0836/81/210258—04$01.00

Figure 2 compares Na$^+$ and K$^+$ concentrations, C_{Na} and C_K, in RP, nucleus (n) and cytoplasm (c). C_{Na}^{RP} and C_K^{RP} are reciprocally related, their sum constant at ~151 μequiv ml^{-1} (Fig. 2*a*). There is a clustering of cells with $C_K^{RP}/(C_{Na}^{RP}+C_K^{RP})>0.7$ (Fig. 2, inset). We consider these cells 'normal' because their cytoplasmic and nuclear cation concentrations resemble those of uninjected cells[5]. Typical of eukaryotic cells, Na$^+$ and K$^+$ activities (measured by the RP) in normal oocytes are, respectively, less and greater than those of the Ringer's (Fig. 2 legend). $C_K^{RP}/(C_{Na}^{RP}+C_K^{RP})<0.7$ results from damage during microinjection and experimental manipulation, but these values allow isothermal analysis of mechanisms. Nuclear data resemble RP data, but most nuclear points fall above the RP line (Fig. 2*b*). (In normal oocytes $C_{Na}^n+C_K^n=171\pm4$ μequiv ml^{-1}.) Also, when $C_{Na}^n>100$ μequiv ml^{-1}, Na$^+$ increase is not stoichiometrically compensated by K$^+$ loss, as in the RP. C_K^c and C_{Na}^c are also reciprocally related, but C_K^c is always <105 μequiv ml^{-1} and $C_{Na}^c>70$ μequiv ml^{-1} (Fig. 2*c*). Obviously, cytoplasm, RP and nucleus handle cations differently.

Cytoplasmic and RP Na$^+$ are not isomolar (Fig. 3*a*, open circles). As gelatin/saline dialysis isotherms are isomolar[4], these data demonstrate the existence of two cytoplasmic Na$^+$ fractions, one shared with the RP and therefore diffusive, and the other restricted to the cytoplasm, or bound. The concentrations of diffusive and bound Na$^+$ (relative to total cytoplasmic water) are denoted by C_{Na}^{c1} and C_{Na}^{c2}, respectively, so that $C_{Na}^c=C_{Na}^{c1}+C_{Na}^{c2}$. Like sucrose, diffusive Na$^+$ has reduced solubility in cytoplasm, the cytoplasm/RP diffusive Na$^+$ distribution coefficient (q_{Na}) being 0.45 (the slope in Fig. 3*a*). The intercept, 75 μequiv ml^{-1}, is the saturation concentration of bound cytoplasmic Na$^+$, max-C_{Na}^{c2}.

The nucleus behaves similarly to the RP (Fig. 3*b*). At low Na$^+$ concentrations nuclear and RP data are superimposable, showing that nucleus and cytoplasm share only diffusive Na$^+$ and that the nucleus interacts with Na$^+$ as though it were an RP or ordinary saline solution (Fig. 3*b*). When $C_{Na}^n>100$ μequiv ml^{-1}, increase in RP (diffusive) Na$^+$ is accompanied by a larger increase in nuclear concentration. Perhaps the nucleus contains macromolecular charge groups which are unmasked when exposed to Na$^+>100$ μequiv ml^{-1} (refs 8, 16).

Cytoplasmic K$^+$, like Na$^+$, consists of two fractions, a diffusive fraction, of concentration C_K^{c1}, shared with the RP, and an unshared, nondiffusive fraction, of concentration C_K^{c2} (Fig. 4*a*). The cytoplasm/RP distribution coefficient for diffusive K$^+$, q_K, is 0.36 (slope, Fig. 4*a*). The intercept at 41 μequiv ml^{-1} is the saturation concentration of bound cytoplasmic K$^+$, max-C_K^{c2}. RP and nucleus concentrations are similar, differing only in a small (19 μequiv K$^+$ ml^{-1}) invariant nuclear excess (Fig. 4*b*). Apparently, nuclear water acts like ordinary or RP water as solvent for K$^+$, but in addition the nucleus contains 19 μequiv ml^{-1} of bound K$^+$.

A previous study of *Rana pipiens* oocytes incubated in ^{42}K$^+$-Ringer's[17] revealed two cytoplasmic K$^+$ fractions indistinguishable from those demonstrated here. Exchange of the fast isotopic fraction, present in both nucleus and cytoplasm, was limited by cell-membrane permeability. The second fraction, restricted to cytoplasm, exchanged too slowly to be measured. As short-term incubations suggested that ^{42}K$^+$ reflects the distribution of diffusive K$^+$, we tested this by incubating RP oocytes for 3–4 h in ^{42}K$^+$-Ringer's, and found that the cytoplasm/RP concentration ratio of ^{42}K$^+$, q_K^*, was 0.36, identical to q_K from the K$^+$ isotherm. Hence, ^{42}K$^+$ exchange with cytoplasmic bound K$^+$ is negligible, and diffusive K$^+$, like sucrose and Na$^+$, is more concentrated in the RP than in cytoplasm. Also, the ^{42}K$^+$ nucleus/RP ratio for normal oocytes was 1.14 ± 0.03, agreeing with Fig. 4*b* in demonstrating nondiffusive nuclear K$^+$. However, bound nuclear K$^+$ exchanges completely with ^{42}K$^+$ (nucleus/RP specific activities ratio $=1.00\pm0.03$) in <3 h, while cytoplasmic exchange is extremely slow.

At equilibrium, the RP—an ordinary water phase with no membrane—and the nucleus are essentially isomolar for diffusive Na$^+$, K$^+$ and sucrose, demonstrating that the nucleus

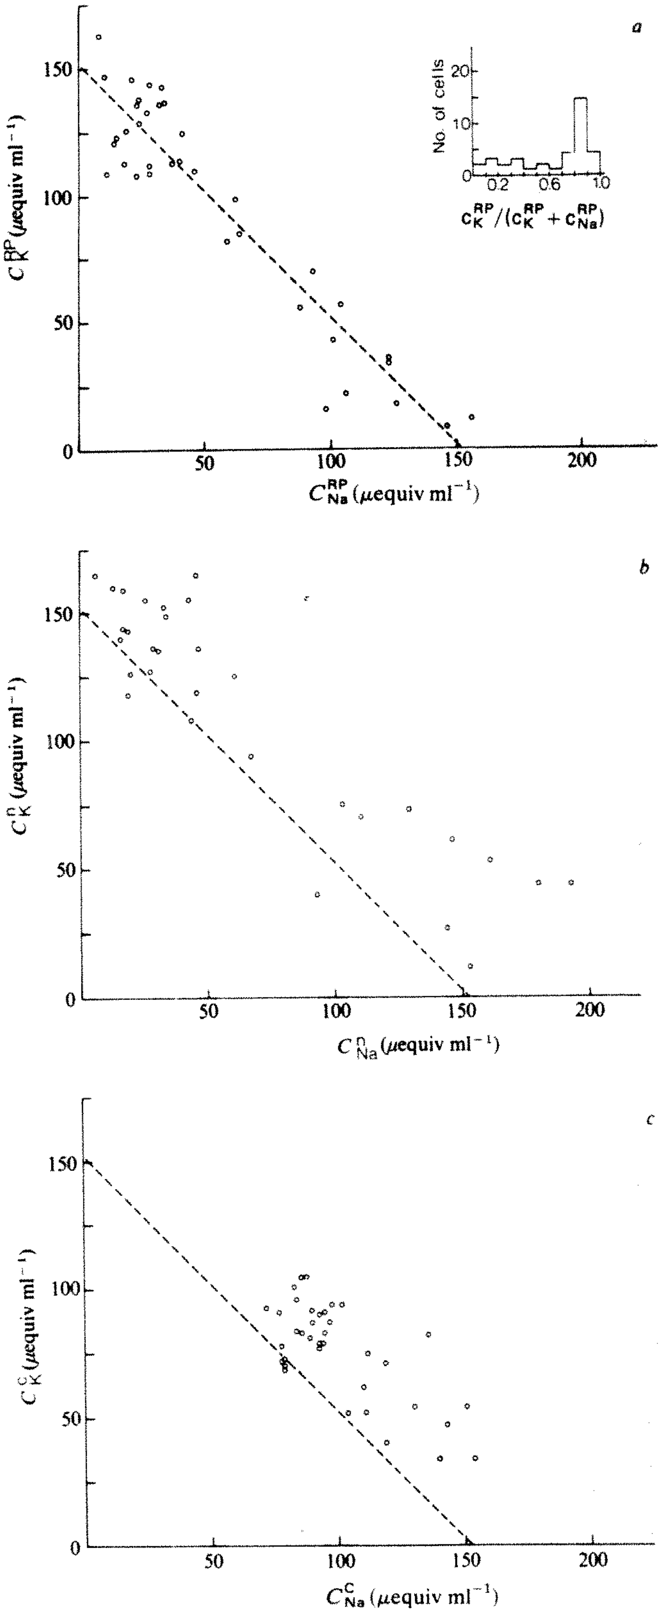

Fig. 2 Concentrations of K$^+$ and Na$^+$ (C_K and C_{Na}) in RP, nucleus and cytoplasm. *a*, RP data for cells fitted by the least-squares line, $C_K^{RP}=-C_{Na}^{RP}+151$ μequiv ml^{-1}. (Inset, frequency distribution of cells as a function of fractional RP K$^+$ content.) Equilibrium dialysis shows that RP gelatin has ordinary water solvent properties. Hence, intracellular solute activities (a_i) can be determined from $a_i=C_i^{RP}\gamma_i^0$, in which $\gamma_i^0\sim0.77$ is the activity coefficient in salines of comparable concentrations[5]. In normal oocytes ($C_K^{RP}/(C_{Na}^{RP}+C_K^{RP})>0.7$) cytoplasmic and nuclear activities are 99 μequiv K$^+$ ml^{-1} and 18 μequiv Na$^+$ ml^{-1}, compared with Ringer's 2 μequiv K$^+$ ml^{-1} and 89 μequiv Na$^+$ ml^{-1}. *b*, *c*, Data for nucleus and cytoplasm, respectively. Least-squares line from RP data (dashed) is shown for comparison.

does not actively transport cations or sucrose. Furthermore, the RP directly reflects effective cytoplasmic free concentrations and hence chemical activities[4]. Except for a small amount of binding, the same is true for the nucleus, which also behaves toward microsolutes like an ordinary aqueous phase embedded in a complex cytoplasm. Nuclear solute control can therefore only be understood when we know exactly how cytoplasm differs from simple aqueous solutions. Phenomenologically, two factors are identifiable: exclusion and binding. Cytoplasmic exclusion of solute i is indexed by q_i, the cytoplasm/nucleus or cytoplasm/RP equilibrium distribution coefficient of the diffusive form. If binding is negligible, as with sucrose and $^{42}K^+$ at short exchange times, the coefficient is equal to C^c_i/C^n_i or C^c_i/C^{RP}_i. When binding is significant, q_i is the slope of the cytoplasm/RP isotherm asymptote. Present determinations are q_s (sucrose) = 0.31 (Fig. 1), $q^*_K = 0.36$, $q_K = 0.36$ (Fig. 4*a*), and $q_{Na} = 0.45$ (Fig. 3*a*). Bound cytoplasmic concentrations are also determined from cytoplasm/RP isotherms; at saturation, C^{c2}_{Na} and C^{c2}_K are 75 and 41 µequiv ml^{-1}, respectively. (There is evidence that when C^{RP}_i is very low, the isotherms are nonlinear[5], implying that some bound cations are in mass action equilibrium with diffusive cations.) Changes in the affinities and/or capacities of cytoplasmic binding and changes in cytoplasmic solvent capacity must be considered as possible mechanisms for transient modulation of the baseline level of nuclear solute activities maintained by the cell membrane[18].

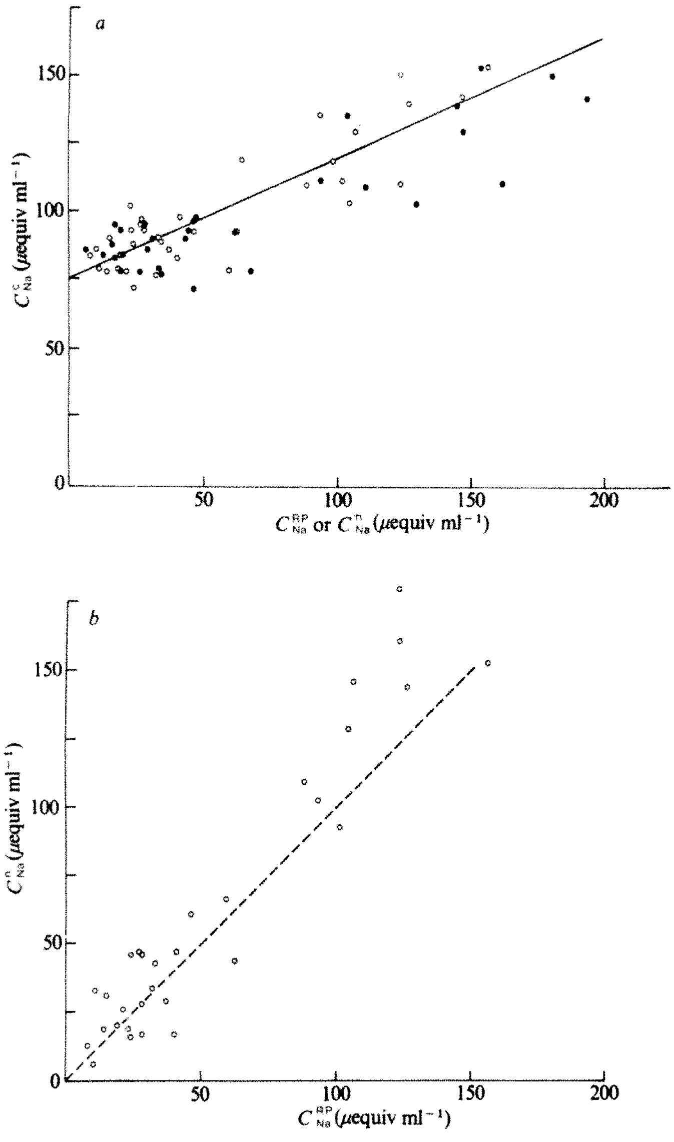

Fig. 3 Sodium isothermal relations. *a*, Cytoplasmic Na$^+$ concentration, C^c_{Na}, versus RP Na$^+$ concentration, C^{RP}_{Na} (open circles), and nuclear Na$^+$ concentration, C^n_{Na} (closed circles). The line is the least-squares line for the cytoplasm/RP data, $C^c_{Na} = 0.45\ C^{RP}_{Na} +$ 75 µequiv ml^{-1}. *b*, C^n_{Na} versus C^{RP}_{Na}. The dashed line is isomolar, the least-squares line (not shown) is $C^n_{Na} = C^{RP}_{Na} + 4$ µequiv ml^{-1}.

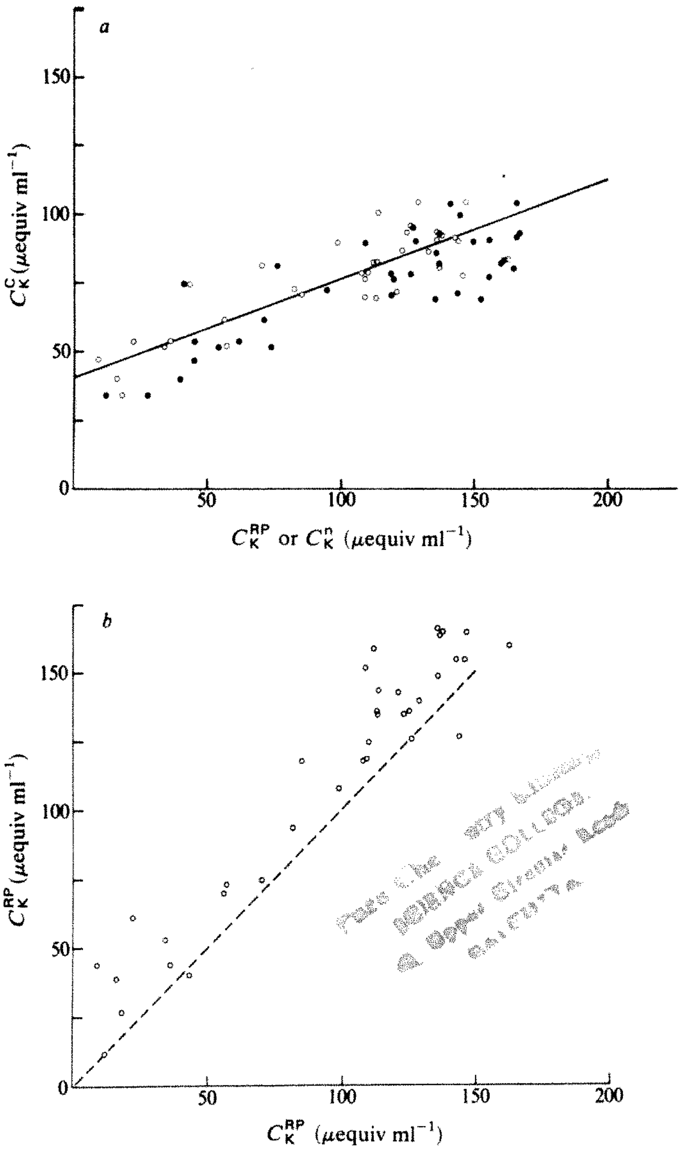

Fig. 4 Potassium isothermal relations. *a*, Cytoplasmic K$^+$ concentration, C^c_K, versus the RP K$^+$ concentration, C^{RP}_K (open circles); the least-squares line is $C^c_K = 0.36\,C^{RP}_K + 41$ µequiv ml^{-1}. C^c_K compared with nuclear K$^+$ concentration, C^n_K (closed circles); the least-squares line (not shown) is $C^c_K = 0.34\,C^n_K + 38$ µequiv ml^{-1}. *b*, C^n_K versus C^{RP}_K. The dashed line is isomolar; the least-squares line (not shown) fitting the data points is $C^n_K = C^{RP}_K + 19$ µequiv ml^{-1}.

Cytoplasmic exclusion and binding can be approached through two paradigms. One assumes that most cell water is saline-like, but is partially in organelles or vesicles, surrounded by membranes with restricted permeabilities and/or active transport properties[19]. The second hypothesizes decreased solubility due to structuring of cell water[5,18]. Vesicle and structured water mechanisms are not mutually exclusive. Oocyte cytoplasm contains abundant candidates (ground cytoplasm, endoplasmic reticulum, lysozomes, mitochondria, yolk platelets) to account for exclusion and binding within either or both paradigms.

Exclusion and binding seem to be widely distributed properties of cells. The low nucleus (or RP)/cytoplasm Na^+ ratio which indicates that the diffusive/total Na^+ ratio in oocyte cytoplasm is low, is paralleled by Na^+-specific electrode determinations of low activity/concentration ratios ('apparent' activity coefficients) not only in oocytes[20,21], but also in neurones[22], epithelia[12,23] and muscle[22,24–26]. Similarly, the high nucleus (or RP)/cytoplasm K^+ ratio of oocytes is paralleled by high activity/concentration ratios determined with K^+ electrodes in oocytes[21] and other cells[5,27]. Deviation of cytoplasmic activity coefficients from those of ordinary salines is direct evidence of solute binding or exclusion. However, because binding and exclusion have opposing influences on activity/concentration ratios, intracellular activity coefficients resembling those in salines do not prove that cytoplasm is a simple water phase[27]. Similarly, one cannot conclude that nucleus and cytoplasm are necessarily physicochemically similar if their Na^+ or K^+ concentration ratios are close to unity.

We thank Drs P. Furmanski, Y.-T. Lau and J. K. Reynhout for helpful criticism. This work was supported by NIH grants GM 19548, GM 26734 and HD 12512, and by an institutional grant from the United Foundation of Greater Detroit.

Structural homologies between prealbumin, gastrointestinal prohormones and other proteins

Hans Jörnvall[*], Anders Carlström[†], Tom Pettersson[†], Björn Jacobsson[‡], Magnus Persson[§] & Viktor Mutt[¶]

Departments of Chemistry I[*] and Biochemistry II[¶], Karolinska Institutet, S-104 01 Stockholm 60, Departments of Clinical Chemistry[†] and Pathology[‡], Karolinska Institutet, Danderyds Hospital, S-182 88 Danderyd, and Department of Numerical Analysis[§], Royal Institute of Technology, S-100 44 Stockholm 70, Sweden

Prealbumin has unusual properties for a plasma protein. It is an unglycosylated small protein composed of four identical 127-residue polypeptide chains, and although generally thought to be of hepatic origin[1], its site of synthesis has not been shown. However, its amino acid sequence[2–4], conformation and molecular interactions[5–8] are known. Prealbumin has a role in retinol[9] and thyroxine[10] transport, and in the metabolic regulation mediated by thyroid hormones[11,12]. A thymic hormone-like activity has also been reported[13]. Prealbumin-like immunoreactivity has been demonstrated in the α cells of the pancreas[14] and in endocrine cells of the small intestine (T.P., B.J., B. Sandstedt and A.C., unpublished results). A relationship with some activity of the gastrointestinal tract is therefore possible. Here we show sequence similarities between prealbumin and the glucagon–secretin type of gastrointestinal hormones, as well as between prealbumin and retinol-binding protein. Possible evolutionary links with prohormones and other functions in a new protein family are demonstrated—these may explain the unusual properties of prealbumin.

The primary structures of mammalian glucagon, secretin, vasoactive intestinal peptide (summarized in ref. 15), gastric inhibitory peptide[16] and the C-terminal part of the possible glucagon prohormone[17], glicentin[18], were compared with the structure of human plasma prealbumin. The hormones are related, forming a family[15]. All possible hormone alignments along prealbumin were tested using a computer; randomly generated sequences with identical total compositions were similarly compared. By this method, the probability of identities shared between the actual structures belonging to the distribution of background similarities could be calculated.

With the exception of gastric inhibitory peptide, all these hormones give only one alignment with prealbumin at a low probability level, and this alignment is the same for the four hormones, starting at position 90 in prealbumin (see Fig. 1). The probabilities, single fits and identical positions suggest that the hormones align uniquely with the C-terminal part of prealbumin. Gastric inhibitory peptide (Fig. 1) falls outside this pattern, but it is very different from other members of the hormone group[15].

To test the significance of the similarities further, comparisons were made with retinol-binding protein[19] (functionally related to prealbumin) and with horse liver alcohol dehydrogenase (no known relationship to any of these polypeptides). In the case of retinol-binding protein, all sequence identities to the hormones were insignificant (fivefold greater chance occurrence than with prealbumin, Fig. 1), and alignments were not unique but multiple (for three hormones) or starting at different positions (two hormones). For alcohol dehydrogenase, probability values were variable, and the alignments were again multiple (three hormones) or single but different (two hormones). Thus, the hormone comparisons with retinol-binding protein and alcohol dehydrogenase support the significance of the similarities in Fig. 1.

The C-terminal location of the similarity as well as the size of prealbumin agree with the idea of an homology between prealbumin and a glucagon prohormone. Glicentin[18] has the glucagon sequence in the C-terminal region and a size similar to that of the prealbumin subunit[18]. The same features apply to the somatostatin precursor[20].

These independent protein data support the patterns of sequence similarities in Fig. 1. The prealbumin homology to a prohormone of the glucagon family is unexpected and resembles other super-families[15] detected by sequence comparisons, for example, lysozyme–lactalbumin[21], haptoglobin–serine proteases[22] or ovalbumin–antiproteases[23]. It is even possible that prealbumin has retained a prohormone function in addition to its known interactions with retinol-binding protein and thyroxine. It exhibits thymic hormone-like activity[13] but independent of this or other activities, the structural homology with

Fig. 1 Results of sequence comparisons between human prealbumin (PRE), pig secretin (SECR), pig and bovine vasoactive intestinal peptide (VIP), part of pig glicentin (GLIC), pig and human glucagon (GLUC) and pig gastric inhibitory peptide (GIP). Amino acid residues are shown by one-letter codes, with similarities between prealbumin and any other peptide in bold type. Positional numbers refer to prealbumin. Probability values represent the chance occurrence of alignment of each peptide independent of the others, as determined by the program described. Unique alignment indicates that no other fit of the peptides along prealbumin gives the same number of identities.

gastrointestinal hormones explains the tissue localization of prealbumin.

The structures of prealbumin and retinol-binding protein[19] were compared using all possible combinations of 30-residue segments. Three pairs of similarities (well below the 0.01 random probability level) were distinguished from all other pairs (above the 0.01 level), and could also be correlated with each other (see Fig. 2). One pair suggests an internal repetition in retinol-binding protein, and the other two pairs relate each of these two repetitions to one segment of prealbumin. The positional alignments of the three pairs detected are similar for the mutually independent comparisons, only deviating a little in the case of the prealbumin segment.

The repetitive region in retinol-binding protein involves 11 identities in 43 residues (26% identity; $P=0.0005$ chance occurrence, Fig. 2), giving values as distinctive as those for the established protein connections between yeast and horse alcohol dehydrogenases. Furthermore, the two segments in retinol-binding protein detected from internal comparisons (positions 17–59 and 58–100, Fig. 2) agree almost exactly with those (positions 15–58 and 60–97) revealed by the comparison with prealbumin. The similarities to prealbumin involve a shift in positional numbers, but are still at the 0.005 probability level (Fig. 2). If not merely reflecting conformational similarities, such shifted numbers could indicate gaps, as shown for another peptide comparison (H.J., V.M. and M.P., unpublished results).

The relative positions of the segments are summarized in Fig. 3*a*. The region marked 'common' in prealbumin has similarities that are less significant than those in the other regions. However, all common regions are compatible with an ancestral connection between prealbumin and retinol-binding protein, and a partial duplication in the latter. If significant, these regions correspond to the most conserved and common function of both proteins. One such region may be the area involved in the binding interactions between prealbumin and retinol-binding protein.

An ancestral connection between the two proteins is also supported by the size of the subunits. A duplication of the common region (consisting of ~40 residues) in retinol-binding protein, and some shifts due to gaps, make the corresponding ancestors similar in length. The present size difference is 55 residues, with prealbumin the shorter subunit, as anticipated by such a scheme.

The position of the two segments in the conformation of the prealbumin subunit is shown in Fig. 3*b*. Both regions cover large areas and cannot be ascribed to single functions. However, in the tetramer, parts of the 'hormone' regions limit the thyroxine binding site (Fig. 3*b*). The association between a primary structure homologous to one hormone and a tertiary structure binding another would, if ancestrally significant, support the idea that receptors and their ligands have a common evolutionary origin[24–26]. In the divergence from the ancestor, prealbumin would then have become a member of the receptor line rather than of the prohormone line. An ancestral connection between nuclear receptors and prealbumin has also been inferred[7] from the presence of a DNA binding site in prealbumin. The start of the hormone region (positions 90–96) forms the bottom of the tetramer's cylindrical impression which constitutes the DNA binding site (Fig. 3*b*).

The central parts of the common region in the prealbumin chain are superficial in the tetramer (Fig. 3*b*), and could therefore be involved in the binding of the retinol-binding protein. However, it is not known whether this is true, and it will be of interest to see if the sequence similarities between the two proteins correspond to folding similarities. If so, this part of retinol-binding protein would contain six β strands, as each common region in prealbumin (Fig. 2) has three β strands[8]. Anyway, known conformational arrangements in prealbumin fit the scheme suggested from the observed homologies. Opposite arrangements of the hormone and common segments would not have provided similar support.

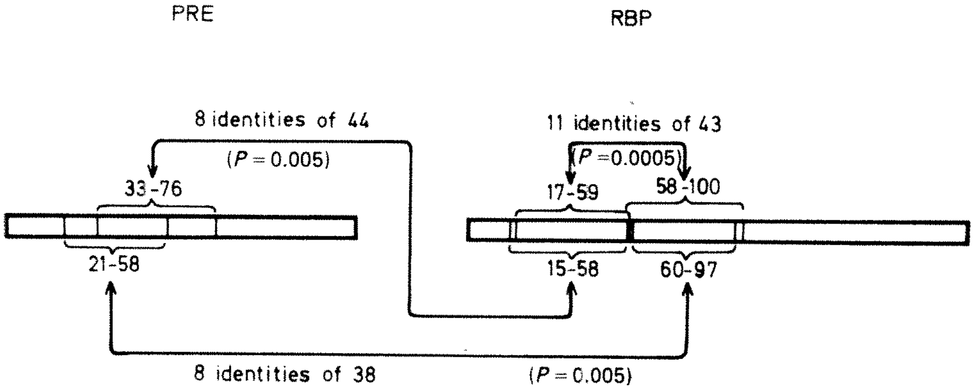

Fig. 2 Schematic representation of the three single pairs (double arrows) of sequence similarities detected in all possible combinations of segment comparisons between and within the subunits of prealbumin (PRE) and retinol-binding protein (RBP). Polypeptides (bars) and similarities (with end positions indicated) are drawn to scale. Probability values (P) represent the chance occurrence.

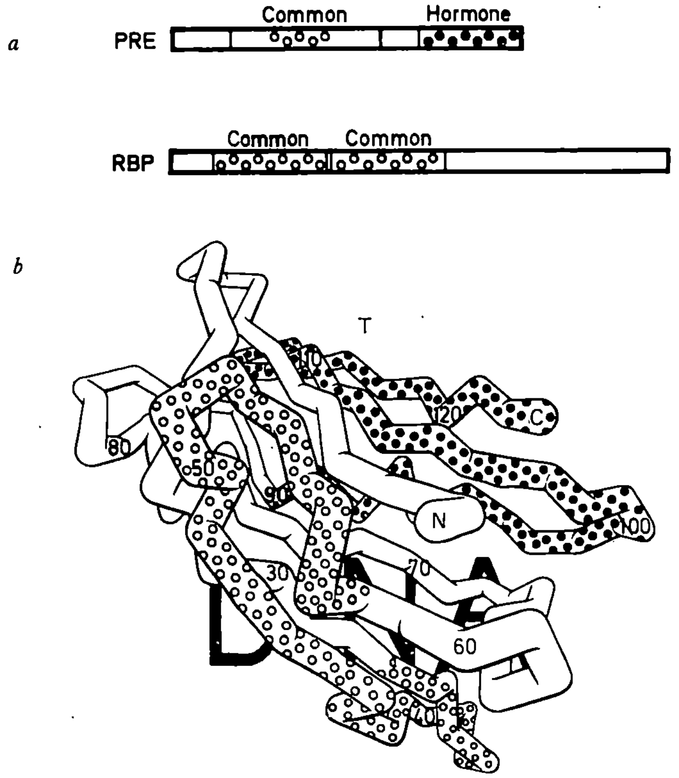

Fig. 3 *a*, Schematic representation of the regions discussed in prealbumin (PRE) and retinol-binding protein (RBP). 'Hormone' is the region homologous to the glucagon–secretin group of peptides; the other three homologous regions are indicated by 'Common'. *b*, Illustration of the regions discussed in a drawing of the conformation of the prealbumin subunit. Filled dots indicate the 'Hormone' region and empty dots the central part of the 'Common' region (positions in Fig. 2). In the native tetramer, a second subunit is above the one shown, with the binding site for thyroxine (indicated by T) in between, and another subunit is behind the one shown with the DNA binding site (indicated by DNA) in between. This drawing was made with the help of Fig. 3*b* of ref. 8.

The sequence similarities observed for prealbumin suggest evolutionary connections with gastrointestinal prohormones and retinol-binding protein. The data are compatible with the known properties of the prohormones, the conformation and binding interactions of prealbumin, and with previous ideas about the origins of receptors. They also suggest another superfamily of related proteins, indicating complex endocrine functions while helping to explain the unusual properties of prealbumin.

We thank Hans Nilsson for the drawing, Dr Steven Feinmark for linguistic help, and the Swedish MRC and Cancer Society for support (projects 13X-3532, 13X-1010 and 620, respectively). *Note added in proof*: Another comparison involving retinol-binding protein has just been reported[27] in which an internal although different duplication was observed (only second in present comparison). The discrepancies illustrate difficulties in comparisons and may question conclusions, but could also indicate further overlapping duplications.

Structure of the binuclear iron complex in metazidohaemerythrin from *Themiste dyscritum* at 2.2. Å resolution

Haemerythrin and myohaemerythrin are non-haem iron proteins utilized by several marine invertebrates in transporting and storing oxygen. Haemerythrin is oligomeric [usually octameric, but also trimeric[1,2], and tetrameric and dimeric (C. A. Appleby, personal communication)] whereas myohaemerythrin is a monomeric analogue of the haemerythrin subunit. Physicochemical investigations[3-5] of these molecules have shown that (1) each subunit binds two iron atoms by means of amino acid side chains, (2) one molecule of O_2 is bound to each binuclear iron centre, and (3) the iron atoms are in the +3 oxidation state in oxy and met forms of the proteins and +2 in deoxy. Models have been proposed for the complexes in haemerythrin and myohaemerythrin on the basis of crystallographic studies of the proteins. A μ-oxo bridged model (Fig. 1*a*) has been proposed from the results of a crystallographic analysis of metazidomyohaemerythrin from *Themiste zostericola*[6]. Based on a similar analysis of methydroxohaemerythrin from *Themiste dyscritum*, previously referred to as metaquohaemerythrin[7], we proposed a confacial bi-octahedron model with no atom identified as a μ-oxo bridge (Fig. 1*b*)[8]. Previously[9], we stated that "at least one of the models is incorrect". In fact, neither completely accounts for the electron density from the present 2.2 Å resolution difference map of the complex and surrounding electron density of metazidohaemerythrin from *T. dyscritum*.

Crystals of metazidohaemerythrin were obtained by direct reaction of oxyhaemerythrin with 0.01 M NaN_3 and subsequent crystallization by dialysis against low ionic strength buffer. The space group is P4, $a = b = 86.61(2)$ Å, $c = 80.90(2)$Å. The 2.2-Å data set, ~60,000 reflections, including Friedel pairs, was collected by the $\omega/2\theta$ step-scan method[10] from three metazidohaemerythrin crystals (27,131 reflections with $I > 2\sigma(I)$, 31,532 total reflections). Both empirical absorption[11] and deterioration corrections were applied.

A previously refined model of methydroxohaemerythrin[12] served as the initial model for this study. All atoms associated with the iron complex were removed, including those beyond the β-carbon atoms in the side chains of the amino acids shown as ligands in Fig. 1*b*. For the model lacking the complex, R $(= \Sigma||F_{o,azide}| - |F_c||/\Sigma|F_{o,azide}|)$ was 0.288. This model was sub-

0028-0836/81/210263—02$01.00

jected to two cycles of restrained least-squares refinement[13] to relieve the calculated phases of bias from the input structure, reducing R to 0.246. A difference electron density map calculated with coefficients $|F_{o,\text{azide}}|-|F_c|$ and calculated phases provided an essentially unbiased view of the electron density associated with the complexes in each of the four crystallographically independent subunits. Features of the difference density, such as resolution of the iron atoms, resolution across the ring of tyrosine 109 and resolution across the six-membered rings formed by the carboxylate groups, the iron atoms and the bridging atom, indicate the high quality of the map.

A straightforward interpretation of the difference density map for metazidohaemerythrin leads to the model shown in Fig. 2 having features in common with each of the earlier ones. The complex consists of two octahedrally coordinated iron atoms bridged by two carboxylate groups and an oxygen atom. The other ligands are three histidine side chains for one iron and two histidine side chains and the azide ion for the other. There is no density connecting tyrosine 109 (114 in myohaemerythrin) and the iron complex. The azide ion clearly binds to only one iron atom, rather than bridging the two as suggested by our earlier, low-resolution metazido study[14]. The observed mode of binding is as predicted by Gay and Solomon in interpreting their polarized, single-crystal spectroscopic results[15]. The coordination portrayed in Fig. 2 has not been observed in any other iron complex or metalloprotein, although it is similar to several small molecule iron carboxylate structures[16].

The model proposed for the complex in metazidomyohaemerythrin and shown in Fig. 1*a* has the bridging oxygen atom (a feature supported by spectroscopic and magnetic studies), but lacks the bridging carboxylate groups. On the other hand, the model proposed for the complex in methydroxohaemerythrin shown in Fig. 1*b* has bridging aspartic and glutamic acid side chains, the details of which were left unspecified. The model also has an additional bridging group which was assumed to be a water molecule or a hydroxide ion. Crystallographic refinement of the methydroxohaemerythrin form at 2.0 Å resolution had previously led to a more detailed view of the complex showing that the carboxylate groups bridge the two iron atoms with separate oxygen atoms on each iron. Tyrosine 109 was found to be too far from the nearest iron atom to be a ligand although it remained in the same eclipsed position observed earlier[8]. It is not coordinated either directly or indirectly through a water molecule, implying that one of the iron atoms is penta-coordinate. The resulting model is essentially the same as the present metazido model shown in Fig. 2, but lacks a ligand at the azide binding site.

A major question posed by the metazido structure and the bridging oxygen is whether the bridging atom in methydroxo is a single oxygen atom or some other species such as hydroxide. Another is whether there is any evidence for a hydroxide ion being bound at the azide binding site. In answer to the first question, we note that it is impossible in the electron density map at the present resolution to differentiate between a single oxygen atom, a hydroxide ion or a water molecule. The only ligand density not accounted for by amino acid side chains in methydroxohaemerythrin was at the bridging position. In accordance with the generally held opinion at the time that in met derivatives, small molecule ligands such as OH^-, N_3^-, SCN^- and H_2O were bound directly to the binuclear iron complex[17–19], we considered the bridging density to be the small ligand. However, as the bridging group in the metazido structure is present in the same location, it seems to be a common feature of the complex and is probably a μ-oxo atom as indicated by spectroscopic and magnetic evidence.

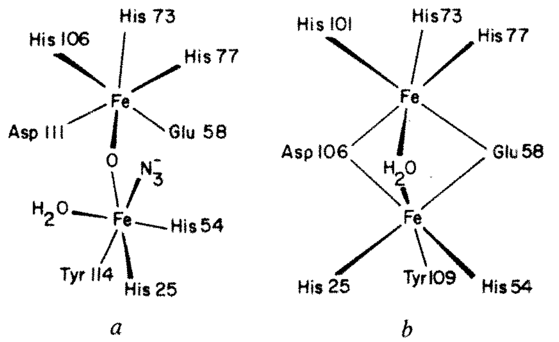

Fig. 1 Earlier models proposed for the binuclear iron complex in (*a*) metazidomyohaemerythrin from *T. zostericola*[6] and (*b*) methydroxohaemerythrin from *T. dyscritum*[8] (drawn from Fig. 4, ref. 9).

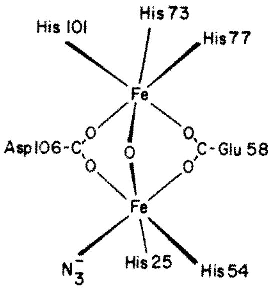

Fig. 2 The iron complex in metazidohaemerythrin from *T. dyscritum*.

To answer the second question and to make a more definitive comparison of the methydroxo and metazido forms of haemerythrin, we have restricted the resolution of the methydroxo data to 2.2 Å and treated it in the same way as the metazido data. We find small peaks in the difference density at the azide binding sites in all four subunits in the asymmetric unit although they are no larger than some noise peaks found in the open solvent regions of the crystal. The low occupancy of the sites indicates that only a fraction of the molecules have a sixth (as yet unidentified) ligand. Thus, the major form of the complex in the conditions pertaining in the crystals has an unexpected penta-coordinate iron atom.

The present model clarifies the contradictory crystallographic models previously proposed for the complexes in haemerythrin and myohaemerythrin. The difficulty arose in part because the met derivatives had been assumed to be similar, but significant structural differences clearly exist between at least two of them. Differences are observed in the spectra of the various states of these molecules, and high-resolution studies of other derivatives of met, oxy and deoxy forms of haemerythrin may allow significant correlations between the spectroscopic and structural results.

We thank W. A. Hendrickson, J. Smith, T. M. Loehr and I. M. Klotz for the exchange of data, information and viewpoints concerning the structure of these molecules. This work has been supported by NIH grant GM-10828.

MATTERS ARISING

Si, Al ordering in Linde A zeolite

ALTHOUGH we congratulate Bursill *et al.*[1] on their excellent high-resolution images of zeolite Linde A, we wish to question some of their interpretation—in particular the evidence on Si, Al ordering.

For a Linde A zeolite with Si/Al ratio of exactly 1, regular alternation of Si and Al leads inexorably to a super-cell with $a = 2.4$ nm and space group $Fm\bar{3}c$ from the pseudo-cell with $a = 1.2$ nm and space group $Pm\bar{3}m$ for fully disordered Si and Al. Although many structure determinations have been made with the pseudo-cell, the superstructure diffractions are easily observable on long-exposure X-ray photographs. Gramlich and Meier[2] obtained a satisfactory refinement of the superstructure of Zeolite A in which alternate tetrahedra had dimensions appropriate for occupancy at least mainly by Si and by Al. Recent refinements of dehydrated K-exchanged zeolite A (ref. 3) and dehydrated zeolite A (ref. 4) (the as-synthesized Na variety) were made to test the concept of zero-coordination, and satisfactory refinements were obtained of the superstructure. All these X-ray diffraction data, and much unpublished data, cannot be explained by the ordering model proposed by Engelhardt *et al.*[5] on the basis of high-resolution magic-angle spinning ^{29}Si NMR measurement. This model yields a unit cell with $a = 1.2$ nm and space group Pm3, and can be ruled our immediately by the X-ray diffraction data which require a cell with $a = 2.4$ nm. In the following, note that zeolite A has strong alternation of Si and Al on the tetrahedral nodes of the framework, and that only a small percentage of nodes are not surrounded by four atoms of the opposite type.

Pluth and Smith[3] found evidence from detailed electron microprobe analyses of A crystals made by Charnell's method that the Si/Al ratio is >1 (~ 1.03). This was supported by population estimates from published[3,4] and unpublished X-ray measurements which indicated less than 12 exchangeable monovalent cations in the pseudo-cell (for example 11.5 Na atoms in dehydrated zeolite A (ref. 4)). Such deviation from the ideal value must cause some Si atoms to be surrounded by less than four Al atoms. Silica-rich regions might have a different stability than regions with Si/Al equal to unity, and Bursill *et al.* might find it useful to measure the Si/Al ratio of their crystals.

Although Pluth and Smith refined their structures with the 2.4-nm cell and space group $Fm\bar{3}c$, they and earlier workers found several observed diffractions which violated the c glide plane. Further measurements are now in progress to discover the source of these violations. Note that these diffractions are weak and might result from the exchangeable cations and not from the Si and Al atoms. In the dehydrated K-exchanged- and Na-A varieties, some exchangeable cations have a low occupancy of sites on the walls of cavities, and local distortions of the framework can be expected. Such distortions must be considered as a potential cause of space group violations.

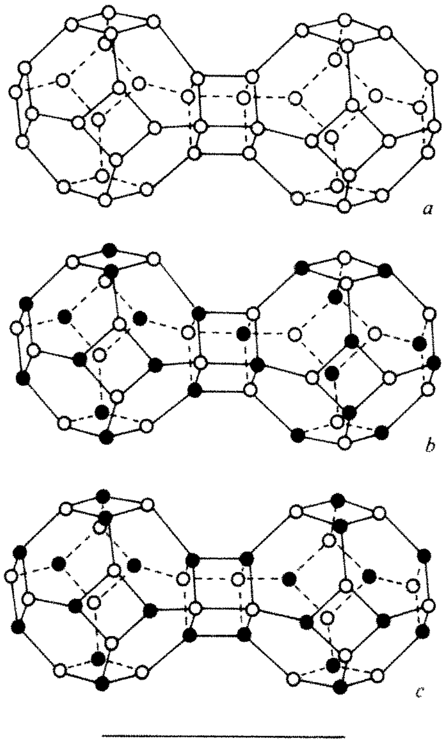

Fig. 1 Three ordering schemes for zeolite A. *a*, Complete disorder of tetrahedrally coordinated cations would give a 1.2-nm cell repeat with space group $Pm\bar{3}m$. *b*, Regular alternation of Si and Al requires 2.4 nm and $Fm\bar{3}c$. *c*, The isometric cell for the model of Engelhardt *et al.*[5] has a 1.2-nm repeat and Pm3; note the absence of a mirror plane in ⟨110⟩ directions.

The ^{29}Si NMR results were interpreted by Engelhardt *et al.*[5] in terms of an ordering scheme in which each Si is surrounded by three Al and one Si, and each Al by three Si and one Al (Fig. 1). This ordering scheme gives an isometric cell with $a = 1.2$ nm and space group Pm3, in contrast with 1.2 nm ($Pm\bar{3}m$) for complete disorder and 2.4 nm ($Fm\bar{3}c$) for regular alternation of Si and Al. The 3:1 ordering scheme is not compatible with the 2.4-nm cell repeat found consistently in long-exposure X-ray photographs, and can be ruled out except for small regions. Simple comparison of NMR data from one zeolite with another is obviously unreliable, and further interpretation is needed of the data in ref. 5. The observation by Bursill *et al.* of hkl (all odd) reflections with $h + l = 2n$ does not confirm "the recent criticism of space group Fm3c". This class of diffractions obeys the F centred lattice deduced by the X-ray crystallographers. Violations of the condition for the c glide plane (l must be even in hhl and $0kl$) are needed to cast doubt on $Fm\bar{3}c$ (for example, observation of 111; 3,3,17; 7,7,23; 13,13,11; 15,15,15 for dehydrated A ref. 4).

We suggest that Linde A zeolite has strong alternation of Si and Al atoms, and that only local regions deviate therefrom. The new refinement of dehydrated A zeolite[4] could be used to make a computer-simulated image for comparison with Fig. 1 of ref. 1: qualitatively a good match is likely, thereby indicating extraction of water by the pre-pumping procedure[1]. We look forward to more important observations of zeolites by electron microscopy, and suggest that existing X-ray diffraction data can provide a fundamental basis for interpretation.

We acknowledge grant NSF CHE 78-26579, and thank E. Flanigen of the Linde Division of Union Carbide Corporation for review.

BURSILL *ET AL.* REPLY—We thank Smith and Pluth for their comments but we are not convinced by their arguments. Recent experimental results reaffirm that Na-A zeolites possess an aluminosilicate ordering scheme, in which each Si ion is connected through oxygen bridges to three Al ions and one Si ion, and each Al ion to three Si and one Al; that is 3:1, rather than 4:0, ordering prevails.

Our reasons for disputing the accepted space group $Fm\bar{3}c$ rests partly on some of the X-ray results of Smith and Pluth[1,2] but chiefly on results from three other, independent techniques: electron diffraction[3–5], high-resolution magic-angle spinning ^{29}Si NMR[6–8], and neutron diffraction[9]. Weak superlattice reflections appear readily in electron diffraction patterns, requiring exposure times of ~ 1 s. enabling many hundreds of crystals

0028-0836/81/210265—02$01.00

to be studied. We established that our preparations are homogeneous, with no evidence for local variations in intensity of weak reflections, and that doubling is observed in all zones when it is expected for a 24.6-Å unit cell. In particular *hhl* (inadvertently printed as *hkl* in ref. 3) reflections satisfying $h + l = 2n$ were observed. As it is not easy to assign unambiguously space groups using electron diffraction alone[4] we have sought further information concerning space group assignment. Surprisingly, rather cogent evidence that the space group is not $Fm\bar{3}c$ comes from Smith and Pluth who meaasured 111; 3,3,17; 7,7,23; 13,13,11 and 15,15,15 intensities for dehydrated Na-A (ref. 1) and 999; 31,1,1, 21,21, 9 for dehydrated K-A (ref. 2). All of these reflections contradict the c-glide operation of $Fm\bar{3}c$. Smith and Pluth suggest that these reflections arise from displacements of cations and/or framework atoms, dismissing the NMR results[6–8], which strongly implicate 3:1 ordering, on the grounds "that simple comparison of NMR data from one zeolite sample with another is obviously unreliable" and that the model proposed[6,7] does not lead to a 24.6-Å cell. The NMR results are especially significant as careful calibrations of the chemical shifts, using known aluminosilicates as standards[8], show the technique is extremely sensitive to the Si–O–Si (Al) coordination. The technique yields results for bulk specimens and merits at least the respect accorded to a crystal structure determination on one or two carefully selected X-ray specimens. We have pointed out[4] that the model proposed by Engelhardt *et al.*[6,7], based on 3:1 ordering, yields an isometric cell with $a = 12.3$ Å and space group Pm3, and suggested that further NMR and diffraction studies, encompassing a range of Si/Al ratios, should prove instructive, as cell doubling may arise to accommodate excess Al (or Si)[4,5].

New data on Si, Al ordering in zeolites have emerged from neutron diffraction studies, carried out in collaboration with A. K. Cheetham. Three dehydrated samples, covering a range of Si/Al ratios, were studied. Our analysis shows that the neutron diffraction patterns cannot be indexed using space group $Fm\bar{3}c$. However, refinement of the structure is proceeding saisfactorily using a space group having rhombohedral symmetry. Analysis of the geometrically possible Si, Al distributions required by this space group, and which maintain 3:1 ordering, required by the NMR results, and which give 24.6-Å cells, as required by the X-ray and electron diffraction results, leads to a new description of the structure, details of which are to be given elsewhere[9].

We believe, therefore, that the 4:0 ordering scheme advocated by Smith and Pluth for Linde A must be viewed with reservation, at least for the bulk of Na-A preparations. Application of the above-mentioned range of techniques to other zeolites, where novel ordering schemes may be uncovered, is indicated.

Modern adaptations in orang-utans?

SMITH AND PILBEAM'S[1] letter, proposing that orang-utan sex differences—body size and certain features of dental and craniofacial morphology—cannot be explained by the species' modern adaptations and thus are 'remnants' of a more terrestrial Pliocene pattern, states that sexual selection among orang-utans is not clearly indicated by field observations, citing Horr[2] to the effect that "direct evidence for male competition in the form of dominance or aggressive encounters is limited".

The Tanjung Puting study[3], now in its ninth year, indicates that all adult male-male encounters involve either aggression or avoidance as do most contacts between sub-adult and adult males. Aggression is the invariable response when two adult males encounter one another in the presence of an oestrous female. The large size of orang-utan males seems to be the result of sexual selection as there is intense male–male competition for oestrous females and female selection of males during consortships[3,4]. In addition, several workers have found orang-utan males and females using differential proportions of resources[3–5] and at least one[3] has argued for an ecological separation of the sexes which may help explain sex differences as well.

Several features of orang-utan dental and craniofacial morphology are at variance with those characteristic of other arboreal frugivores—this can be explained by the fact that orang-utans spend an average of 40% of their feeding time on bark, young leaves, insects and other foods[3]. During some months orang-utans spend less than 20% of their foraging time consuming fruit. One instance of meat-eating among a wild orang-utan population has just been reported (Sugardjito, personal communication). Furthermore, some of the fruits (for example *Mezzettia leptopoda*) eaten by orang-utans are extremely hard. Chimpanzees use tools to open very hard fruits[6], but orang-utans spend hours opening hard nuts with their molars, which may account for their exceptionally thick molar enamel.

Finally, note that orang-utans can be quite terrestrial, bringing them closer to chimpanzees in this regard than is usually realized[3]. At Tanjung Puting adult males averaged 66 min per day on the ground with one male spending up to 6 h per day on the forest floor. A clear understanding of modern orang-utan adaptation suffices to explain most morphological features cited by Smith and Pilbeam as indicative of a more terrestrial Pliocene pattern. In regards to the fossil evidence for terrestrial patterns, we need post-cranial remains of ancestral orang-utans before we can discuss such patterns.

SMITH AND PILBEAM REPLY—The data reported by Galdikas are interesting, but the implications for our argument are unclear. What is directly known of ancestral orang-utans (their teeth and something of their distribution) is suggestive of a more terrestrial niche than that usually described for the extant species. Whether or not features of the extant animal support this hypothesis is secondary because one would expect the modern species to be more or less adapted to what it does. Also, whether or not the behaviours observed by Galdikas are sufficient to explain the morphological features in question is entirely speculative.

Biology and social science: wedding or rape?

Edmund Leach

Genes, Mind, and Culture: The Coevolutionary Process. By Charles J. Lumsden and Edward O. Wilson. Pp.512. ISBN 0-674-34475-8. (Harvard University Press: 1981.) $20. The book will be published in the UK in July, price £12.

THIS book comes so close to being a parody of the genre to which it belongs that I have had difficulty in believing that it is not intended as an academic hoax. Edward Wilson has made important contributions to the study of the social behaviour of insects and has achieved a wider notoriety as popularizer of the concept of sociobiology. He is also the author of a notably undistinguished book entitled *On Human Nature* (Harvard University Press, 1978); Lumsden is "a physicist who has extended his research into theoretical biology". The authors jointly claim an "abiding respect for social theory, the neurosciences and psychology". I cannot comment on their knowledge of the neurosciences and psychology but, on the evidence here presented, they appear to have no understanding of social theory whatsoever.

The basic proposition of the book stems from a belief that "the advance of men over chimpanzees and other higher primates was attained during an exceptionally rapid burst of evolution . . . over a period of approximately three million years". This alleged rapidity of a postulated unilinear evolutionary progress is held to be causally associated with a special kind of feedback reinforcement between the genetic constitution of human beings and their culture (here renamed "euculture"). This latter theme is expounded with the aid of a massive battery of diagrams, graphs and sophisticated-looking algebraic equations.

From my own doubtless prejudiced but none the less professional point of view, the whole of this elaborate apparatus is devoid of meaning because it assumes that human culture can be broken down into clusters of traits (which the authors call "culturgens") which can then be counted and subjected to statistical analysis.

The notion of culturgens is defined at some length and is summarized as "equivalent to the artifact type employed in archaeology (by D. L. Clarke)". From then on the whole argument presupposes that culturgens are readily identifiable entities. With very few exceptions, contemporary social and cultural anthropologists are unanimous in holding that human culture cannot be broken down into units of this or any other kind. The late D. L. Clarke, who was once my pupil, would certainly have rejected the idea.

However, empirical evidence plays only a secondary role in the authors' presentation. It is only drawn upon to illustrate points which they already judge to be self-evident. A typical example of the way this is done comes on p.6:

> From the time of the beginnings of a materials-based culture in the ancestral *Australopithecus* to the Upper Palaeolithic era of modern *Homo sapiens* the brain tripled in size. The cranial capacity of *Australopithecus* was 400–500 cc., comparable to that of the chimpanzee and gorilla. Two million years later *Homo erectus* had attained a capacity of 1000cc. Another million years saw an increase to 1400–1700 cc. in Neanderthal man and 900–2000 cc. in modern *Homo sapiens.*

Yet the authors must certainly know: (i) that is is far from clear that any of the Australopithecine species so far identified was directly ancestral to *Homo;* (ii) that *Australopithecus,* though man-like in shape, was very small, so it is not surprising that it had a small head; (iii) that the evidence available concerning the early hominids and the early varieties of *Homo* is statistically miniscule (in particular, as the authors' figures indicate, it is quite possible that all the *Homo* skulls fall within the range found in modern man); (iv) that since, in modern man, there is no correlation at all between cranial capacity and manifested intellectual capacity the size of our heads has no bearing whatever on the theme of the book which is "evolutionary advance" (whatever that means).

The "parody of science" aspect of the presentation can be illustrated from Chapter II at the end of which we are told that:

> Epigenesis is the total process of interaction between genes and environment during the course of development with the genes being expressed through epigenetic rules.

This explains the otherwise baffling opening sentences which read:

> The key element in the theory of gene–culture coevolution is the role of the epigenetic rules in culturgen choice. These rules and the bias curves they generate can serve as the molecular units in postulational-deductive models of the social sciences.

If we dig through the jargon it turns out that all this really means is that man's genetic endowments make it likely that some aspects of culture will be more elaborately developed than others. Thus visual and auditory discriminations, as manifested in speech and music and lexicon, are always more precise than those which depend upon taste and smell.

These platitudes about sensory perception are then extended into the field of custom and the concept of culturgens comes into its own. Once again the crass idiocy of the whole proceedings can only be illustrated by quotation:

> Female puberty initiation rites originate most frequently in societies where a young girl continues to reside at least half the time in her mother's household (in other words where uxorilocal or bilocal residence rules are in force), as well as in societies that depend heavily on the work of girls and young women to make a major contribution to sustenance activities.
>
> Recognising that some culturgens are more derivative and communicative in function than others, it is possible to delineate what appear to be chains of causation connecting the principal habitat, economic strategy, and both primary and derivative cultural choices. A very reduced example is the following:

Habitat and economy	Principal culturgens	Derivative culturgens
Desert herders	→ Polygyny, patrilineality, patrilocality	→ Absence of formal female initiation ceremony

Just what this could have to do with genetics is hard to imagine, unless of course the authors suppose that uxorilocal and patrilocal populations are racially distinct! But, for the record, it deserves note that the first half of the first paragraph is gibberish while the second half is such a let out that it would cover almost anything. "Female puberty initiation rites" is a broad category but the most drastic of the better known forms are those which involve clitoridectomy. These practices were traditionally confined to regions of East Africa where nomadic pastoralists with a more or less patrilineal/patrilocal/polygynous form of social organization are particularly prominent. It would be difficult to imagine a worse exemplification of the Lumsden–Wilson "chains of causation".

All the other examples of "gene–culture translation" which the authors mention (and they mention very few) are similarly defective. For example they claim that there is:

> a nearly universal avoidance of marriage and full sexual relations between full brothers and sisters. The epigenetic rule appears well

established: a deep sexual inhibition develops between those who live in close domestic contact during the first six years of life.

But no such rule has been "well established". On the contrary there is good evidence that in modern Western society sibling incest is quite common and there is no good reason to suppose that it is rare elsewhere. Moreover, in direct contradiction to what is asserted by Lumsden and Wilson, there is unambiguous evidence that monogamous marriage was widely practised in ordinary peasant families in Egypt during the first three centuries of our era and very probably for millennia before that. It does not require "epigenetic rules" to explain why marriages of this sort are usually forbidden; the proscription follows directly from the social theory for which Lumsden and Wilson have such abiding respect but so little understanding.

The human species is not genetically uniform but the variations seem to be minor. No correlation has yet been established between known genetic variations and morphological variations. Equally there is no clear correlation between morphological variations (the so-called "racial types"), cultural variations and/or modes of subsistence. But equally there are no cultural universals except at the level of such generalizations as "all human beings have speech", "all human societies distinguish between domestic space and non-domestic space".

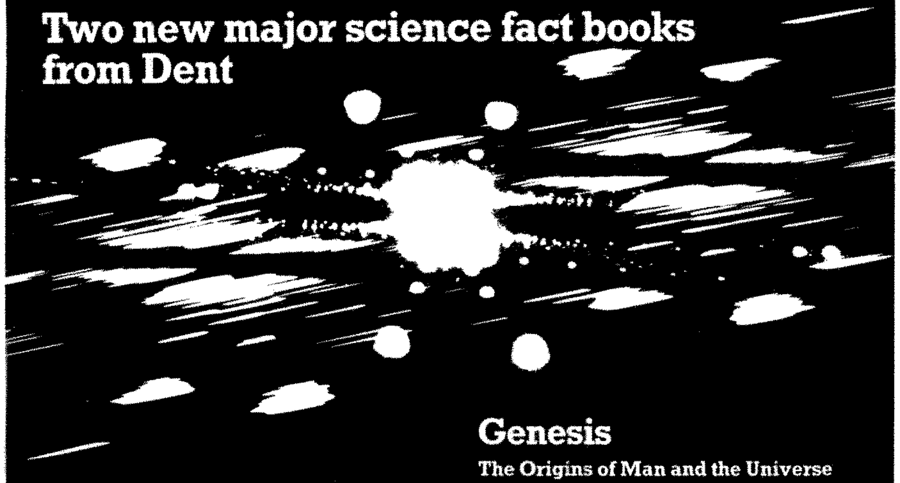
If epigenetic rules have had consequences for human evolution, it is difficult to see what sort of rules they might have been. On this central feature of the authors' argument the phoney mathematical apparatus which characterizes this text offers no illumination.

The book ends by setting a programme for social science:

> The decomposition of social behaviour into objective functional units, the discovery of new and sometimes surprising epigenetic rules, the measure of human genetic diversity, the tracing of the microevolution of the features of behavioral epigenesis, the paleobiological reconstruction of the origins of culture, the retrodiction [*sic*] of ethnography and connection of the results to new and more powerful covering laws in economics and sociology, perhaps even a sighting down the world-tube of possible future histories–these are activities that will come increasingly to occupy the social sciences as the links between biology and the study of culture are more powerfully forged.

I will readily agree that the findings of biology and of social science need to be compatible if either are to rate as science. But what is called for is mutual respect on both sides. The jargon loaded take-over bid proposed by Lumsden and Wilson is just bunk. We need a marriage — not a rape. ☐

Edmund Leach is a Fellow of King's College, Cambridge.



Two new major science fact books from Dent

Genesis
The Origins of Man and the Universe
JOHN GRIBBIN
With the same fluency of exposition as he showed in his much-praised *Timewarps*, John Gribbin now brilliantly describes how the earth has evolved through space and time, concluding with a chapter about the destination of mankind in the light of our new-found knowledge.
'John Gribbin's best book. Very good indeed.' *Professor Martin Rees, Director of the Institute of Astronomy, University of Cambridge*
Illustrated with 8 pages of photographs and 15 diagrams £7.95

The Edge of Infinity
Beyond black holes to the end of the universe
PAUL DAVIES
In his latest book Paul Davies, author of the highly acclaimed *Other Worlds*, takes us beyond black holes to naked singularities and the destruction of spacetime. Naked singularities, unclothed by black holes, not subject to any known laws, represent the threshold to a strange new physical world.
Illustrated with 52 line drawings £7.95

Marine mineralogy

Roger G. Burns

Underwater Minerals. By D. S. Cronan. Pp.362. ISBN 0-12-197480-4. (Academic: 1980.) £24.80, $57.50.

THE publication of J. L. Mero's *The Mineral Resources of the Sea* by Elsevier 16 years ago drew attention to the vast mineral deposits on the seafloor. Subsequent events — notably expanded oceanographic research, improved mineral beneficiation and extraction processes, real and threatened embargoes of industrial minerals and fuels, expansion of coastal state jurisdiction to the 200 mile limit, and legal ramifications of the United Nations Law of the Sea Conferences towards deep-sea mining of manganese nodules — have heightened the public's awareness of the potential of submarine mineral resources.

The appearance of Dr Cronan's book, therefore, is particularly significant at this time of rapidly accumulating information from modern oceanographic and marine geochemical research. In one concise volume, Cronan surveys several types of underwater mineral deposits, relates their origins to current global plate tectonic models, describes submarine exploration methods and explores some of the consequences of mining marine minerals. He calls upon his own experiences and observations from years of oceanographic cruises and laboratory research. The text focuses on various types of mineral deposits mainly located beneath the oceans; the extraction of minerals from seawater by modern processes or from ancient evaporite deposits is not discussed.

Chapters in Cronan's book are devoted to placers and aggregates, including deposits of gold, platinum, diamond, cassiterite (tin oxide), ilmenite and other heavy minerals mined near continental margins; phosphorites on continental shelves; miscellaneous authigenic minerals such as zeolites and barite; manganese nodules and encrustations from deep sea floors, marginal seas and lakes; metalliferous sediments related to volcanic activity along spreading centres, mid-ocean ridge crests and fracture zones, island arcs and submarine volcanoes; and sub-surface deposits such as ore and coal seams adjacent to continents, and sulphide mineralization in modern or uplifted (ophiolite) ocean floor basalts. The concluding three chapters relate marine mineral deposits to recent theories of plate

To help scientists cope with the complex problem of information retrieval, *The Use of Scientific Information Services* by R. Davidge and E.R. Wooding describes the use of information services in libraries, and contains a listing of reference sources. The report is available from The Library, Royal Holloway College, Egham Hill, Egham, Surrey TW20 0EX, UK, price £2.

tectonics and ocean evolution, describe methods for exploring underwater mineral deposits, and review some of the factors leading to the mining, and consequences resulting from exploitation, of seafloor minerals.

On the whole, the author does an excellent job in surveying such a broad subject. He references, perhaps uncritically, a wide spectrum of published papers including many of his own noteworthy contributions, so that a beginner is well informed about each topic while a researcher is guided to significant, albeit familiar, publications. Obviously, in one 362-page book, there is inevitable lack of depth of coverage in some topics. However, recent readily available specialist texts and monographs complement Cronan's book by providing detailed coverage of marine manganese nodule deposits and other specific marine minerals. The author has achieved his objective to write an up-to-date textbook of interest to undergraduate and postgraduate students, civil servants concerned with marine affairs and people generally interested in the marine environment. □

Roger G. Burns is Professor of Mineralogy and Geochemistry in the Department of Earth and Planetary Sciences at the Massachusetts Institute of Technology.

Stylish distillation for petrologists

M. P. Atherton

Metamorphic Petrology: Mineralogical, Field and Tectonic Aspects. 2nd Edition. By Francis J. Turner. Pp.524. ISBN 0-07-065501-4. (McGraw-Hill: 1981.) £25.95, $ 40.05.

THE second edition of Francis Turner's book is a considerable modification and updating of a volume, first published in 1968, which has been a milestone on the path towards our understanding of metamorphic rocks. It has increased in size from 403 to 524 pages, and although many of the original diagrams have been kept, many new ones have been added. Nevertheless, even with these additions the stylish character of the book has been maintained. There are eleven chapters as opposed to eight in the first edition, and most of this change has involved a new division and expansion of the subject, rather than the addition of entirely new material. The references are now placed at the end of the book rather than at the end of each chapter, and lie next to an extensive author index. It is interesting to note that even though many new authors are cited, Eskola, Fyfe, Verhoogen, Goldschmidt and Tilley still dominate the references.

In spite of the fact that much fresh material and many new ideas have been introduced, the main thread of the original book is maintained, and is "still by way of Eskola's facies concept" which allows the mineralogical and field material to be most readily "perceived, marshalled and analysed". The new edition also follows the approach in two earlier books (*Metamorphic Reactions and Metamorphic Facies* by W.S. Fyfe, F.J. Turner and J. Verhoogen *Geol. Soc. Am. Mem.* 73, 1958; *Igneous and Metamorphic Petrology* by F.J. Turner and J. Verhoogen, McGraw-Hill, 1960) both classics of their time, in that they were the first to present an integrated experimental and thermodynamic approach in the field of petrology. Thus it contains ACF, AKF, AFM diagrams indicating the chemographic relations of mineral assemblages defining the facies, PT diagrams, some simple thermodynamic theory and applications, and many maps of metamorphic areas showing the general geology and metamorphic zonal patterns.

In the account of these elements of metamorphism the book is excellent, and insofar as the aim of all metamorphic geologists as to be able to accurately plot the PT path of metamorphic rocks, the discussion on experimental data, Shreinemaker's diagrams and the use of thermodynamics is sensible and rightly critical — as is to be expected from such an experienced researcher and teacher whose working life has spanned the old and the new in metamorphic petrology. I particularly liked the addition of recent ideas on pore solutions, ionic reactions, Shreinemaker's analysis, geobarometry and geothermometry, burial metamorphism and new mineral equilibria.

However, if the aim of the metamorphic geologist is to plot the path of his rocks in PT space, I think it is also necessary to consider the textures in the rocks, to integrate them with the deformation history and with the sequence of reactions involving a fluid phase which occurred during metamorphism. This new edition includes little on these important aspects although, in fairness, much of the progress made in those areas, particularly in integrating them, was made after the first edition. Their incorporation into the present book would have involved a completely fresh approach, indeed a much longer book.

Despite these comments this new edition will, I am sure, continue to be influential and be much referred to. It should be read by every thinking student of metamorphism because it puts the subject into proper historical context and is the distillation of the lifetime views of a sharp-eyed, thoughtful and influential metamorphic petrologist. □

M. P. Atherton is Reader in Geology at the University of Liverpool.

Records of the past

John Currey

Skeletal Growth of Aquatic Organisms: Biological Records of Environmental Change. Topics in Geobiology, Vol.1. Edited by D.C.Rhoads and R.A. Lutz. Pp.750. ISBN 0-306-40259-9. (Plenum: 1980.) $47.50, £29.93.

THIS book explores what we can learn from the skeletal structure of aquatic organisms about the environment in which they lived, and how the environment affected their lives. The editors point out that until recently much of the drive for such studies has come from palaeontologists interested in reconstructing palaeoenvironments, but that now ecologists are also becoming interested in how the recent past can be revealed by skeletons.

The editors have clearly put much thought into the organization of the book, and have given their contributors clear briefs. As a result, they have produced a book that is admirable for the beginner and also for old hands.

There are 16 chapters and 12 appendices. Twelve of the main chapters concern molluscs; they range from a general overview of shell growth and form in bivalves to particular examples of the effect of the environment on shell structure of *Mercenaria*, and the recognition of developmental types from larval shell morphology. The balance in this mollusc section seems right; the major emphasis is on molluscs as a whole, and how the environment influences shell growth, yet there are some examples of how these principles apply to particular populations or species. In all the contributions it is reiterated that while the environment has marked effects on the shell, the interpretation of, for instance, check lines, changes in mineralogy, or oxygen isotope ratio, needs great care. The message, however, is not that the subject is so difficult that only people who have worked on it for 20 years should attempt to publish but rather that it is one in which both the fascinations and the pitfalls are densely distributed.

After the contributions on molluscs, the four on other groups (barnacles, corals, fish sagittae and polychaete jaws) seem meagre, though they are all interesting. The editors defend themselves against this criticism by stating that most work on environmental influences on skeletons is being done on molluscs. This may be true, but if so it is a shame.

A particularly good feature is the appendices. They are really instructive and will enable people, after a few mishaps no doubt, to prepare thin sections or acetate peels, or to distinguish crossed foliated structure from ordinary crossed lamellar structure. There are also useful chapters and appendices that deal with demographic and statistical matters.

One of the few unsatisfactory features of this book is that the subject of the effect of selective predation on morphology is rather neglected. It has been known for some time that the intensity of predation may affect both intraspecific and interspecific variation of shell morphology. Some of this variation is very like that produced by environmental differences; indeed it is often a real problem, even in living populations, to disentangle the two. Furthermore, though some of the differences are the result of selection taking place within a generation, some have quite high heritable components. Tevesz and Carter do mention this problem briefly in their chapter on the unionaceans, but it should perhaps have been discussed more fully somewhere.

I noticed only a few examples of laxness in editing. For instance, to give what is essentially the same equation as

$$L_t = L_\infty\ (1 - \mathrm{e}^{-kt})$$

and

$$N_t = N_{\max}(1 - c\mathrm{e}^{-r_0 t})$$

in two different places is needlessly confusing. Also, in my copy (and therefore, presumably, in several hundred others) the pages in the appendices were hopelessly jumbled. This interesting, handsomely produced, well-illustrated book deserves many buyers — but they should all carefully check pages 640 onwards for continuity. □

Historians of science confront the hydra

Robert Fox

The Ferment of Knowledge: Studies in the Historiography of Eighteenth-century Science. Edited by G.S. Rousseau and Roy Porter. Pp. 500. ISBN 0-521-22599-X. (Cambridge University Press: 1980.) £25, $39.50.

OVER the past decade, the historiography of eighteenth-century science has been totally recast. In the process, change and complexity have emerged as the leading characteristics of a period which, not so many years ago, was seen as a rather pedestrian interlude between the heady days of the scientific revolution and the expansive age of modern professional science that dawned in the first half of the nineteenth century. The reassessment owes much to the 13 contributors to this absorbing volume of essays. All of them have played a major role, in areas as diverse as industrial science and technology (treated here by Donald Cardwell), the chemical revolution (Maurice Crosland), the life sciences (Jacques Roger), "mathematical cosmography" (the title of Eric Forbes's contribution) and geology (Roy Porter). In *The Ferment of Knowledge,* however, their brief was to review the state of their particular art and to relate work in their field to larger cultural perspectives. "Strong interpretations" and "coherent analysis" were the objectives of the stock-taking, and it is by these lights that the book must be judged.

What, then, are the "strong interpretations" that emerge, and where are the new beacons? Remarkably, at least one tentative answer to these questions already seems possible. This is because the most obvious historiographical casualty of the 1970s is the very one that has traditionally dominated studies of science in the age of the Enlightenment: the notion of a unified, transcendent Newtonianism guiding confrontations with nature either as an inspiration or as a target for criticism. John Heilbron's revisionism on this point emerges from his plea for a more detailed study of the practice, as opposed to the metaphysical context, of experimental physics in the eighteenth century: as he observes, the single epithet "Newtonian" is at best unhelpful when applied to a discipline which underwent complete redefinition between the 1720s and 1800 and which flourished not only in Britain but also in regions of the Continent, notably in Germany, where the writ of Newton barely ran. Simon Schaffer makes even greater play of the conflicting traditions in eighteenth-century natural philosophy: with engaging panache, he argues for an analysis that would see natural philosophy as an autonomous form of discourse informing, and being informed by, the practice of scientific investigation, without ever being part of it. In this way, he may well make better sense not only of the many-headed hydra that scholars of the Newtonian tradition have had to wrestle with but also of anti-Newtonianism of the kind proposed by John Hutchinson in the realm of matter-theory.

Some of the nice problems of interaction raised by Schaffer also appear in Steven Shapin's sophisticated study of the "social uses" of science. In his quest for a "new contextualism", Shapin eschews straightforward notions of interaction between the discrete realms of scientific theory on the one hand and social context on the other. For Shapin, the realms are inseparable, with the result that the content of scientific ideas (and not, for example, merely their diffusion) can only be understood if we also understand the social significance they possessed in the minds of their creators. Such an approach has already yielded a fundamental reinterpretation of Boyle's Christianized corpuscularianism (in the work of J.R. Jacob), and a consideration of differing social uses may also be the key to one of the great conundrums of eighteenth-century historiography: the existence of what appear to have been competing Enlightenments, including both "radical" (the term is Margaret Jacob's) and High Church versions which repudiated Newton's carefully articulated theism.

The Ferment of Knowledge would have been welcome enough if it had merely reviewed a fruitful field of research; the editors and their well-chosen contributors have ensured that it fulfils that task admirably. But the book also says much, by implication, about the state of the history of science as a whole. Time and again, it demonstrates the unprecedented receptiveness of historians of science to work in other disciplines. The techniques of anthropology and modern social history make a welcome appearance (the latter being used to particularly good effect in W.F. Bynum's richly documented paper on medical care). Michael Foucault, too, flits across the stage, though to responses that range from the critically tolerant to the dismissive. The marriage between the history of science and the social sciences would appear to have been fully consummated, to the obvious benefit of a discipline which has striven long and hard to divest itself of an embarrassingly antiquarian past. The aptness of the term "ferment" when applied to recent developments in the history of science needs no underlining. □

Does creation deserve equal time?

Reports from Arkansas (of which there are not many) suggest that the creationists have established a strong bridgehead there (see *Nature* 21 May, p.179). Creation and Darwin are to have equal time in the school curriculum, but how this will be done has not been decided (and may never be, if the American Council for Civil Liberties manages to overturn the bill rushed through the Arkansas legislature in March). The creationists of Arkansas would therefore be heartened by the exhibition on the "Origin of Species" mounted by the British Museum (Natural History) in London to mark its centenary this week. The exhibition, to be reviewed by Professor Barry Cox next week, is splendidly designed, persuasively instructive and, with a few exceptions, philosophically unobjectionable. But the exceptions are significant and striking. At the entrance to the exhibition gallery are two panels, one of which accurately describes the origins of Darwin's theory of the "Origin of Species". The other panel, almost but not quite as prominent, says flatly that there are other ways of accounting for the diversity of species, among which "the theory of Creation" stands out. The doctrine of equal time, hitherto used for deciding which politicians should speak on television for how long during election campaigns, is clearly making headway. Should it?

What can creationists fairly claim of time in the school curriculum or of space in public exhibitions? To what extent should teachers and exhibition designers pretend agnosticism when explaining neo-Darwinian notions of evolution by natural selection because they know that many of those they are addressing sincerely hold conflicting beliefs? Superficially, these questions resemble that of whether Darwin's theory, as now elaborated, is a scientific theory in Sir Karl Popper's sense (see *Nature* 12 March, p. 75 and later *Correspondence*). Certainly there are connections. If Darwinism is untestable by Popper's criteria, and thus by his narrow definition metaphysical, and if Creationism inspired by religious belief is also (but more frankly) metaphysical, are not the two theories equipotent and thus deserving of equal time? These are the arguments that have enabled those who call themselves scientific creationists to make such headway in the past few years, in the United States in particular. It is also likely that many of those who urge that Darwinism is "only a theory" do so because it does not conform with their religious convictions. Yet the issue of equal time is an issue in its own right, and one that deserves a simple resolution.

The issue is not a simple extension into this century of the fierce rows about God and Darwinism that occupied some of the Victorians, especially in Britain. Then, with religion firmly entrenched and sometimes backed by the force of law, it was natural that people such as Huxley should have seized on Darwinism as a way of substantiating their long-standing disbelief. Now, with the shoe on the other foot — religion less widely practised and in most places disestablished — the argument is different and more subtle. The scientific community is not, as popular legend has it, monolithically irreligious even if card-carrying believers are proportionately fewer than in the general population. And the fact that science and religion can coexist is a sign that, behaviourally, science and religion are not always antithetical. People, it seems, can spend their weekdays in laboratories observing phenomena which they suppose are causally determined and Sundays on their knees, believing that some events are differently arranged. (Sects differ in their estimates of the importance of physically non-causal events, as evidenced by their differing assessments of the function of prayer somewhere between the extremes of cathartic wish-fulfillment and putatively effective interruptions of causal processes.)

To many professional people, this awkward philosophical compromise is offensive, but mistakenly. It is not even a philosophically untenable position to suppose that the present world is well-determined, but that it was all set in train in, say, 4004 BC, the year that Bishop Ussher figured out that the world began. Continuing inspired non-causalism is harder to accommodate, but even that circle can be squared in the minds of many people, professional scientists included. But much of modern religion is drawn in such a way that inconsistency crops up less openly. In any case, in most fields of scientific enquiry, the supposed conflict between science and religion is entirely irrelevant. For the practice of science, what matters is that investigators should be unprejudiced in their expectations of the outcome of an experiment or a series of observations, and unbiased in their interpretation thereof. Even so, with the passage of time, once inexplicable phenomena have become susceptible to physically causal explanations, so that the number of unsolved problems behind which God might be lurking has shrunk. And there are some fields of enquiry in which some (not all) religious convictions are an impediment to scientific enquiry. Fundamentalists who become palaeoanthropologists have a hard life, as may devotees of astrology who work in stellar dynamics. For the rest, however, the scientific community has a duty to be as tolerant of religious conviction among its members as of, say, differing political convictions. For the most part, it is.

The trouble, in Arkansas and the British Museum (Natural History) — which should change its name — is that tolerance has gone too far. It is one thing to be tolerant of religious conviction and quite another to give religiously inspired hypotheses equal time with theories which are scientific in the sense that (correct or otherwise) they purport to relate to effects and causes which are themselves capable of being understood. Correspondence in the past few months has shown that it is possible to argue, within the convention that effects are related to identifiable causes, about the validity of neo-Darwinism. The theory of Creation is not, as the museum's placard suggests, one of the possible refinements of neo-Darwinism that may in due course emerge from more careful study of evolutionary data but a radical alternative which has the further property of not being a scientific theory: however stated, the theory of Creation relates effects to causes which are *ad hoc* and, by definition, not susceptible to understanding.

If the museum had sought to advertise to those who will be flocking to its new exhibition during the next few months that the "theory of evolution would be abandoned tomorrow if a better, theory appeared" (*Nature* 12 March, p.75), it would have done better to refer as an alternative to the theory that Hoyle and Wickramasinghe have been advocating in the past few years, which entails the repeated replenishment of the surface of the Earth with life forms from elsewhere. That, at least, will be capable of verification in the years ahead. If the objective were merely to avoid offending the small proportion of fundamentalists among its religious visitors, it could have simply said that Darwin's theory is the most persuasive of the scientific theories of evolution so far, and acknowledge that some people do not look for a scientific explanation of everything. To refer to the theory of Creation as an alternative to Darwinism is, however, to fudge the issue. Creation is not a different scientific theory but an explanation of the diversity of species of a different kind. Science museums, and science teachers, have the task of

0028-0836/81/220271-02$01.00

cultivating an understanding of what scientific explanations are. Naturally, if some among their audiences prefer supernatural explanations, toleration is in order. But not equal time.

Organizing change

Last week was formative, even traumatic, for the British government's arrangements for the sponsorship of technical innovation. It began with a report from the Advisory Council for Applied Research and Development on operations of the National Research Development Corporation, set up immediately after the Second World War as a means of exploiting inventions not taken up by private industry, and which has been for the past two decades the chief means of exploiting inventions arising within publicly supported laboratories, in universities and elsewhere. The week finished with public confirmation that the corporation is to be merged, as soon as possible, with the other and more controversial arm of the British government's patronage of industrial innovation — the National Enterprise Board. By all accounts, both organizations have been working closely together since the beginning of the year, when Sir Frederick Wood, then chairman of the corporation, was appointed chairman of the board as well. Now there is to be legislation to formalize a merger.

Politically, the rearrangement will have considerable advantages. The National Enterprise Board is, for the present British government, a curious hangover from the past. It is the survivor of the organization set up in 1965 by Sir Harold Wilson's Labour government, which is best remembered for having spent a great deal of public money persuading companies to merge with each other, sometimes successfully (as with General Electric Company), sometimes unsuccessfully (British Leyland). The present British government, ideologically opposed to public intervention in private industry, has nevertheless found it necessary to keep the rump of the old organization if only as a means of disposing of the public investments that have accumulated over the years. But the government (like its supporters) has never been easy with this inherited embarrassment. It will obviously be of some assistance if the board can appear to disappear, and the name being canvassed for the new organization — the British Technology Corporation — may help in that direction.

The proposed merger nevertheless makes sense. Each of the proposed partners needs strengthening. The National Enterprise Board, accustomed as it is to persuading bankers to act in unfamiliar ways, is short of a knowledge of what technology is about. The corporation, on the other hand, knows a lot about technology but is financially unadventurous, perhaps because of its over-zealous avoidance of borrowing from the Treasury to enlarge its operations. In principle, then, the impending merger should provide an organization more effective than the sum of its parts. The combined organization may become the elusive ideal after which British governments have striven for decades — a cost-effective way of using public money to encourage industrial innovation.

This is why all those concerned with the merger should read the report of the advisory council with close attention. It is possible that the problem of supporting innovation with public funds has been transformed since the corporation and the board were first conceived. One of the complaints that the council makes against the corporation is that it has in the past been too concerned that innovations coming its way should already be protected by patents. Somebody convinced that his new mousetrap will drive all other mousetraps from the market must first take out a patent and then, if his invention has not been snapped up by a mousetrap manufacturer, must ask the corporation to help with the cost of development. The trouble, the council properly says, is that in present circumstances many of the most interesting innovations consist not of patentable inventions but of know-how, "intellectual property". The complaint against the National Research Development Corporation is indeed softened by a recognition that the corporation has recently been changing its ways, but plainly a merger with the board will help in this direction, if only because the board is more used to backing companies than patents.

Another of the council's complaints against the present arrangements bears on the relationship between the National Research Development Corporation and the universities and government laboratories. Hitherto, the corporation has had a right to first refusal of all innovations springing from the use of public funds. It has not always been imaginative in its dealings with innovators in these places. Rightly or wrongly, many in this constituency have a sense of grievance. The advisory council now suggests that this monopoly should be dispensed with, on the grounds that there should be more than one source of support for promising ideas. This argument is not accepted by the National Research Development Corporation (which claims already to have acted on the council's other recommendations). The reluctance is understandable but unjustifiable.

Too much TV?

The geosynchronous orbit is a scarce natural resource. There is only one orbit about the Earth in which objects will appear to be stationary from any point on the surface of the Earth. Obviously such a unique facility should be used sensibly. By good fortune, national ambitions to put satellites into this orbit are moderated by international negotiation and agreement within the International Telecommunications Union, originally established to see that terrestrial broadcasting systems did not interfere with each other. Aware of the technical possibility that geosynchronous satellites might be used for broadcasting television signals directly into people's homes (with the help of a small dish antenna), the union called an international conference in 1977 to carve up the geosynchronous orbit among its member states. The report of the British Home Office (which combines responsibility for the regulation of domestic broadcasting with that for such matters as the administration of British prisons) shows that the decisions then taken should be reconsidered.

The report (see page 277) is stimulated by the British Government's wish not to waste the five channels of television broadcasting doled out to in 1977. But this is an awkward time. The Home Office has just suffered the trauma of deciding that British television-watchers should be allowed a fourth channel, to be run under the supervision of the Independent Broadcasting Authority and financed from the profits of the commercial television companies who occupy one of the three existing channels of domestic television. Much of the Home Office's strategy on broadcasting in the past few months has been designed not to harm the profits of the commercial television companies, for that would jeopardize the "success" of the fourth channel. Only this can explain the caution with which would-be operators of cable networks are being licensed. The offer of a further five television channels is not a gift but an embarrassment.

The British Government deserves some sympathy in its embarrassment. The 1977 decision that each member of the International Telecommunications Union should be entitled to five geosynchronous direct-broadcasting channels was ill considered and premature. Then, as now, it was not clear what balance that will eventually be struck between direct broadcasting to people's homes and the more efficient use of the geosynchronous orbit by means of broadcasts to community antennas. The American members of the union had the sense to opt out of the 1977 decision, and will consider how the geosynchronous orbit should be carved up among themselves only in 1983. Elsewhere, the mere availability of the new channels is certain to lead to a waste of effort in the development of broadcasting system whose economic place in the market cannot be determined while national governments (the British included) decline to let competing and complementary systems, such as cable networks, develop freely.

Budget cuts cast shadows overseas

US agencies count costs of Reagan

Washington

The Reagan Administration, stung by criticism from Western allies of budget-based decisions to terminate or substantially withdraw from a number of international scientific projects, is taking a close look at ways in which it may be able to repair some of the damage and prevent further unnecessary friction in the future.

Of particular concern to the new Administration is that the foreign policy function of certain types of international scientific agreements — for example, a science and technology programme agreed with Spain in 1976 as part of an exchange for being allowed to place US military bases in the country — could be jeopardized if the projects are evaluated merely on the strength of their scientific merits and the vocal energy of their domestic constituency, often very small within the scientific community.

Already, Secretary of State Alexander Haig has written to Mr Reagan's budget director, David Stockman, complaining of the fact that cuts imposed either directly by the Office of Management and Budget (OMB), or indirectly by internal decision within agencies such as the Department of Energy or the National Science Foundation (NSF), have been carried out in a manner which constitutes a unilateral abrogation of international commitments.

Among the projects listed by Mr Haig which appear to have been treated in this way is the international solar polar mission, planned jointly with the European Space Agency, from which the National Aeronautics and Space Administration (NASA) has proposed withdrawing its planned spacecraft (a decision which both congressional committees and NASA officials are busy trying to reverse, perhaps through a reduced NASA commitment which would involve the European Space Agency building the two spacecraft involved). Another is the possible cancellation of national energy assessments supported by the Department of Energy and already promised by embassies in countries such as Greece, Tunisia and Venezuela.

What concerns the State Department most is that the scientific attachés of foreign embassies in Washington are telling their capitals that US promises of scientific and technical collaboration should be looked at sceptically in the future. "While budget reductions are a clear goal for this Administration, one of its principal foreign policy objectives is to render the United States a reliable international partner," wrote Mr Haig — who had previously interceded with OMB to rescue foreign aid funds and NASA's Galileo mission to Jupiter, planned with heavy West German involvement — in his letter to Mr Stockman.

International collaboration in scientific programmes is seen by Washington science policy officials as falling into three categories: that carried out by individual scientists and their institutions as part of the normal process of science; that in which both sides receive the benefit of more cost-effective technical knowledge; and that carried out with some broader foreign policy goal in mind.

It is the last of these three which is particularly threatened, particularly when an international treaty or bilateral agreement has been arranged through the State Department, and then handed to another agency for execution.

One major dilemma now facing the Reagan Administration, for example, is what to do about the International Institute for Applied Systems Analysis (IIASA) in Vienna. Faced with the need to make cuts of over $300 million — almost 25 per cent — in its proposed 1982 budget by the new Administration, NSF decided to eliminate the $3 million US contribution to IIASA for which it is at present responsible.

Unless this decision is changed by the Administration, IIASA would have to close in 1983. Scientists claim that the institute has been carrying out some useful research, even though some express doubts about its full value. However, IIASA also provides an important channel for East/West communication.

Moves are therefore under way to discover whether the closure of the institute — which would anger the Austrian government considerably, since it has put a lot of money into providing facilities — can be averted. For the 1982 contribution, already committed under IIASA's constitution, NSF is working out whether it can provide money from other sources within the foundation.

Recognizing that the problems raised by the controversy over the international solar polar mission and IIASA contributions have deep roots in beliefs about the proper political role of the federal government in support for science, the State Department has set up an inter-agency committee to discuss possible guidelines for the future. Two suggestions it is likely to discuss are that OMB should be presented, early in its budget cycle, with an overall picture of overseas implications. The other is that the State Department itself might be given funds for supporting international scientific activities which it feels have important political functions, but might not generate the required support within an individual agency.

At the same time the agencies themselves are looking closely at their own policies and procedures. Few solutions are in sight, but one consolation to US scientists is that, as a result of recent events, the whole issue has been placed high on the State Department's agenda at an early stage and is already receiving close attention from what are usually described as the "top levels" of government. **David Dickson**

Anxieties of Oslo secrets trial

Stockholm

A trial whose outcome could affect freedom of research is being held in Oslo. Two defendants are at present accused of revealing information prejudicial to Norway's security. But this is not a normal spy case: the defendants collected the information exclusively from public sources as part of a research project funded by the Norwegian Research Council for Science and the Humanities, and there is no suggestion that they intended to pass it on to any foreign power.

The two men are Nils Petter Gleditsch of the Oslo International Peace Research Institute (PRIO) and Owen Wilkes, a New Zealander formerly at PRIO and now at the Stockholm International Peace Research Institute. They maintain that freedom of research should be upheld, and that they have not in any case revealed information which could damage Norway's security. They say that what they have discovered from open sources, a foreign power (that is, the Soviet Union) could investigate in far more detail with intelligence satellites. They conclude that the Norwegian government's reticence about military affairs is keeping secrets from the Norwegians themselves, not from the Russians.

The history of the case is this: Gleditsch and Wilkes published their research report, "Intelligence installations in Norway: their number, location, function and legality" in February 1979 as part of a PRIO project (still continuing) on the location and functions of military facilities in Norway. They timed the publication to coincide with another trial then being held, in which three Norwegians — a publishing house executive and two journalists who had collected the names of Norwegian secret servicemen — were accused of collecting information which could damage the country's national security. Gleditsch and Wilkes wanted to show how easy it is to obtain from open sources information considered to be very sensitive.

The prosecutor general ordered an investigation into the Gleditsch–Wilkes report, and in March 1979, the chief of

0028-0836/81/220273-02$01.00

defence staff, General Sverre Hamre, told the Norwegian police that he considered it a threat to the activities of Norwegian defence and national security. Having questioned the authors and PRIO staff closely associated with preparing the report, the police completed their investigations in June 1979 and sent preliminary charges against Gleditsch to the court. They charged him on three counts: two under the penal code — revealing information which ought to be kept secret in the interests of national security relative to foreign powers, and acquiring this information or making it available to others — and one under the law on defence secrets — recording, copying, or publishing sketches of fortifications or associated installations. According to Norwegian practice, the police also appointed three independent experts to evaluate the report. The intelligence service proposed two of these (one was the former head of the service) and Gleditsch and Wilkes the third. Not surprisingly, the experts nominated by the intelligence service supported General Hamre's opinion that the report threatened national security. The formal indictment charges Wilkes as well as Gleditsch with all three charges, which carry a maximum penalty of 4½ years imprisonment.

The technical intelligence facilities described in the Gleditsch–Wilkes report collect and analyse data from electronic intelligence satellites, monitor and analyse military and diplomatic radio signals, and intercept and interpret electronic and telemetric communications. Although the authorities are traditionally tight-lipped about such installations, the authors point out that it was very easy to find out about them by using, for example, the ordinary telephone directory and public lists of government-owned property. They also learned a lot by observing the installation's antennas: their size, shape and layout. The authors maintain that if the Soviet Union, with its sophisticated spy satellites and, presumably, other more traditional techniques of spying, is interested in the installations, it would already know a great deal about Norwegian security. They claim that the authorities' secrecy is mainly directed towards the Norwegian population itself, pointing to police reaction to the publication of their report in Norwegian, shortly before the trial began. For two years the report has been available in English and the police have made no attempt to confiscate it; however, they have now declared the publication of the Norwegian translation illegal.

Support for Gleditsch and Wilkes has come from the International Peace Research Association, the Norwegian Writers' Union and political youth organizations in Norway. The trial is expected to last for another week or so, and the verdict will follow a couple of weeks after that. One or both sides will almost certainly appeal. **Wendy Barnaby**

UK nuclear power

Plans panned

For the second time this year, Britain's Central Electricity Generating Board (CEGB) has received a rap over the knuckles for not providing enough information about the economic case for its planned nuclear power programme. Hard on the heels of sharp criticism from the House of Commons Select Committee on Energy last March, the Monopolies and Mergers Commission last week published a report on the board's finances (HC 315, HMSO, £9.30). The Monopolies Commission was asked to find out whether CEGB is charging a fair price for the electricity which it supplies to the consumer through regional electricity boards.

The commission says that one of the chief reasons for the high cost of electricity in Britain is CEGB's previous tendency to invest in new plant before strictly necessary. Decisions to order new plant, it concluded, have often been based on over-estimates of future demand, and economic cases have been made on over-optimistic estimates of construction times, capital costs and the ultimate performance of power stations.

The commission's report is particularly critical of the decision, to build the second advanced gas-cooled reactor at Heysham, taken in 1979 as part of the government's decision to embark on a further nuclear programme, probably based on the Westinghouse design of the pressurized water reactor. Failing approval at next year's public inquiry, CEGB hopes to keep open the option of basing the programme on the notoriously costly British-designed AGR by building Heysham II.

Although the commission acknowledges that CEGB has learnt from its previous mistakes with the AGR, it still criticizes the board for not providing sufficiently detailed cost estimates for Heysham II, even though the decision to build it was taken largely on strategic grounds.

The commission also faults CEGB's case for future nuclear power stations on economic grounds. It says that the board's estimate of net effective cost assumes unrealistic improvements in future construction time and operational performance. Margins of error in cost estimates, together with a better indication of the board's assumptions, should have been presented to the government when making an economic case for the nuclear programme. The board should also have compared the cost of building new nuclear stations with the cost of refurbishing old coal-fired stations.

The commission, however, has praised the way in which CEGB keeps a check on its current expenditure and seems to be impressed with the performance of its Barnwood division, unpopular with many of its contractors, in keeping a detailed check on cost increases during construction. The commission's report, however, ends on a rather gloomy note. Even if CEGB implements all its recommendations, the commission cannot foresee any substantial cut in electricity prices to the consumer. **Judy Redfearn**

Gloom on research

A high-level meeting of research councils from Germany, France, the United Kingdom and the United States was held in the English country town of Abingdon on the weekend of 16–17 May. The occasion, arranged by Sir Geoffrey Allen, chairman of the British Science and Engineering Research Council, is the second in a series of consultations begun with a meeting called by Professor H. R. Leibnitz, then the president of the Deutsche Forschung Gemeinschaft in June last year.

The objective appears to have been an exchange of views, most of them gloomy. The United States participants (Dr John Slaughter and Dr H. R. Langenberg, respectively director and deputy director of the National Science Foundation) left their fellow-administrators with the impression that the Reagan budget had been a body blow whose effects will not be confined to the United States, but that the United States is also worried by more long-standing problems — the difficulty of recruiting teachers of engineering for United States universities, for example.

European participants in the meeting are said to have welcomed their transatlantic colleagues into the company of the impoverished, and to have urged that if the United States now faces a period of entrenchment it would be worthwhile thinking of collaboration with European collaborative ventures such as those at CERN. The occasion seems also to have been one for concerted European complaint about the budgetary threat to the solar polar mission, the plan to send two spacecraft (one European, one American) into polar orbits about the Sun.

US science funding

Rewards of genius

Washington

Acting on the theory that intellectual and cultural breakthroughs can be accelerated if latent genius is permitted to flourish free of the more material considerations of making a daily living, one of the newest — and wealthiest — foundations in America has announced the first of a series of five-year, no-strings-attached awards to "exceptionally talented" individuals.

The awards are being made by the trustees of the John D. and Catherine MacArthur Foundation set up two years ago from the estate of the late Chicago insurance and real estate millionaire. The

0028-0836/81/220274-02$01.00

foundation, which has assets of $841 million, last week announced 21 individual awards worth a total of over $4 million, with another 29 expected later in the year.

Eight of the initial recipients are scientists, and include Stephen Wolfram, a 21-year-old physicist at the California Institute of Technology, the Harvard geologist and paleaontologist Stephen Jay Gould, and oceanographer and climatologist John Imbrie of Brown University and the University of Rhode Island.

The names were chosen by the trustees of the foundation from a list of nominations proposed by 100 educators, scientists and artists who acted as scouts in what other foundations, more conventional in their granting of awards, have dubbed the "search for genius". There are no conditions attached to the way that the money — between $24,000 and $60,000 a year for each individual, depending solely on age — can be used, nor can the award be withdrawn within the five-year period.

The MacArthur Foundation's novel approach to the support of intellectual activities is perhaps the most ambitious of a number of attempts to meet the charge that more conventional forms of funding discourage innovative or risk-taking work.

Last year, for example, Berkeley physicist Richard A. Muller, winner of the National Science Foundation's (NSF) Alan T. Waterman award based on research for which he had initially encountered difficulty in obtaining support, told a congressional committee that individuals engaged in innovative research often had similar experiences, for example when their proposed project did not fit neatly into one or another disciplinary compartment.

Dr Muller's testimony and other similar complaints led Congress to ask NSF to assess current funding mechanisms to find out how well they are working. So far these studies have not uncovered any substantial problems, nor pointed to any particularly radical solutions.

Furthermore, a task group set up last year by NSF's advisory council on the funding of innovative high risk proposals has reported that "on the whole, the foundation's procedures seem to be effective".

In the light of the comments received and of its own investigations, the task force, headed by Halsey Royden, dean of the school of humanities and sciences at Stanford University, suggested that NSF programme officers be given greater encouragement to support innovative risk-taking proposals and that a small Group on Innovative Research Topics be set up under the deputy director, to "promote promising research that does not fit naturally into the framework of existing programs and divisions of the NSF."

Both proposals are now being considered by NSF. However, Dr Langenberg points out that the task force specific recommendations are likely to be absorbed into the bigger organizational changes now under way. **David Dickson**

High-energy physics

On the rocks

The Swiss tunnel expert Giovanni Lombardi, who has honeycombed the Alps with road and rail tunnels, denied last week that it might be impossible to build the tunnel for LEP — the next big project of the European nuclear physics laboratory CERN.

The assertion, in the British magazine *Consulting Engineer*, would have prevented governments from approving LEP construction at next month's crucial CERN Council meeting. Lombardi is not only a world-recognized expert on Alpine tunnelling but also CERN's principal geological adviser.

Lombardi and CERN do however admit to geological difficulties in that part of the LEP tunnel which will go under the limestone of the Jura, to the north-east of the CERN site. The worst of the troubles have however been avoided by shrinking LEP from 30 km to 27 km circumference, it is said. In this way, the tunnel should avoid the folded core of the Jura, a region of unstable limestone which Lombardi knows to contain water and mud-filled caverns.

Even so, progress through the Jura will be uncertain and based on "forage à l'avancement", where a small (2-inch) hole is drilled 20–30 m ahead of the main borer to probe for boundaries between limestone layers. At hundreds of metres below the water table, there may be mud and pebble-filled "karsts" at these rock divisions which will have to be emptied and filled with concrete before drilling through. If water-flow through the karst is too great, it can be impossible to place the concrete.

Uncertainties of this kind have persuaded smaller member states of CERN, led by Sweden, to demand guarantees that the CERN budget will not be raised to meet any extra costs. It has thus been agreed that future CERN budget increases can be vetoed by any state, while for decreases a two-thirds majority is sufficient. And CERN's director-general, Herwig Schopper, has agreed in principle that LEP cost escalations would be met by lengthening the time over which LEP is built.

Strenuous efforts to delineate the geology of the Jura are under way at CERN, but the principal reconnaissance gallery will not reach the tricky region until April next year. So CERN is also drilling a hole vertically above the deepest part of the proposed tunnel under the Jura and making geophysical observations from within it to find the water table and the trend lines of the various limestone boundaries. The results of this investigation will not, however, be known for another three months.

Meanwhile CERN is preparing for its mid-year council meeting on 25 June at which delegations from the 12 member states would normally approve the 1982 budget. This year the budget contains an appropriation for LEP, which is not being costed separately. The debate will centre on precisely what level the budget should take, and what guarantees can be given on LEP cost overruns.

Sweden, apart from its doubts on the latter score, is in political crisis, and will almost certainly abstain; Norway may do the same; and the Netherlands are in the midst of elections and cannot predict their position. Moreover, the CERN Council delegations of many of the member states have not yet been officially briefed (this includes Britain) and so the outcome is far from certain. Procedurally, if eight states vote for the budget including LEP, and none votes against, LEP can go ahead, and this seems likely, although Schopper would like to leave the door open for a few months after June to achieve a unanimous decision. **Robert Walgate**

Hormone legislation

Consumer protest

Brussels

The failure of the European Community's council of agriculture ministers to make significant progress on banning the use of natural and artificial hormones in livestock production is forcing European consumers to take retaliatory measures. The Bureau of European Consumers' Association is now trying to persuade the sympathetic member states to block meat imports from the United States, New Zealand, Australia and elsewhere.
